Competing with insects for food, fibre and shelter

Dr PG Allsopp
BSES Limited, PO Box 86, INDOOROOPILLY, QLD, 4068, AUSTRALIA, pallsopp@bses.org.au

Humans need food, fibre and shelter to survive. To get these, we compete with insects, the most successful group of animals on the planet. We attempt to 'control' the impact of such pest species, often with mixed success. In the past, we've relied on the use of single-strategy approaches. These often fail, either through a poor understanding of the insect's biology and ecology, and/or through changes to the insect's biochemistry or behaviour. Modern pest management rests on a paradigm of Integrated Pest Management (IPM), where a combination of strategies is used to manage pest populations so that their economic impact is minimised. The development of these strategies rest on the talents of many disciplines, from chemistry to biology to economics to product marketing. In developing these systems, the questions have changed from 'How do we kill this pest?' to 'Why do populations of this pest reach levels high enough to cause economic damage?'; this is where ecology plays a vital role. However, there are strong social aspects to the development and adoption of this integrated approach. Development of new products and processes needs to be coordinated and managed. End users (farmers) need to be convinced that adopting these strategies will benefit them; this requires their involvement in the research process. Differences in pest biologies and ecologies and in the expectations of end users mean that there is no simple recipe for successful IPM. Creativity and innovation are vital to feed, clothe and house people.

What's in a Name and Who's your Relative

Peter Cranston, *Penny Gullan*
Department of Entomology, University of California, Davis, CA 95616, USA pscranston@ucdavis.edu

Unambiguous communication about our friends and relatives depends upon their having distinctive names. These tell us much about their identity and perhaps something about relationships. Likewise species of organisms, which are the units of biodiversity need unique names. Insects are by far the most diverse group of organisms, with numbers of species easily exceeding 1.5 million. Although many have been named, the completion of the task remains distant, as does discovery of the true diversity in the face of loss of natural habitats and of taxonomists (those that name and classify life). However it is incumbent on us to document who we share our planet with, and to understand the evolutionary relationships amongst them. These are two distinct tasks but the practices and expertise involved in each are complementary. New approaches to both tasks, together with a revival of interest in the taxonomic framework for biodiversity studies, allow some optimism for greater productivity. For example, the U.S. National Science Foundation ring-fenced funds a decade ago to support the transfer of information from the older generation of taxonomists to the younger. The broadly trained output of this PEET (Partnerships for Enhancing Expertise in Taxonomy) program are dispersing and forming centres of expertise, often in non-traditional institutions and in the countries with high diversity that have lacked modern skills. Also emanating from the USA is a mega-project to document the 'Tree of Life' – an ambitious attempt to identify the relationships of all the organisms on the planet, especially using DNA data and bioinformatics tools. Thus far, funding has included provision for study of selected major insect groups – which after all comprise so much of the 'tree'. Australia has the mechanisms in place for comparable efforts, but funding to the ABRS (Australian Biological Resources Study) has been too slight to reverse an ongoing decline in support for taxonomy. Europe especially ought to follow the US model. Major advances in working methods for decribing our biota have resulted from the availability of the internet to disseminate information and the power of computing to manage the extensive databases that are generated by any study of biodiversity. Data management packages complement software designed to help non-experts identify organisms – many of these tools emanated in Australia, some in Brisbane at the University of Queensland. This combination of a newly-recruited skilled cohort of taxonomists with major research tools and appropriate federal support allows us to believe that the task of documenting and understanding those we share our planet with is attainable.

Entomology in Australia – a proud heritage

Dr J Daly
CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, AUSTRALIA, joanne.daly@csiro.au

Entomology is important to Australia. Insects, and their relatives, have major economic impact, they are vital in the ecosystems and they make great model biological systems. They are also fun. Australian entomologists engage in a wide range of occupations in agriculture, resource management, academic research, biosecurity and in urban systems, to mention a few.
CSIRO Entomology is the oldest Division in CSIRO and throughout its 77 year history CSIRO scientists have worked with others to bring about miracles – control of major pests and weeds, and the documenting our unique biodiversity.

ENVIRONMENTAL CHANGE, MOSQUITOES AND DISEASE: AT WHAT RISK AUSTRALIA?

Philip Weinstein,
Professor of Population Health, University of Western Australia

Summary: In the last couple of decades, the world has seen the 'emergence' of a whole variety of new diseases, like Ebola fever, HIV/AIDS and SARS. Many familiar diseases have also extended over wider areas and now affect many more people than ever before, including diseases transmitted by mosquitoes (like malaria and dengue fever). Many researchers argue that this is a result of humans causing major changes to the natural environment, thereby creating new opportunities for microbes to infect large numbers of people. Australia is no exception to the many countries with dramatically changed ecosystems, with major modifications that include agriculture, irrigation, mining, deforestation, and urban development. Have these environmental changes left us vulnerable to worsening levels of mosquito transmitted disease? This talk examines the evidence for a relationship between environmental change and the risk of mosquito transmitted disease in Australia, and discusses new threats to our shores from microbes like Japanese Encephalitis Virus.

Use of microarrays to detect insecticide resistance mechanisms in *Anopheles* malaria vectors

C Strode, JP David, J Vontas, K Louis, J Hemingway, H Ranson
Liverpool School of Tropical Medicine, Pembroke Place, Liverpool, L3 5QA UK

Insecticide resistance is a serious threat to sustainable malaria control in Africa. We have developed a small-scale microarray for the malaria mosquito *Anopheles gambiae*. This array contains unique fragments from all the major genes associated with metabolic resistance to insecticides. These include the cytochrome P450s, esterases, glutathione transferases, partners of the P450 oxidative metabolic complex, redox genes and a large number of control genes, to facilitate normalization and interpretation of the data. We have used this 'detoxification chip' to identify the genes up-regulated in insecticide resistance strains of A. gambiae and the preliminary results of these studies will be presented. In addition, we are also using this chip to address several questions related to the regulation and induction of these supergene families. Finally, the feasibility of using the 'detox chip' to monitor resistance mechanisms in field populations will be addressed.

Effect of Conventional Insecticides on Sunn Pest Egg Parasitoids *Trissolcus grandis* and *T. semistriatus* (Hymenoptera: Scelionidae)

M Saber, *M J Hejazi*[2]
"Department of Plant Protection, Maragheh College of Agriculture, Tabriz University, Maragheh, Iran, saber@tabrizu.ac.ir"

Lethal and sublethal effects of fenitrothion and deltamethrin, commonly used insecticides for controlling sunn pest *Eurygaster integriceps* Put. in Iran, were assessed on egg parasitoids *Trissolcus grandis* Thoms. and *T. semistriatus* Nees. Adult parasitoids were exposed to fresh residues of the insecticides and LC_{50} bioassays were carried out. LC_{50}s of fenitrothion for *T. grandis* and *T. semistriatus* were 16.2 and 7.9 ppm, respectively. The LC_{50} values of deltamethrin were 155 and 145.6 ppm for *T. grandis* and *T. semistriatus* respectively. Sublethal effects of the insecticides on life table parameters were measured for parasitoids exposed to rates near to LC_{50}'s of the insecticides within the first 24 hrs after emergence. Fenitrothion and deltamethrin reduced longevity by 12.7 and 17.6% for *T. grandis* and 13.2 and 22.5% for *T. semistriatus*, respectively. Reproductive capacity of exposed females was significantly affected in either species. The sex ratio of the progeny of both parasitoids was not affected significantly but was male based. The intrinsic rate of increase for *T. grandis* were 0.298, 0.289 and 0.296 and for *T. semistriatus* were 0.297, 0.293 and 0.295 female offspring per female per day in control, fenitrothion and deltamethrin respectively. Doubling time values for *T. grandis* in control, fenitrothion and deltamethrin were 2.32, 2.40 and 2.40 respectively and for *T. semistriatus* were 2.33, 2.37 and 2.35, respectively. The sublethal effects in this study indicated that sublethal effects must be considered to evaluate accurately the selectivity of insecticides in favor of the parasitoids.

Nectar feeding moths learn single odours during flower visiting.

P Cunningham,
Department of Zoology and Entomology, University of Queensland, Brisbane 4072, Australia.

Floral odours play a major role in plant-insect communication. We examined the influence of a number of single floral odours on the innate and learnt foraging behaviours of the moth *Helicoverpa armigera*. In wind tunnel and flight cage tests, we showed (1) moths could distinguish between flowers augmented by single odours (2) moths could learn single odours present in flowers on which they had foraging experience, which occurred regardless of whether the flower had a relatively simple or complex odour blend and (3) moths showed the ability to learn more than one component from a single flower, with equal preference for the learnt odours. The results imply that moths can learn single odours within complex floral blends, which may enable them to discriminate among odour profiles of individual flowers from the same species. We discuss this behaviour within the context of nectar foraging in moths and odour signalling by flowering plants.

How do mangrove ants in North Australia survive inundation?

M.G. Nielsen, K. Christian, and D Birkmose
Department of Biological Science, University of Aarhus, DK 8000 Aarhus C, Denmark
biomgn@biology.au.dk

More than 20 ant species inhabit mangroves in Darwin Harbour, NT, where the tidal movement is up to 8 metres. Some of these species live exclusively in mangroves and have adapted specific strategies to survive the frequent inundations. The most marine living ant species is *Polyrhachis sokolova*, which nest in the mud in places where they can be flooded by 62 % of the high tides and with up to 2 metres of seawater over the nest entrance. During inundation the ants cluster in air-pockets in the nest. The CO_2 concentration in the deeper part of the nest can in some circumstances exceed 10 %. The tide and the movements of the 'ground water' flush the air in the nest, so the CO_2 rich air is replaced with atmospheric air every two weeks. The ant *Camponotus anderseni,* which exclusively nest inside twigs of *Sonneratia alba* trees, prevent intrusion of water into the nest cavities by having a soldier plug its head into the nest entrance. During longer inundation, the CO_2 concentration in the nest chambers can exceed 30%. Simultaneously, the ants reduce their respiratory rates down to 1% of normal respiration. The extreme environmental conditions in the nests of mangrove ants allow investigations of adaptations of the ants to stressful conditions.

The sex pheromone of the first Australian Lymantriidae, *Teia anartoides*: Theromo-labile diverse pheromone blend

A.M. El-Sayed, A.R. Gibb, K. A. Moss, S. Fielder, D. Comesky, B. Bunn, D.M. Suckling
PO BOX 51, Lincoln, 8152, New Zealand, AEl-Sayed@hortresearch.co.nz

The Painted Apple moth, Teia anartoides (Walker) has been recently introduced to New Zealand. This invasive species has the potential for significant economic and ecological damage to New Zealand horticulture and forestry due to its wide host range. As part of the eradication program initiated by the New Zealand Ministry of Agriculture and Forestry (MAF), the sex pheromone of the Painted Apple moth (the first Australian Lymantriid) was investigated using GC-EAD analysis; female extracts dervatization followed by GC-MS and TLC analysis. The major sex pheromone compound of female Painted Apple moth was identified as 6Z, 9E-heneicosadien-11-one. Other minor pheromone compounds includ: 6Z, 9Z-Heneicosadiene, 6Z-9R,10R-Epoxyeicosene, 6Z-9R,10S-Epoxyheneicosene, 6Z, 9Z-Heneicosadiene-11-ol, 6Z-Heneicosene-11-one and 6Z, 8E-Heneicosadiene-11-one were also identified in the female sex pheromone gland. In field cage experiments, a blend of 6Z, 9E-heneicosadien-11-one (100), 6Z, 9Z-Heneicosadiene (100), 6Z-9R, 10R-Epoxyeicosene (5), 6Z-9R, 10S-Epoxyheneicosene (10), 6Z, 9Z-Heneicosadiene-11-ol (5), 6Z-Heneicosene-11-one (1) and 6Z, 8E-Heneicosadiene-11-one (25) was as attractive as calling females or gland extracts. Field trapping experiments conducted in Auckland, New Zealand supported these results. 6Z, 9E-heneicosadien-11-one was found to be a thermo labile compound and rearranged to other products under ambient temperature, rendering the synthetic pheromone lure inactive after two days. The newly identified pheromone can by used in population monitoring, detection and any eradication program of this invasive species.

Exploiting biodiversity and chemical ecology in a 'push-pull' strategy for management of stemborers in Africa

Z. R. Khan, J. A. Pickett and A. Hassanali
International Centre of Insect Physiology and Ecology (ICIPE), PO Box 30772, Nairobi, KENYA, zkhan@icipe.org

Lepidopteran stemborers cause major yield loss in maize production throughout Africa. Studies are described that have led to the development of a 'push-pull' strategy for minimising stemborer damage in maize-based farming systems for eastern and southern Africa. Development of the strategy originally involved the selection of plants that could be employed as trap crops to attract stemborer colonisation away from maize, or as intercrops to repel the pests. The two main trap plants that were identified are Napier grass, *Pennisetum purpureum,* and Sudan grass, *Sorghum vulgare sudanensis,* both of which attract greater oviposition by stemborers than cultivated maize. The intercrops giving maximum repellent effect are molasses grass, *Melinis minutiflora,* and a legume species, *Desmodium uncinatum.* 'Push-pull' trials in farmers' fields reduce stemborer attack and also increase levels of parasitism of stemborers on maize plants, resulting in a significant increase in maize yields. The trap crop and intercrop plants also provide valuable forage for cattle. The plant chemistry responsible for stemborer control involves release of attractant semiochemicals from the trap plants and repellent semiochemicals from the intercrops. In fields intercropped with *M. minutiflora,* parasitism of stemborers is also increased by certain chemicals repellent to ovipositing adults being the same as those produced by maize plants heavily attacked by stemborers.

Lethal and sublethal effects of different ecotypes of *Melia* against *Plutella xyostella* Linn.

G Singh, V Kaur and D Singh
Department of Entomology, P. A. U. LUDHIANA – 141004, INDIA gursh198@yahoo.co.in

Extracts from drupes of *Melia azedarach* (Linn.) ecotypes growing in three states of India viz. Rajasthan, Punjab and Himachal Pradesh representing different geographical regions i.e. plains, arid and hilly areas, respectively, were evaluated against second instar larvae of diamondback moth, *Plutella xylostella* (Linn.). LC_{50} of the extract from arid region of Rajasthan was the lowest (1.472 %) followed by that from plains of Punjab (1.794 %) and the maximum (2.296 %) for the extract from hilly areas of Himachal Pradesh. The survivors demonstrated various kinds of sublethal effects such as prolongation of larval period, reduction in pupal weight, deformation of pupae (up to 69.68 %) and inhibition of adult emergence (up to 92 %). A highly pronounced curtailment of fecundity (up to 8.5 against 68.5 in control) and significant reduction in oviposition period of the adults (up to 3.5 days against 7.4 in control) was also recorded. The extract from arid region of Rajasthan, with relatively higher mean temperature (28^0 C), low humidity (56 %) and minimum rainfall (15.5 mm), excelled in producing lethal and sublethal effects; only 1.0 % normal adults survived at the end in comparison to 3.5 and 5.5 % in case with the extracts from the plains and hilly areas, respectively. Inferences of the study give important indications for entomologists and tree breeders.

Control of *Liriomyza trifolii* pupae with solar radiation

H Tanaka, K Yoshikawa, T Sugimoto*, Y Takaura & M Shibao*
Agric Food Environ Sci Res Ctr Osaka Pref & *Kinki Univ 442 Shakudo, Habikino, Osaka 583-0862, Japan, h.tanaka@afr.pref.osaka.jp

Subterranean *Liriomyza trifolii* pupae were successfully controlled with solar radiation after cropping of a leaf vegetable, *Chrysanthemum coronarium* var. *spatiosum*. Covering ground with transparent polyvinylchloride film elevated temperature to 54 C at a depth of 2 cm beneath the soil surface, and no flies emerged to attack the next crop in late May. Lethal high temperature and duration combinations for the pupae were investigated in laboratory, and the pupae were all killed by exposure to either 44 C for 24 h, 46 C for 3 h or 48-54 C for 30 min. Soil temperatures under the film were measured in a closed greenhouse, and maximum high temperatures of 48 C or higher were attained at a depth of 2 cm on a fine day from early April to mid October. Thus the physical control method is effective for practical use from early April to mid October in Osaka prefecture.

Nutritional effects of five different oilseed rape cultivars on the survival rate and fecundity of cabbage aphid *Brevicoryne brassicae* (Homoptera: Aphididae)

M. H. Kazemi, M. Jamshidi, P. Talebi – Chaichi and H. Alyari
PO Box 1655 Faculty of Agriculture. Islamic Azad University of Tabriz, Iran. Email: mhkazemi@iaut.ac.ir

The cabbage aphid, regarded as one of the most important insect pests of oilseed plants in most parts of Iran, causes economic losses on the crop. In the present study, the biological responses of the cabbage aphid fed on 5 rapeseed cultivars namely Urica, Hayola 401, Hayola 308, Parkland and Pf (7045, 91) was investigated at 4-6 phenological leaf stage, under glasshouse conditions of 24^{o}C±1, with 65-75% R. H. and photoperiod of 16:8 (L: D) periods. Antibiosis was determined by studying the percentage survival of the nymphs, duration of their development time, fecundity (total number of progeny per female produced within the first 10 and 15 days reproductive cycle) and finally calculating the relevant intrinsic rate of natural increase (r_m values). The analysis of variance indicated that, there were significant differences ($p<0.05$) between the varieties. At 4-6 leaf stage, the highest mean "r_m" value (0.3229 ± 7.516E-0.3 and 0.3210 ± 7.783E -0.3) was estimated for rearing on Hayola 401 with the smallest (0.1958 ± 1.645 E-0.2 and 0.1957 ± 1.461 E-0.2 on the Pf (7045, 91) within the first 10 and 15 day periods respectively. Thus in this study, Hayola 401 is regarded as the most susceptible and the Pf (7045, 91) as the most resistant variety in relation to the aphid.

Above- and belowground nutritional ecology of the invasive maize pest *Diabrotica virgifera virgifera* (Crysomelidae, Galerucinae) in Europe.

J. Moeser, S. Vidal
Institute for Plant Pathology and Plant Protection, Georg-August University Goettingen, Grisebachstr. 6, 37077 Goettingen, email: jmoeser@gwdg.de

500 years after the introduction of maize into Europe its most important pest *Diabrotica virgifera virgifera* LeConte (Coleoptera, Chrysomelidae, Galerucinae) has finally caught up. First detected in Europe 1992 near Belgrade it has spread into 15 European countries since then. We studied the nutritional ecology of adults and the larval performance on European maize cultivars and several alternative host plants. 1) The nutritional ecology of adults in Hungary was studied by performing gut content and pollen analyses. Adult beetles were using the majority of all flowering weeds as alternative pollen sources. The use of maize tissue and alternative pollen resources was depending on maize phenology, diversity of flowering weeds and sex of the beetles. 2) We developed a new method, which allowed measuring the food conversion efficiency of *D. v. virgifera* larvae. Larval performance differed significantly between the tested maize varieties. They performed as efficiently on several other grass species (common weeds and winter wheat). The performance was related to the total nitrogen content, the C/N ratio and the phytosterol composition of the host-plants. The results of our study have multiple implications for management-strategies such as crop rotation or weed control and will help to develop IPM strategies for Europe.

The Impact of Areawide Pest Management on Carabids in Indiana/Illinois, USA

C. R. Edwards, C. K. Gerber, A. Radavich, and L. W. Bledsoe
901 W. State St., Purdue Univ., W. Lafayette, IN 47907-2089, USA, edwards@purdue.edu

The study was conducted over a 6-year period in a 41.4 km^2 contiguous area. The target pest species was the western corn rootworm (WCR), *Diabrotica virgifera virgifera* LeConte. The study was designed to test the feasibility of using semiochemical (cucurbitacins) insecticide-baits as the primary management tool for WCR on an areawide basis. Observations in 2000 indicated that the insecticide-bait might be negatively impacting some non-target organisms. Therefore, a study was undertaken in 2001-2002 to determine the impact on non-targets. The study was carried out in 8 fields (4 within the WCR managed area and 4 within the control area). Four sampling methods were utilized to gauge impact on non-targets; pitfall traps, sweep-net sampling, Pherocon® AM traps, and direct counts on plants. In the pitfall trapping study, carabids were the most abundant non-target species observed. The data showed that significantly lower numbers of carabids were found within the managed area following treatment when compared to the control area. This indicates that the areawide program had a negative effect on this non-target. However, heavy rainfall confounded the results. It is not known at this point whether the toxic effect was the result of the semiochemical alone, the combination of the semiochemical with the insecticide, the insecticide alone, or one of the previous in combination with rainfall.

Action and regulation of defensin in *Ornithodoros moubata* (Acari: Argasidae).

Y. Nakajima, D. Taylor and M. Yamakawa
Institute of Agriculture & Forestry, University of Tsukuba, Tsukuba, Ibaraki, JAPAN, demartaylor@yahoo.com

Generally, arthropod antibacterial peptides are inducible in response to injury or bacterial infection. On the other hand, *Ornithodoros moubata* shows up-regulated gene expression of defensin in response to blood feeding. In the present study synthetic tick defensin was used to investigate the spectrum and mode of action of natural tick defensin. Although originally purified as a *S. aureus*-killing antibacterial peptide, synthetic tick defensin shows a broad spectrum that kills many other Gram-positive bacteria including medically important *E. faecalis*, *S.aureus* and MRSA at low concentrations. Synthetic tick defensin shows extremely low hemolytic activity against human erythrocytes. The mode of action of defensin was confirmed to be due to the peptides interacting with and disrupting the cytoplasmic membrane. Tick defensin seems to also interfere with cell separation as shown by the presence of multiple aberrant cross-walls. This is the first report of abnormal cell division as a result of defensin treatment. *Ornithodoros* defensin gene expression appears to be mediated by a newly cloned Rel/NF-κB family transcription factor OmRel. Synthetic tick defensin demonstrates high antibacterial activity against Gram-positive bacteria and low hemolytic activity suitable for pharmaceutical applications.

Biosynthesis of worker mandibular gland components in social bees.

Shigeru Matsuyama, Hiromi Sasagawa,
Inst. of Applied Biochem, Univ. of Tsukuba, 1-1-1, Ten-nou dai, Tsukuba, Ibarki 305-8572, Japan, honeybee@sakura.cc.tsukuba.ac.jp

Biosynthetic pathways of several worker mandibular components in *Apis cerana japonica* and *A. mellifera* were examined by incorporation experiments using deuterate labelled compounds.

Molecular Cloning and Recombinant Expression of Antimicrobial Peptides from House Fly, *Musca domestica*

WANG Jin-Xing, ZHAO Xiao-Fan, WANG Lai-Cheng, LI Lei, DU Xin-Jun,
School of Life Sciences, Shandong University, Jinan 250100, China, email:jxwang@sdu.edu.cn

Two antimicrobial peptide genes, the cecropin and defensin, were cloned by from the houseflies, *Musca domestics*. The full length of the cecropin cDNA was 403 bp and the open reading frame of the cDNA encoded a 63 amino acide procecropin. A potential signal sequence of twenty-three amino acids was identified, ending with the residues QSEA. A single cleavage reaction at Ala-23 therefore would generate the mature forty-amino acid *Md*-Cec peptide. The N-terminal portion of the molecule is highly basic, while the C-terminal domain is predominantly hydrophobic. The sequence identity with other cecropin was between 80% and 97%. The open reading frame of the defensin encoded a 92-amino acid peptide, which contained an NH_2-terminal signal sequence (1~22) followed by a propeptide and the mature peptide (53~92). The sequence identity with other insect defensin is between 51% and 73%. The mature peptide, with a predicted molecular weight of 4.0 kDa, and pI of 8.69, has 1 negative charged amino acid and 4 positive ones. The cecropin and defensin were expressed in *E. coli* and yeast and the recombinant peptides in yeast had the activity against several Grame negative and positive bacteria. The recombinant cecropin and defensin were confirmed by amino acid sequencing.

RAPD molecular marker identification in NB_4 D_2 and NB_{18} Silk worm *(Bombyx mori)*

RV Kumar. and B.K.Chikkaswamy
Department of Sericulture, Bangalore University, Jnanabharthi, Bangalore, INDIA 560056
venki2550@yahoo.co.in

Bivoltine races of silk worm *(Bombyx mori)* NB_4D_2 and NB_{18} are subjected to genomic DNA isolation and purification. The purification of DNA is subjected to PCR amplification to know the polymorphic and monomorphic RAPD molecular marker through Agrose gel electrophorosis method. The number of polymorphic and monomorphic bands indicated degree of divergent in silk worm races. After knowing the sequence of DNA amplification also recorded the significance among the races to adopt the various geo-eco physiological conditions by knowing molecular marker sequence which are target at the level of DNA. Further degree of genetic relationship will be discussed in detail.

Molecular marker of genomic DNA in Silk worm (Bombyx mori)

B.K.Chikkaswamy and Venkatesh Kumar. R
Department of Sericulture, Bangalore University, Jnanabharthi, Bangalore, INDIA 560056
drchikkaswamy@rediffmail.com and venki2550@yahoo.co.in

The genomic DNA of silk worm *(Bombyx mori*) one of the race called NB_4 D_2 extracted and purified as per the standard method. Silk worm genomic library of 0.5 - 2.0 kb in length was generated by digesting NB_4 D_2 genomic DNA with Pst_1 restriction endo nucleus and is ligated Pst_1 digested dephosphorylated PUC_{18} plasmid. The recombinant clones were selected by dot blotted and hybridized with translated radio labeled NB_4 D_2 genomic DNA. 248 out of 1055 recombinant plasmid which carrying only single insert and showing absence of hybridization signal selected as a probes for RFLP separation.

Genetic differentiation in three Cryptophlebia **(Lepidoptera: Tortricidae)** *species of economic importance in South Africa*

A.E. Timm, H. Geertsema & L. Warnich
Department of Entomology and Nematology, University of Stellenbosch, Private Bag X1, Matieland, South Africa, 7602; atim@sun.ac.za

The false codling moth, *Cryptophlebia leucotreta,* is one of the most damaging and catholic insect pests in South Africa. The pattern of genetic differentiation was studied in this species and compared with those of the litchi moth *C. peltastica* and the macadamia nut borer *C. batrachopa*. Populations of all three species were collected throughout their known range in South Africa from a variety of tropical, subtropical and deciduous hosts. Populations were studied using amplified fragment length polymorphism (AFLP) analysis and nucleotide sequence variation of the mitochondrial cytochrome oxidase 1 (COI) gene. Significant intraspecific variation was detected in all three species although *C. leucotreta* appeared as the most variable species, while *C. batrachopa* was the least variable. Analysis of molecular variance (AMOVA) revealed a high level of variation within populations for all three species. Estimates of the absolute number of migrants between populations (Nm) based on data obtained from mitochondrial and nuclear DNA markers indicate that *C. leucotreta* has a strong geographical structure with low gene flow between geographic populations. However, populations collected from different hosts differed only slightly. Furthermore, evidence was found for gender related dispersal. The results obtained are explained and used to provide insight into managing population levels of *Crytophlebia* spp. in different environments.

Assessment of bacteriophage WO involvement in *Wolbachia*-induced CI within the *Culex pipiens* complex

Dr. Y.O. Sanogo, Dr. A. Eitam and Dr. S.L. Dobson
Department of Entomology, University of Kentucky, S-225 Agricultural Science Center North, Lexington, KY-40546, USA yibosee@yahoo.com

The *Culex pipiens* complex includes some of the most medically important mosquitoes due to their cosmopolitan distribution and their capacity to vector infectious diseases. Members of the complex differ in their ecology, behavior, physiology and vector competence. To date, no consensus has been achieved about the taxonomical status of representatives of this group. Opinions of their relationship range from distinct species with no gene flow to physiological forms with considerable introgression. Most populations of *Culex pipiens* are infected with *Wolbachia*, a maternally inherited bacterium, which causes cytoplasmic incompatibility (CI) resulting in embryonic mortality. In prior molecular characterization, we have demonstrated that *Culex* populations differ in the bacteriophage WO that is thought to infect *Wolbachia* (Sanogo and Dobson, 2004). To test the hypothesized involvement of bacteriophage WO in determining CI in *Culex*, crosses have been conducted between nine *Culex* strains that differ in their bacteriophage WO infection types. Here, we will present the crossing results and discuss the correlation between bacteriophage WO and CI type. We will also discuss the results in relation to the restriction of gene flow among naturally occurring *Culex pipiens* populations. Reference: Sanogo YO and SL Dobson. 2004. Insect Molecular Biology (*in Press*)

Japanese oak wilt as a newly emerged forest pest in Japan: why does a symbiotic ambrosia fungus kill host trees?

N Kamata, K Esaki, K Kato, H Oana, Y Igeta, R Komura
Graduate School of Natural Science and Technology, Kanazawa University, Kakuma, Kanazawa, Ishikawa 920-1192, Japan; kamatan@kenroku.kanazawa-u.ac.jp

"Japanese oak wilt (JOW) has been known since the 1930s, but in the last fifteen years epidemics have intensified and spread to the islands' western coastal areas. The symbiotic ambrosia fungus *Raffaelea quercivora* is the causal agent of JOW, and is vectored by *Platypus quercivorus*. This is the first example of an ambrosia beetle fungus that kills vigorous trees. Mortality of *Quercus crispula* was approximately 40% but much lower for associated species of Fagaceae, even though each species had a similar number of beetle attacks. It is likely that other oaks resistant to the fungus evolved under a stable relationship between the tree, fungus and beetle during a long evolutionary process. *Quercus crispula* was probably not part of this coevolution. *Platypus quercivorus* showed the least preference for *Q. crispula*, yet exhibited highest reproductive success in this species. Therefore, *P. quercivorus* could spread more rapidly in stands with a high composition of *Q. crispula*. *Platypus quercivorus* can reproduce only one year on each *Q. crispula* tree. The relationship among *Q. crispula – R. quercivora – P. quercivorus* seems evolutionary unstable. JOW seems to be an invasive pest of *Q. crispula*. Concentric patterns of JOW spread also support this hypothesis.
"

A new approach To field application of sterile insect technique (Sit) in the management of red palm weevil, *Rhynchophorus Ferrugineus* Oliv. (Coleoptera: Curculionidae).

R Krishnakumar
Department of Entomology, College of Agriculture, Vellayani, Kerala – 695 522, India.

The red palm weevil *Rhynchophorus ferrugineus* Oliv. is one of the most devastating pests of palms especially coconut all over the world. Being an internal borer the infestation by this pest will be visible only at the later stage when the palm collapses. Efforts were taken to manage the red palm weevil in the coconut garden using sterile insect technique. A new approach to this technique was devised by studies at the Department of Entomology, College of Agriculture, Vellayani, Thiruvananthapuram, Kerala, India. In this new method the initial population was estimated by relative method by counting the different life stages of the weevil present inside the infested palms. The male weevils were sterilized using Co-60 gamma irradiation source and released in the ratio of 10:1 of sterile to normal. Weevils were then recaptured using pheromone traps and were assessed for sterility. The life table studies revealed that the multiplication rate of red palm weevil as eight and based on that subsequent generation releases were carried out. The overall studies showed that release of sterile insects at 15 days interval for 17 times in three generation was sufficient to manage the red palm weevil effectively at field level.

The effect of kaolin particle films on pests of field vegetable crops.

JE Barker, A Fulton, KA Evans, G Powell
Department of Agricultural Sciences, Imperial College London, Wye Campus, Ashford, Kent, TN25 5AH, UK; g.powell@imperial.ac.uk

The revocation of many commercial insecticides has increased the need to evaluate practical alternatives for the control of insect pests on field vegetable crops. One innovative approach being pursued is the use of novel physical barriers that can be applied to crops to protect them from insect attack. The use of kaolin particle films that are sprayed onto the plants has previously been assessed and used successfully in the protection of top fruit. Our aim is to investigate the potential of these particle films for pest management in field vegetable crops. The studies include both field trials and laboratory investigations, the latter concentrating on particular pests of the Brassicaceae including *Delia radicum*, *Myzus persicae*, *Plutella xylostella* and *Pieris brassicae*. Results from the laboratory studies and preliminary field trials will be presented.

Resistance cultivars & species of the woody ornamental *Lagerstroemia* spp. to the flea beetle, *Altica litigate*.

RI Cabrera, JA Reinert, C McKenney
Texas A&M University, Res. & Ext. Center, 17360 Coit Road Dallas, Texas 75252, USA; j-reinert@tamu.edu

"The woody ornamental crape myrtle (*Lagerstroemia* spp.) is a most popular flowering shrub/small tree due to its colorful and lengthy summer flowering and a relatively low landscape maintenance that includes an almost pest-free nature. *Altica litigate*, a metallic blue-green flea beetle that develops high populations on several species of native wildflower primroses (*Oenothera* spp.), can severely damage young crape myrtle plants in container production. In a field (open nursery) study, containerized liners of eleven cultivars of crape myrtles, representing two species (*L. indica* and *L. fauriei*) and their interspecific hybrids, were exposed to high populations of flea beetles to observe their feeding choice and damage. In laboratory experiments young leaves from these crape myrtle cultivars were used to bioassay the flea beetle adults in a no-choice feeding study. Cultivars of *L. indica* were the most susceptible to have severe damage and defoliation by flea beetles, while a remarkable resistance was found in *L. fauriei* cultivars and most of its interspecific hybrids.
"

Insecticidal activity of extracts from Australian flora.

AH Basta, RN Spooner-Hart, DL Leach, H Rasikari
Centre for Horticulture and Plant Sciences, University of Western Sydney, Locked Bag 1797, Penrith South DC NSW, 1797, Australia; a.basta@uws.edu.au

Extracts from approximately 450 different indigenous plant species in the families Lamiaceae, Myrtaceae and Proteaceae were screened in the laboratory for their bioactivity against a number of key arthropod pests, including two-spotted mite (TSM), Tetranychus urticae, greenhouse thrips (GHT), Heliothrips haemorrhoidalis, and diamondback moth (DBM), Plutella xylostella. Several extracts were also assessed against two termite species, Nasutitemes exitiosus and Coptotermes frenchi. Bioassay parameters assessed included acute mortality, antifeedant activity, repellency and effects on growth and development. Only five extracts of extracts showed high bioactivity. One (CP020177) showed high acute dermal toxicity against a number of arthropods tested (LD50 and LD95 values in ppm w/v respectively), including TSM (3797, 8108), DBM (1259, 2185), GHT (3196, 10701) and N. exitiosus (813, 1393). These investigations suggest there is potential for the development of novel pesticides from Australian flora.

Pesticide resistance in Brazil & IRAC-BR activities: current situation & perspectives.

PCRG Marçon, AC Santos, F Orsi, RNC Guedes, C Omoto
IRAC-BR, Caixa Postal 168, MOGI MIRIM, SP 13.800-970, Brazil; guedes@ufv.br

Recognition of pesticide resistance problems in Brazil dates of the late 1960s, but it was not followed by further studies until the 1990s, when the interest was renewed due to reports of insect-pest control failures. The establishment of the Brazilian Insecticide Resistance Action Committee (IRAC-BR) in 1997 was a reflex of this concern and provided new impetus to pesticide resistance studies in the country. The major activities of the IRAC-BR have been centered on institutional, research and educational programs. The institutional program is based on the promotion of the Committee and its activities, while the research program establishes priorities and provides support for projects of interest. At present, the research effort is centered in two long-standing projects, *Tuta absoluta* in tomatoes and *Spodoptera frugiperda* in maize/cotton, and several other shorter-term projects. The educational program provides basic training in Insecticide Resistance to a diverse public. Annually, IRAC-BR offers short-courses, workshops, lectures and round-table discussions in different regions of the country. IRAC-BR also sponsors a National Research Award, in two categories, undergraduate and graduate research projects. This award was created to stimulate creativity, positive criticism and human resource formation in Insecticide Resistance Management in Brazil. These initiatives from IRAC-BR have been well received in Brazil and the fruits from this effort are beginning to ripe.

Anopheline insecticide resistance in agroecosystems with high & low insecticide use in Northern Thailand.

HJ Overgaard
International Water Management Institute – Southeast Asia Regional Office (IWMI), PO Box 1025, Kasetsart University, Bangkok 10903, Thailand; h.overgaard@cgiar.org

Thailand has during recent decades experienced a diversification of the agricultural sector leading to more pesticide intensive cropping systems. About 80% of the pesticides used are for agricultural purposes. Insecticide use is particularly common in fruit orchards. Recent research from rural areas in northern Thailand indicates that anopheline density and diversity decrease as the area of fruit orchards increase. The conversion of forest to intensively managed agricultural systems may have an immediate negative effect on the abundance of malaria mosquitoes, but the long-term effect might results in highly resistant mosquito populations, due to the selection pressure of agricultural insecticides. In November 2003, mosquitoes were collected by outdoor human landing catches at three locations in a malaria endemic area in northern Thailand. The three locations were a fruit orchard (high pesticide use), a cornfield (low pesticide use), and a village. There was no significant difference in the density of primary malaria vectors between locations although more mosquitoes were collected in the fruit orchard. Preliminary results from bioassays on insecticide susceptibility show a slight possibility for resistance development in the area. There is a high probability that insecticide resistance is conferred by the heavy use of insecticides in the fruit orchard.

Induction & transmission of Bt-tolerance in the flour moth *Ephestia kuehniella.*

O Schmidt, MM Rahman, HLS Roberts
Insect Molecular Biology, University of Adelaide, Glen Osmond, SA 5064, Australia;
otto.schmidt@adelaide.edu.au

"The use of *Bacillus thuringiensis* endotoxins to control insect vectors of human diseases and agricultural pests is under threat from the possible evolution of resistance in major pest species. In addition to high levels of resistance, produced by receptor insensitivity, several cases of tolerance to low to medium levels of toxin have been reported in laboratory colonies of lepidopteran species. Since the molecular basis of some of these cases of tolerance to the toxin are not known, we explored alternative mechanisms. Here we present evidence that tolerance to a Bt-formulation in a laboratory colony of the flour moth *Ephestia kuehniella* can be induced by pre-exposure to a low concentration of the Bt-formulation and that the tolerance correlates with an elevated immune response. The data also indicate that both immune induction and Bt-tolerance can be transmitted to offspring by a maternal effect and their magnitudes are determined by more than one gene.
"

Population genetics of kdr-type resistance to pyrethroids in the peach-potato aphid, *Myzus persicae*.

J Anstead, I Denholm, MS Williamson
Rothamsted Research, Harpenden, Herts, AL5 2JQ, UK; martin.williamson@bbsrc.ac.uk

The peach-potato aphid, *Myzus persicae,* is an important agricultural pest in many parts of the world. It is mainly controlled through insecticide applications and has developed strong resistance to most of the major chemical classes as a result of their widespread use. Resistance to pyrethroids is particularly problematic in *M. persicae* and is primarily the result of a target site resistance mechanism termed knockdown resistance (or k). We have found that this is caused by either one (L1014F) or two (L1014F + M918T) point mutations in the domain II region of the para-type voltage-gated sodium channel (the target for pyrethroids). Aphids that carry the double mutation are highly resistant to even the most potent pyrethroids, surviving doses of deltamethrin in excess of 100ppm. To facilitate rapid monitoring for pyrethroid resistance in *M. persicae*, we have developed an allelic discrimination PCR assay to determine the genotypes of the two mutations in individual adults using fluorescent Taqman® MGB probes. We are using this assay to study the origins and spread of the mutations in a diverse range of *M. persicae* populations.

Modelling distributions & richness of ant species in South Carolina, USA.

548 Portia Rd, Blythewood, SC, USA; tdvs@clemson.edu

Pitfall collections at 243 sites distributed through four physiographic regions and 29 landscape types defined by SCGAP Analysis program were used to build a GAP layer for ant species. The layer models the predicted distribution and richness of ant species in South Carolina, USA. More than 80 species were collected and modelled. Distributions were modelled using physiographic region as a coarse filter. County lines and SCGAP landscape type were used as fine filters. Spatial analysis was conducted to determine the predicted species richness for each physiographic region and SCGAP landscape type.

Bio-Identifier" – A DNA-based diagnostic tool identifying invasive species at the border.

D Gleeson, K Armstrong, A Rodrigo, M Goode
Ecological Genetics Lab. Landcare Research, PB. 92170, Auckland, New Zealand;
gleesond@landcareresearch.co.nz

Invasions of insect pests have significant consequences for the economy, environment and health in New Zealand. Therefore, the ability to perform rapid and accurate identifications of intercepted organisms is an essential tool. One of the major difficulties in the identification of intercepted material is that it often involves insect immature life stages and strains for which reliable taxonomy based on morphological characters is absent. Therefore, methods that enable accurate and rapid diagnosis of taxa, whether they be well-defined species, or biotypes, are of crucial importance. Developments in DNA technology have resulted in a range of molecular techniques applicable to such applications. Much genetic data also exists in public databases, such as GenBank (NCBI), and can be utilised to develop comprehensive databases across wide-ranging taxonomic groups. We have shown, however, that DNA diagnostic techniques developed without consideration of phylogenetic relationships, or without taking into account the diagnostic value of markers, can give false identifications. Another key feature is the ability to taxonomically assign an unknown specimen even if specific DNA data is not available from that particular organism. These needs have resulted in the development of "Bio-identifier", which is a web-based DNA diagnostic tool integrating poweful bioinformatic tools and validated DNA databases, with links to risk assessment profiles and other taxonomic databases.

Spill over feeding on native Myrtaceae by *Uraba lugens.*

"DJ Kriticos,_KJB Potter, TM Withers, S Mansfield, C Inglis, L Renney"
Forest Research, Private Bag 3020, Rotorua, New Zealand; darren.kriticos@forestresearch.co.nz

Uraba lugens, a serious pest of *Eucalyptus* (Myrtaceae) in Australia, is now well established in southwest Auckland. Due to concerns about the potential impact of *U. lugens* on native New Zealand Myrtaceae, the survival and development of *U. lugens* was assessed on 11 native species under controlled conditions. In no-choice tests, larvae developed from 6th instar to pupation on 5 of the 11 species tested; only one species (*Metrosideros umbellata*) supported development from egg to pupation. Two sequential field surveys were performed in southwest Auckland to target early and late instar larvae. Within the survey area, all Australian hosts of *U. lugens* and all native New Zealand Myrtaceae were checked for the pest. Of the five native species found in the survey area (n = 441 trees), only *M. excelsa* was attacked by *U. lugens*. In the first survey 1% of the *M. excelsa* were infested (all < 1m from an infested Australian host) and 6% were infested in the second survey (43% < 1m and 86% < 10m from an infested Australian host). These results suggest that damage to native New Zealand Myrtaceae will be caused by wandering larvae and is likely to be limited to areas adjacent to infested Australian Myrtaceae.

On the road to perdition? Invasives & novel plant-insect interactions.

WJ Mattson_ DA Herms
Forestry Sciences Laboratory, N. C. Research Station, 5985 Highway K, Rhinelander, WI 54501; wmattson@fs.fed.us

Whenever, a novel interaction is initiated, i.e. between a naïve host plant and a foreign phytophagous insect, there is the potential for a death spiral ecological trajectory, i.e. where the insect populations increase explosively but the plant's populations plummet because their capacity to compete, reproduce, and survive is severely debilitated by the foreign insect. Although the possibility of such a trajectory for novel plant/insect interactions is often perceived as common knowledge, interactions of this kind are actually very poorly and disparately documented. We analyze several such interactions in North American wooded landscapes and argue that the potential for severe interactions of this type are most likely when the phytophagous insect has an intimate feeding relationship with its naive host plant. Feeding intimacy is defined by the amount and duration of contact between the insect's mouthparts and/or its body and living plant tissue.

Distribution of an indigenous & an introduced biotype of *Bemisia tabaci* (Gennadius) in Reunion Island using microsatellite markers.

H Delatte, B Reynaud, M Granier, JM Lett, WR Goldbach ,M Peterschmitt
CIRAD, Pôle de Protection des plantes, 7 chemin de l'IRAT 97410 Saint Pierre la Réunion, France; reynaud@cirad.fr

Since 1997, *Tomato yellow leaf curls virus* (TYLCV) has been responsible of great losses on tomato production in Réunion island. *B. tabaci* infestations were not observed on vegetable crops before the detection of TYLCV in 1997, although *B. tabaci* had been reported several times in the island since 1938. After 1997, two genotypes of *B. tabaci* were differentiated in Reunion. One was identified as biotype B and is supposed to have been recently introduced, whereas the other is distinct from any genotype analysed so far. Since the latter genotype was also found in Madagascar, Mauritius and Seychelles, it was considered native from the South west of the Indian Ocean and was named Ms. The distribution of both biotypes was studied throughout Reunion using a genotyping technique based on microsatellites markers. *B. tabaci* was sampled in 30 different locations typical of the various ecosystems found in Reunion. Wherever possible the whiteflies were collected on crops and weeds to investigate an eventual host specificity of the biotypes. The B biotype was mainly found in vegetable crops and its geographic distribution differ from the Ms distribution. Future equilibrium between the invasive and the indigenous biotypes is discussed regarding to virus epidemiology .

Rhagoletis cingulata Loew (western cherry fruit fly) in the Netherlands (Diptera: Tephritidae)

B Aukema, H Stigter, J Smit

National Plant Protection Organisation (NPPO), Section Entomology, Geertjesweg 15, 6706 EA Wageningen, The Netherlands; h.stigter@minlnv.nl

Rhagoletis cingulata Loew, is known as a serious pest of cherries in the western United States and Canada. It can infest sweet and sour cherries, *Prunus avium* and *P. cerarsus*, respectively and can cause considerable damage. In 1999, a single specimen of *R. cingulata* was trapped in a Malaise trap in the province of Zeeland. This first Dutch record initially was referred to *R. indifferens*, but later it appeared to be the closely related *R. cingulata*. The following years the species was found at several localities in the coastal dune region, exclusively on *Prunus serotina*. Because the species is listed as a quarantine species for Europe (Council Directive 2000/29/EC, Annex IAI) in 2003 a national survey was carried out both in *Prunus serotina* and in cherry orchards. In total 271 Pherocon AM traps were placed, 181 traps in natural environment and 90 traps in cherry orchards. On the yellow sticky traps 3204 specimens of *R. cingulata* were trapped, 3201 specimens in the natural environment and 3 specimens on the traps in cherry orchards. Based on this survey we conclude that *R. cingulata* is established in The Netherlands.

Distribution potential of three *Anoplophora* species in Europe (Coleoptera: Cerambycidae: Lamiinae): a climex study.

D de Boer, H Stigter, B Aukema
Plant Protection Organisation (NPPO), Geertjesweg 15, 6706 EA Wageningen, The Netherlands; h.stigter@minlnv.nl

"Numerous exotic invasive species can be inadvertently transported across international borders into regions where they do not already occur via trade in their host plant or host plant commodities. They can also transported as "hitchhikers" with commodities other than their host. Wood-boring species can be carried in solid wood packaging material such as packing cases, pallets, spacers and dunnage, accompanying traded goods. All three *Anoplophora* species (*Anoplophora glabripennis* (Motschulsky), *Anoplophora chinensis* (Forster) & *Anoplophora malasiaca* (Thompson)) have a Asiatic orgin and closely related to one another. The ranges of the three species have increased as a result of widespread planting of their hostplants. As polyphagous, wood-boring insects they have followed the expanding ranges of a wide variety of trees, including *Acer* spp., *Populus* spp., *Salix* spp., *Malus* spp., *Citrus* spp., *Prunus* spp. and *Ulmus* spp. Within China, *A. glabripennis* causes serious damage to *Populus* plantations, whereas *A . chinensis* is a serious pest of fruit- and ornamental trees. *A. malasiaca* is the most dreaded pest of *Citrus* in Japan. Host plants grow across much of Europe and using the computer program CLIMEX, several regions of Europe were highlighted as areas where climate is most suitable for the pest`s establishment. "

Biodiversity: threats for the present, opportunities for the future

P Raven
Director, Missouri Botanical Gardens, USA

The explosion of world population from 2.5 billion people in 1950 to more than 6.3 billion now, coupled with rising standards of affluence and expectations for consumption and the widespread use of inappropriate technologies, has changed the condition of the world from a sustainable condition only 30 years ago to an unsustainable one now. In other words, all ecological indicators, taken on a global scale, trend downward. Indeed, it has been estimated that it would take the productivity of two additional planets equivalent to Earth if all humans were to enjoy the standard of living characteristic of Australia and other industrialized countries. This clearly indicates that population, affluence, and technology must be addressed to find global stability. Against such a background, we are struggling to learn more about biodiversity, and believe that the 21st century should be a time when our deepening knowledge of biology gives us the ability to construct a sustainable world in which starvation and poverty will be alleviated. However, even by generous standards, we have catalogued no more than a sixth of the eukaryotic organisms on Earth, and very probably an even smaller proportion of the insects. We understand in any detail only a small proportion of those to which we have given names, and are moving to deal with the rest mostly in ways that would have been more suitable for the 18th century than for the 21st.

Efforts in Australia have led the world in learning about local biodiversity, but are coming under increasing competition for funding as other priorities increasingly dominate Commonwealth and State budgets. The relatively modest investments made in this country and elsewhere have demonstrated huge potential to assist greatly in the attainment of sustainability and social justice throughout the world, and it appears to be sure folly to neglect the opportunities that are available to us now, which are greater than any that we shall have in the future. Continued exploration, the more widespread use of databases, and conservation strategies fit for a rapidly changed and already seriously altered world must be adopted for the sake of future generations.

Insects: a class act through history

MR Berenbaum
Dept. Entomology, 320 Morrill Hall, University of Illinois, 505 S. Goodwin, Urbana, IL 61801-3795, USA, maybe@uiuc.edu

There is perhaps no impending ecological crisis about which the world cares less than the potential extinction of insect species. Even science fiction writers who routinely mine the environmental science literature for film and novel scenarios find the prospect to have little dramatic potential, despite the fact that a considerable body of evidence attests to the vulnerability of insects and other arthropods to population decline. Insect extinction is a reality; at least 72 species are listed as extinct worldwide by the International Union for Conservation of Nature and Natural Resources (IUCN). This tiny number, relative to the number of described species, is reflective more of the lower level of concern for their welfare in general and the greater degree of difficulty in documenting their population declines than it is any extraordinary immunity from extinction on the part of arthropods, in comparison with other organisms. What few comparative studies have been done in fact suggest otherwise. Due to the tremendous trophic diversity of insects, extinctions within other taxa can be accompanied by unrecognized (or at least unheralded) insect extinctions. Although the extinction of many bird species, for example, has been meticulously documented, the status of their arthropod ectoparasites is rarely documented, much less mourned. Making the case for protecting the blood-sucking parasites of a more charismatic vertebrate struggling for survival is perhaps the ultimate challenge in conservation biology.

hy conservation of arthropods, and unappealing invertebrates in general, is such a hard sell derives in large part from a general lack of appreciation of the enormous impact of insect goods and services on human health and welfare throughout history and into the present. The consequences of extinction in select taxa are potentially of tremendous economic importance (and certainly on a par with those of more frequently exploited science fiction scenarios). Enlightening policymakers and the public of the necessity for continued cohabitation of the planet with insects is among the greatest challenges faced by contemporary entomologists and may involve new knowledge, new vocabulary, and new outreach efforts befitting the new century.

Documenting ecosystem services provided by insects, an effort used with increasing frequency to promote conservation efforts in other groups, has rarely been attempted and presents a set of unique challenges. Such efforts are inevitably hampered by the paucity of data on life histories and ecologies, particularly for species that have experienced drastic reductions in population size. The same can be said, perhaps even more forcefully, for arguing from the perspective of biodiversity prospecting. Substances of pharmaceutical value may be difficult to extract or produce in economically viable amounts given the small size of the producers and the difficulties associated with mass rearing.

Moral and aesthetic arguments for conserving insects have rarely met with the same level of success as they have with more conspicuous, majestic, or symbolically powerful species. Outreach efforts in the context of insect conservation should be sensitive to the power of language. The value of an accessible and appealing common name, for example, particularly one that reflects distinctive life history attributes, is inestimable. The best hope, though, for success is for entomologists as a group to make every effort to reach out to the public to cultivate an appreciation for the Class Insecta; there are more than a million stories and they are all ultimately worth telling.

"Honeybee vision, navigation and 'cognition': Basic principles and technological applications"

*MV Srinivasan, SW Zhang J Chahl**
Centre for Visual Sciences, Research School of Biological Sciences, Australian National University. Defence Science and Technology Organisation, Australia

Insects, in general, and honeybees, in particular, perform remarkably well at seeing and perceiving the world and navigating effectively in it, despite possessing a brain that weighs less than a milligram and carries fewer than 0.01% as many neurons as ours does. Working together with our colleagues, we have been trying to unravel the secrets of their success.

Although most insects lack stereo vision, they use a number of ingenious strategies for perceiving their world in three dimensions and navigating successfully in it. For example, distances to objects are gauged in terms of the apparent speeds of motion of the objects' images, rather than by using complex stereo mechanisms. Objects are distinguished from backgrounds by sensing the apparent relative motion at the boundary. Narrow gaps are negotiated by balancing the apparent speeds of the images in the two eyes. Flight speed is regulated by holding constant the average image velocity as seen by both eyes. Bees landing on a horizontal surface hold constant the image velocity of the surface as they approach it, thus automatically ensuring that flight speed is close to zero at touchdown. Foraging bees gauge distance flown by integrating optic flow: they possess a visually-driven "odometer" that is robust to variations in wind, body weight, energy expenditure, and the properties of the visual environment.

Integrated pest management in the age of biotechnology: how can we be better off in the long run?

SS Liu
Institute of Applied Entomology, Zhejiang University, Hangzhou 310029, China. shshliu@zju.edu.cn

"A "pest" in "integrated pest management" or IPM subsumes any living organisms that bother people. Here we focus on insect pests in crop systems. First we review briefly the origin and development of the IPM paradigm. Next we present a series of outstanding case histories to illustrate how successes and failures of IPM have been brought about. We then use these case histories to pose a few key questions as to how we can improve IPM. Finally we take a glance towards the future of IPM in the age of biotechnology.
Recent research on honeybee perception and cognition is beginning to reveal that these insects may not be the simple, reflexive creatures that they were once assumed to be. For example, bees can learn rather general features of flowers and landmarks, such as colour, orientation and symmetry, and apply them to distinguish between objects that they have never previously encountered. Bees exhibit "top-down" processing: that is, they are capable of using prior knowledge to detect poorly visible or camouflaged objects. They can navigate through labyrinths by learning path regularities, and by using symbolic signposts. They can learn to form complex associations and to acquire abstract concepts such as "sameness" and "difference". Bees are also capable of associative recall: that is, a familiar scent can trigger recall of an associated colour, or even of a navigational route to a food location. All of these observations suggest that there is no hard dichotomy between invertebrates and vertebrates in the context of perception, learning and 'cognition'; and that brain size is not necessarily a reliable predictor of perceptual capacity. Finally, some of the above principles – especially those that relate vision and navigation – are offering novel, computationally elegant solutions to persistent problems in machine vision and robot navigation. Thus, we have been using some of the insect-based strategies described above to design, implement and test biologically-inspired algorithms for the guidance of autonomous terrestrial and aerial vehicles.

Contact: Prof. Mandyam V. Srinivasan
Centre for Visual Sciences, Research School of Biological Sciences, Australian National University
P.O. Box 475, Canberra, A.C.T. 2601, Australia
Phone: +61-2-6125-2409; Fax: +61-2-6125-3808; email: M.Srinivasan@anu.edu.au
Web: http://biology.anu.edu.au/rsbsweb/profiles/srini.shtml

Key elements of the IPM paradigm include: (1) pests are biotic components of ecosystems capable of inducing stress and reducing crop yield or quality, and management activities must envisage pests within such an ecological perspective and work in harmony with natural control; (2) multiple tactics such as cultural control, plant resistance, biological control or physical control are used in a compatible manner, and most importantly naturally occurring biological control should be promoted to the greatest extent possible and application of broad-spectrum synthetic insecticides be minimized, to maintain pest damage below the economic injury level; (3) creatures dubbed key pests are allowed to survive at low abundance in the ecosystem; and (4) cost/benefit analyses must take into account the interests of and impacts on producers, society and the environment. This IPM paradigm is considered to be the best science available to the solution of pest problems, and no major departures from the basic research and implementation paradigm have occurred in the past 40 years, although significant changes have taken place in technological advances and tactical options available. Nevertheless, ecological research findings and IPM implementation experiences over the years have contributed significantly to providing strong support to the underlying principles and improving the elaboration of details.
Examples are used to illustrate the successful and unsuccessful approaches that have been used to develop and implement pest management programs. The final victory of the vedalia beetle and associated drama demonstrate that (1) an introduced pest can be effectively controlled by the right natural enemy introduced from the pests origin; (2) the beauty of naturally occurring biological control can be immediately devastated by a humanistic approach, and (3) to follow blindly a correct IPM idea, without adequate ecological research, can be unproductive. The history of migratory locust control in China records that habitat manipulation, not chemical control, solved, perhaps for good, the worst pest problem that has devastated the life of Chinese people for thousands of years. Rice IPM in Asia illustrates that (1) even in annual crop systems naturally occurring biological control plays a vital role in suppressing the pests; (2) a participatory approach among farmers, extension service and researchers is needed to effectively implement IPM; (3) sound ecological research is necessary to avoid misuse of seemingly powerful tactics; and (4) forceful legislative measures can be a powerful tool to aid in IPM implementation. Experiences in cotton IPM suggest that practical IPM strategies can be derived only through an experimental approach, and (2) extensive and expensive strategic modelling with computers has not provided much insight of use to practical IPM. The recent successful *Bemisia* IPM in the United States highlights that a 'super-bug' can be brought under sustainable control by IPM, mainly through a right integration of biological and chemical controls. The experiences of brassica IPM in New Zealand, Australia, and China illustrate that (1) classical biological control can form the central element of effective pest management programmes; (2) effective naturally occurring biological control can be promoted by simple IPM strategies; and (3) field comparative experimental studies can offer direct and convincing evidence of the efficacy of biological control. The commercialized successes of augmentation biological control in greenhouses in Europe demonstrate that even in highly artificial crop systems, biological agents can be promoted to bring pests under control and the approach is sustainable. The recent history of deployment of transgenic insecticidal plants indicates that (1) insect resistance to these crops in the field can be effectively delayed by appropriate resistance management strategies, and these plants offer new opportunities for integrating plant resistance with biological control to develop more successful IPM programs.
Philosophically there are two conflicting approaches to IPM, one rooted in naturalism and the other in humanism. The key

elements of the IPM paradigm proclaim it as naturalism. To follow a philosophy of naturalism means that we must work with nature whiling trying to manipulate its features for our benefits. The case histories demonstrate that as we become equipped with more powerful tactics, we need to use them more gently and intelligently to avoid disasters and to gain the best benefits in the longer term. We assert that the IPM paradigm, as it has evolved to date, has proven to be a robust construct for the solution of pest problems. The key weaknesses with our pest control research and practices in recent years have come from a habitual desire to view IPM simply as a substitute for "pest control", with little thought given to the underlying ecological principles and the implications for maximizing the inherent resistance to insect pests in the ecosystem. Major technological advances in chemistry, biochemistry, behavioural science, neurophysiology, molecular genetics, and genetic engineering can be expected to produce a new array of products and materials that are less toxic and hazardous to humans and the environment than conventional pesticides in the years to come. Deployment of transgenic insecticidal plants and other new technologies guided by the IPM paradigm are likely to enable us to develop sustainable pest management systems that will maximize economic, social and environmental benefits for society in the long run.

Genetically modified crops and food security: an African perspective

JA Thomson,
Department of Molecular and Cell Biology, University of Cape Town, South Africa

In Africa 70% of the population depends on agriculture as the sole source of income. However, Africa's crop production is the lowest in the world and 25% of grain is imported. It is estimated that sub-Saharan Africa will have a shortfall of nearly 90 million tons of cereal by the year 2025. Biotechnology and the use of genetically modified (GM) crops are some of the tools that could improve efficiency, quality and productivity. At a UNIDO meeting in Nairobi last year, agricultural experts from some 13 African countries prioritised biotechnology-derived crops as follows: insect resistant (Bt) African maize varieties, resistance to African plant viruses, resistance to parasitic weeds, decreased mycotoxin levels in maize and drought tolerant crops.

Maize streak virus is endemic in Africa, causing huge economic losses to both commercial and small scale farmers. Colleagues and I have developed maize that produce a severely mutated form of the replication associated protein, resulting in highly resistant plants. These are being bred into commercial varieties of maize. A consortium of African and American scientists are developing cassava resistant to the *African cassava mosaic virus*.

A major parasitic weed is Striga, or witchweed. It attacks the roots of poorly growing crops and intertwines its roots with them. Field trials have been carried out on herbicide resistant maize with very promising results.

South Africa recently began planting Bt white maize for human consumption and we are finding a decrease in the levels of post-harvest fungal infection with a concomitant decrease in mycotoxin content. Bt cotton, although not a food crop, is providing a much-needed increase in revenue to small scale farmers.

The source of our genes for the development of drought tolerant maize is a South African indigenous "resurrection plant" which can loose 95% water content and, upon watering, "resurrect" in three days. Our first transgenic plants are showing resistance to water loss, heat and salt.

While GM crops are not a panacea for feeding Africa, we cannot afford to turn out backs on any technology that could improve food productivity. Indeed, 30% of the global transgenic crop area of 67.7 million hectares in 2003, equivalent to over 20 million hectares, was grown in developing countries. The absolute growth in GM crop area between 2002 and 2003 was almost the same in developing countries (4.4 million) and industrial countries (4.6 million hectares), with the percentage growth more than twice as high (28%) in developing countries compared with industrial countries (1.1%). It is clear that farmers, who in Africa are so often also consumers, know a good thing when they see it.

Insect symbionts – life with multiple genomes

SL. O'Neill
School of Life Sciences, The University of Queensland, Brisbane, Australia

Vertically transmitted microbial symbionts of insects have been painstakingly observed and recorded for well over a century. Not until quite recently though has the true extent of the ubiquity of these associations been fully realized. Similarly a mechanistic understanding of how these agents interact with insects and their importance to the biology of their hosts has only very recently begun to be appreciated. Two broad classes of symbionts are present in insects. The classical nutritional mutualists that provision host insects with required metabolites (e.g. *Buchnera* of aphids and *Wigglesworthia* of Tsetse) and the reproductive parasites that manipulate the reproductive biology of their hosts to maximize their own transmission often at the expense of host fitness (e.g. *Wolbachia* and *Cardinium* that infect a broad range of different insect species).

The recent sequencing of a number of diverse insect symbiont genomes is beginning to peel away the mystery that surrounds these interactions. The completion of full genome sequences of the nutritional symbionts of aphids, tsetse flies and carpenter ants together with the sequencing of the widespread reproductive parasite genome, *Wolbachia pipientis,* is providing insight into the mechanisms that allow these microorganisms to infect and interact with hosts. We now understand the types of molecules that nutritional symbionts provide to their hosts, how they are delivered and the selective pressures that have shaped these associations. For the first time we can start to assess the potential mechanisms by which reproductive parasites manipulate insects and generate host phenotypes like cytoplasmic incompatibility, parthenogenesis, feminization and male-killing.

Together with an understanding of the basic biology of host-symbiont interactions has come the potential to utilize symbiont systems for applied outcomes. Paratransgenesis has emerged as an exciting possibility for modulating the ability of insects to transmit pathogens to humans, plants and livestock. For example, the engineering of bacterial symbionts of *Rhodnius proxilus* to prevent this insect from being capable of transmitting trypanosomes to humans is well developed as a potential future disease control strategy. In addition *Wolbachia* is being developed as an agent that might similarly be used to either suppress insect populations or modify their disease transmission potential. In this case its ability to rapidly invade host populations and skew insect population age structure are features that might facilitate its future use in applied entomology.

Genetic basis for variability of Cry1Ac expression among commercial transgenic *Bacillus thuringiensis* (Bt) cotton cultivars in the United States

JJ Adamczyk Jr, WR Meredith, J Gore
"USDA-ARS, Southern Insect Management Research Unit, 141 Experiment Station and Lee Rds. P.O. Box 346, Stoneville, MS 38776, United States of America, jadamczyk@ars.usda.gov"

The amount of Cry1Ac in transgenic *Bacillus thuringiensis* (Bt) or Bollgard® cotton varies among commercial cultivars. These expression differences have been correlated to survival levels in Lepidoptera, indicating that all Bollgard® cultivars do not provide the same level of control. The objective of this study was to determine if differences in expression among commercial cultivars of Bollgard® cotton were under simple genetic control. If so, these findings could influence the way breeders select cultivars by selecting for efficacy in addition to agronomic traits. Crosses were made in the greenhouse with a high expressing and a low expressing cultivar. The parents, F_1, and F_2 generations were planted in the field. The amount of Cry1Ac was quantified using a commercial ELISA kit. Highly significant variances within the two F_2 breeding populations were due to genetic segregation for Cry1Ac expression. Using the modified Castle-Wright formula, estimation of the number of contributing genes in both breeding populations was small. These data show that genetic background has a major effect on Cry1Ac expression. Because backcrossing is the primary method used by commercial cotton breeders, the selection and use of donor and/or recurrent parents that will result in a high level of Cry1Ac expression is crucial.

Wild and cultivated sesame (*Sesamum* spp.) resistance to *Antigastra catalaunalis* (Dup.) (Lepidoptera: Pyralidae)

DB Ahuja, RK Kalyan, ZS Solanki
"Department of Entomology (Rajasthan Agricultural University), Agricultural Research Station, Mandor (Jodhpur) 342 304, India,
Deshbandhu4@rediffmail.com"

Sesamum indicum L. and wild relatives (*S. alatum* Thonn., *S. laciniatum* Klein., *S. mulayanum* Nair, *S. malabaricum* Burm., *S. radiatum* Schumach & Thonn) were evaluated in the laboratory (27 ± 0.5 ^{0}C, 75 % RH) for resistance to *Antigastra catalaunalis* (Dup.). On sesame (*S. indicum*) the larval period and the larval to adult periods averaged 12.6 and 17.6 days, respectively, compared to larval periods of 9.33 - 9.75 days and larval to adult periods of 15.5 - 16.0 days on wild species. Pupal periods were similar on all species. Larval survival ranged from 10.25% on S. *malabaricum* to 35% on *S. alatum*. S. *malabaricum* did not support larval growth (no adult emergence), whereas adult emergence ranged from 05.55 - 11.76% on other wild species. Adult emergence was 80% on cultivated sesame. Growth indices and survival index were highest for larvae reared on *S. indicum*. Fourth instar larvae inflicted little feeding damage (0.0 to 05.0 %) to seeds of the wild species in the laboratory. No damage was observed on wild species in the field. This research has identified a source of *A. catalaunalis* resistance in wild *Sesamum* spp

Decrease in the Colorado potato beetle densities on manure-amended soils: another proof of the mineral balance hypothesis?

A Alyokhin, G Porter, E Groden, F Drummond
5722 Deering Hall, Department Of Biological Sciences, University Of Maine, ME 04469, USA, anei.alyokhin@umit.maine.edu

The mineral balance hypothesis suggests that the organic matter and microbial activity associated with organically managed soils affords a buffering capability to maintain nutrient balance in plants. An optimal nutrient balance, in turn, results in both good plant growth and resistance to herbivory. We determined effects of soil amendment practices on the Colorado potato beetle populations in potato fields and investigated their interactions with crop rotation and pest management approach. Beetle densities were almost universally lower in the plots receiving manure as soil amendment, while crop rotation and pest management approach had little or no effect. Unlike beetle abundance, plant height and canopy cover were comparable between the plots receiving manure and synthetic fertilizer. Furthermore, tuber yields were higher at the manure-amended plots. In direct accordance with the mineral balance hypothesis, there was a amatic dissimilarity in the mineral composition of potato leaves collected from manure- and synthetic fertilizer-amended plots. Overall, we detected differences in concentrations of nitrogen, calcium, magnesium, phosphorus, aluminum, boron, copper, iron, manganese, and zinc. Mineral content of potato foliage was responsible for 40-57% of the variation in the Colorado potato beetle populations observed among the experimental plots.

Major insect pest shifts following the adoption of bollgard cotton in North Carolina, 1996 to 2003.

JS Bacheler, DW Mott
"Dept of Entomology, Box 7613, North Carolina State Univ., Raleigh, NC 27695-7613 USA jack_bacheler@ncsu.edu"

In an 8-year, large-scale evaluation of pest shifts resulting from the adoption of Bt (Bollgard) cotton by North Carolina's cotton producers, 623 pairs of Bollgard and conventional cotton fields were assessed from 1996 through 2003 for mid- to late-season boll damage. Bollworm, *Helicoverpa zea* (Boddie) damage to bolls averaged approximately 3-fold higher in conventionally protected cotton (4.7% vs. 1.7%), while stink bug, mostly *Acrosternum hilare* (Say), damage to bolls averaged more than 3-fold higher in Bollgard cotton (3.0% vs. 0.9%). European corn borer, (*Ostrinia numbilalis* (Hübner), and fall armyworm, (*Spodoptera frugiperda* (J.E. Smith), damage to bolls was very light from 1996 to 2003. Overall boll damage during this period favoured Bollgard cotton by 1.3% (4.9% vs. 6.2%). Bollgard cotton was treated an average of 2 times less per year (2.65 vs. 0.85 applications) than conventional cotton. Considering the average technology fee for Bollgard cotton seed, late-season insect control costs, the penalty of boll damage, and proposed relative scouting costs: the overall economic returns of Bollgard cotton (for insect-related costs only), averaged over the 1996 to 2003 commercial availability period, were approximately $15.00 (US)/hectare greater than that of conventionally protected cotton.

Management of forests for the future - site selection and environmental change

A Battisti
University of Padova, Dep. Environmental Agronomy, Agripolis 35020 Legnaro PD Italy, anea.battisti@unipd.it

1. The major part of the European forests originate from a strong modification of the native forest ecosystems, mainly based on the introduction of conifer species from outside their natural range. 2. Most of the literature on forest insect pests concerns tree species considered as economically importantconomic importance can be related either to the cost of the investment or to the expected benefits. 3. The forests subjected to insect attacks may vary according to the climate change, as it may affect the distribution of the insect pests to a greater extent than that of the host trees. 4. The environmental change affects indirectly the tree-insect relationships because of the new functions of the forests (e.g. CO2 sink, renewable energy sources, touristic use) which may results in new management options. 5. Little is known about stability mechanisms of low- or no-disturbed patches of European forests, which could be potentially used to assess the resiliance of the pristine habitats to the environmental change. 6. Extreme events, such as the high temperature in the summer of 2003, may allow 'a posteriori' test of hypotheses on the consequences of the climate change on the tree-insect relationships. 7. A few management options (e.g. use of trees within the species range, mixed versus pure stands, improvement of the understory) have been proposed to counteract the effects of the environmental change, but there is limited experimental evidence supporting each of the suggested options.

Use of mineral oils in tropical and subtropical citrus IPM in Asia: potential and impediments

GAC Beattie, O Nicetic, DJ Rae
Centre for Horticulture and Plant Sciences, University of Western Sydney, Locked Bag 1797, Penrith South DC, NSW, 1797, Australia,
a.beattie@uws.edu.au

Extensive studies since 1993 have shown significant potential for using biorational horticultural and agricultural mineral oils in citrus IPM programs in Asia. We summarise results that show that these products can be used to control a wide range of pests and diseases simultaneously in programs based on application of multiple evenly and adequately (generally low volume) applied low-concentration (£ 0.5% v/v) sprays. We show that these programs are cost effective and that they can be used to significantly reduce currently excessive use of broad-spectrum synthetic pesticides. We discuss impediments to widespread adoption of this technology and means of overcoming them. These include poor farmer education, 'quick kill' and 'the only good insect is a dead insect' paradigms, chemical companies and their distributors, marketing of relatively cheap, substandard highly phytotoxic petroleum-derived sprays oils, government policies, regulations and their enforcement, and incompatibilities stemming from inappropriate overuse and mixing of pesticides, fertilisers and emulsifiers.

Mapping stem borer and armyworm resistance and putative resistance factors in tropical maize.

DJ Bergvinson, S García-Lara, A Burt, JT Arnason.
"CIMMYT, Apdo Postal 6-641, D.F., 06600, Mexico, d.bergvinson@cgiar.org"

Maize production in tropical ecologies can be severely reduced by stem borers s (*Diatraea spp.*) and fall armyworm, *Spodoptera frugiperda* (J.E. Smith). The International Maize and Wheat Improvement Center (CIMMYT) as developed tropical sources of resistance to these pests for use in the development of molecular maps to identify quantitative trait loci (QTL) for the observed resistance. Using two molecular maps [CML131 (S) x CML67 (R) and Ki3(S) x CML139(R)], QTL were identified using composite interval mapping. Five major QTL in bin 1.06, 7.03, 8.02/6, and 9.03 explained 41% of the phenotypic variance (σ^2_p) for leaf feeding damage. Three QTL for leaf toughness, a trait considered important in resistance, were located in bin 1.06/11 and 8.06 and explained 37% of σ^2_p. Chlorophyll QTL did not overlap with insect resistance factors, with the major QTL being located in 4.08 ($\sigma^2_{p=}43\%$). QTL for cell wall bound phenolic acids (*trans*-ferulic acid, 8-5′ diferulic, and 8-5′ diferulic acid) clustered with resistance in bin 1.11. This observation is consistent with a broad-based, structural resistance mechanism for tropical maize resistant to lepidopteran field pests. Based on these studies, candidate genes have been identified and will be discussed.

Understanding aphid damage and development in canola crops

F Berlandier
Western Australian Department of Agriculture, Locked Bag No. 4, Bentley Delivery Centre WA 6983
Australia, fberlandier@agric.wa.gov.au

Canola crops grown for oilseed in Western Australia are regularly infested by the aphids *Brevicoryne brassicae* (L.), cabbage aphid, *Lipaphis erysimi* (Kaltenbach), turnip aphid, and *Myzus persicae* (Sulzer), green peach aphid. Research into whether economic damage results from these infestations has been under way for a number of years. Early work showed that high levels of aphids in canola did cause temporary damage, but these infestations did not translate into losses in oilseed production. This was explained by the ability of canola plants to compensate for insect damage. Canola's ability to compensate for aphid damage is influenced by rainfall and to a lesser extent, plant cultivar. In addition, the level of plant drought stress influences the rate of aphid population development on canola. Aphids develop at faster rates on susceptible cultivars of canola when plants are undergoing drought stress than on unstressed plants, and will eventually cause significant and irreparable losses in oilseed production. Understanding the influence of these factors on oilseed production will aid in the decision making process for aphid control measures. The details of this research are discussed.

Recent advances in the management of *Rhopalosiphum padi*, a vector of barley yellow dwarf luteovirus

NA Bosque-Pérez, ES Jiménez-Martínez, SD Eigenbrode
Department of Plant, Soil and Entomological Sciences, University of Idaho, PO Box 442339 Moscow, Idaho, USA 83844-2339. nbosque@uidaho.edu

The bird cherry-oat aphid, *Rhopalosiphum padi* (L.) (Homoptera: Aphididae) is one of the most economically important aphids on wheat worldwide. *R. padi* damages the host by direct feeding and by transmitting *Barley yellow dwarf virus* (BYDV). This luteovirus causes a serious disease of cereals worldwide. Management of *R. padi* is achieved via multiple practices including chemical, cultural and biological control, but relies heavily on insecticides. Seed-applied insecticides can reduce aphid densities and BYDV incidence. Planting date modifications may be used to avoid aphid flights and reduce BYDV incidence. However, such modifications are not always a practical management option. Natural enemies, including parasitoids and predators provide aphid control and may influence virus spread. Models have shown that the effect of vector preference for virus-infected plants on virus spread is influenced by the frequency of diseased plants. We have recently demonstrated that *R. padi* behavior is influenced by BYDV infection of wheat plants and that this is mediated by plant volatiles. Knowledge of the factors that influence *R. padi* responses to BYDV-infected plants would be useful for understanding vector behavior and movement, and virus spread. The potential implications of these findings for the development of management options will be discussed.

Efficacy of a pyrethroid and a systemic seed-treated insecticide to manage a pest and a pathogen

JD Bradshaw, ME Rice, and JH Hill
Iowa State University, 110 Insectary, Department of Entomology, Ames, Iowa 50011

Bean pod mottle virus causes qualitative and quantitative damage to soybeans and is transmitted most efficiently by the bean leaf beetle, *Ceratoma trifurcata* Forster. During the summers of 2002, 2003 and 2004, potential strategies for managing bean leaf beetles and *bean pod mottle virus* were evaluated at Iowa State University research farms. The current management strategy in Iowa recommends one early and one mid-season lambda-cyhalothrin application. Our study determined the efficacy of applying a systemic, seed-treated insecticide (thiamethoxam), either alone or in combination with foliar applications of lambda-cyhalothrin. Six (2002) and seven (2003 and 2004) management strategies were evaluated. In 2002, the following treatments were used: thiamethoxam seed treatment, lambda-cyhalothrin foliar application in late May, lambda-cyhalothrin foliar application in early July, thiamethoxam seed treatment with a lambda-cyhalothrin foliar application in early July, lambda-cyhalothrin foliar application in late May and early July, and an untreated control. In 2003 and 2004, one treatment was added — thiamethoxam with a lambda-cyhalothrin foliar application 10 days later. The effectiveness of these strategies was measured by comparisons of beetle abundance, enzyme-linked immunosorbant assayed soybean sap, seed weight and quality.

Invasive ant species in continuous and fragmented areas in the Atlantic forest

CRF Brandão, RR Silva
"Museu de Zoologia, USP, PO Box 42494 São Paulo, SP, Brasil, crfbrand@usp.br, rrsilva@ib.usp.br"

We investigated the role if invasive ant species along the Atlantic forest, one of the world biodiversity hot spots, taking *Wasmannia* spp. as a model organism representing the invasive species. We based our study on fifty 1m^2 litter samples, submitted to Winkler extractors for 48 hours, collected in each of 26 regularly spaced localities along some 20^o degrees of latitude, representing two main classes of altitudes (sea level and 800-900m). We concentrate collecting in the evergreen dense forest in the wet season. As localities in the southern half on the forest are continuously covered by forest, while in the northern half the forest is fragmented, we investigated whether the fragmented half bears significantly more invasive ants than in the continuous forest. For the northern half,we investigated if there is a significant correlation between fragment size and the invasive ants present in the samples. We studied also the effect of the presence of invasive species in each sample regarding the total number of ant species per sample.

A novel approach for rapid screening of grapevine rootstocks for resistance to grape phylloxera, *Daktulosphaira vitifoliae* Fitch (Homoptera: Phylloxeridae).

AE Burns, KS Powell
"Primary Industries Research Victoria, Department of Primary Industries - Rutherglen Centre, RMB 1145 Rutherglen, VIC Australia 3685,
anna.burns@dpi.vic.gov.au "

Quarantine and the use of resistant rootstocks are currently the only long-term options for managing the viticultural insect pest, grape phylloxera, *Daktulosphaira vitifoliae* Fitch (Homoptera: Phylloxeridae). Phylloxera management in Australia is unique because most commercial vineyards are planted with ungrafted European grapevines and the focus of management is on quarantine to restrict spread of the insect. Most viticultural regions are therefore susceptible to infestations and effective rootstock recommendations need to be developed. Conventional approaches to screening for phylloxera resistance include laboratory and field-based studies. A new protocol was developed to screen grapevine rootstocks for phylloxera resistance under glasshouse conditions. Grapevines grafted to three rootstocks of American parentage used in south-eastern Australia were screened for resistance to the two most common phylloxera genetic strains, G1 and G4. The rootstocks were significantly more resistant to both strains of phylloxera than the ungrafted vines. Population development was significantly reduced on all rootstocks. Furthermore, populations of the G4 strain were significantly greater than the G1 strain on ungrafted roots, indicating different degrees of virulence between the strains. This screening technique is considered to be more reliable than excised-root bioassay systems, which exclude a whole plant response, and field-based studies where external variables can influence results.

Towards appropriate *Bt*-Corn IRM strategies for the Asian corn borer, *Ostrinia furnacalis* (Guenee) in major corn growing areas in the Philippines: field surveys of alternate host plants and biological studies

MT Caasi-Lit, EC Fernandez, LD Taylo, MAA Capricho, EG de Leus, JP Mantala, IL Latiza
Entomology Laboratory, Institute of Plant Breeding, College of Agriculture, University of the Philippines Los Baños, 4031 College, Laguna, Philippines, mcl@ipb.uplb.edu.ph or binglit@hotmail.com

The institution of refugia as conventionally defined for temperate areas accompanies the introduction of Bt-corn into the Philippines. The refugia concept has underlying assumptions based on population dynamics, which, in turn, rely also on plant-insect relationships, including alternate hosts. Our survey showed tomato, pepper, sitao, okra, cotton and sugarcane as alternate crop hosts and aguingay, napier, tigbi, paragrass and wild sorghum as weed hosts. The abundance of these plants in and out of the cornfield was noted. ACB completed its development on aguingay, napier and tigbi using fresh stalks under laboratory conditions. Several laboratory experiments determined larval and ovipositional preference. Larvae preferred to feed and adults preferred to oviposit on corn, napier, aguingay and cotton. On the other hand, ACB completed it growth and development on whole plants of all selected alternate hosts except tomato and pepper, which appear to be transient hosts only. Further investigation of other hosts and their relationships with ACB in different cropping systems is recommended. Under tropical conditions, the natural great plant diversity may necessitate changes in, if not a total re-thinking of the refugia concept as an insect resistance management strategy.

Evaluation of plant resistance, chemical, and cultural control to manage populations of the sunflower stem weevil and impact on natural enemies

LD Charlet, RM Aiken, RR Meyer, A Gebre-Amlak
USDA, ARS, Northern Crop Science Laboratory, Box 5677, University Station, Fargo, ND 58105-5677 charletL@fargo.ars.usda.gov

The sunflower stem weevil, *Cylinocopturus adspersus* (LeConte) (Coleoptera: Curculionidae), is a pest of cultivated sunflower. Since the 1990s, damage has been reported and populations have been increasing in the sunflower production regions of Colorado and Kansas. Adult weevils emerge from overwintered stalks and females lay their eggs at the base of sunflower stalks. Larvae feed apically in the stems and then descend to the lower portion of the stalk and excavate overwintering chambers into the stem cortex. If the larval population in a plant is high, the stem, weakened by tunneling or overwintering chambers, will break causing a loss of the entire plant. The purpose of this 3-year project was to investigate tactics including a combination of planting date and foliar and seed treatment insecticide applications to lower weevil densities in the stalks and thus reduce losses caused by lodging. Trials included chemical application based on both plant stage and degree-day models. A second goal was to investigate genetic resistance as a potentially valuable resource and screen available sunflower hybrids, accessions, and lines for tolerance to lodging or low weevil densities in the stalks. The impact of these methods on weevil parasitoids which attack the larvae also was studied.

Examining the origins of insect pests on rice: effects of rice domestication on tritrophic interactions

YH Chen, C Bernal
International Rice Research Institute, DAPO 7777, Metro Manila, Philippines, y.chen@cgiar.org

Many insect pests on rice only feed on the genus *Oryza*, suggesting that prior to domestication, these insects fed on the wild progenitors or relatives of cultivated rice. While rice domestication has increased its suitability to cultivated conditions, other physical and chemical plant traits have also been altered that may affect interactions between rice, insect pests, and their natural enemies. Understanding how domestication has altered tritrophic interactions may help determine why some rice pests are so difficult to control and which plant characteristics can help control pest populations. We investigated the role of rice domestication on tritrophic interactions by comparing the abundance of key rice pests (stemborers, planthoppers, leafhoppers) and their natural enemies on *O. sativa* and *O. rufipogon*, widely considered the wild progenitor of cultivated rice. Plots were sampled for insects on a bimonthly basis using vacuum sampling and destructive sampling. In addition, we measured physical traits such as plant allocation, tillering, stem diameter, and timing of plant growth. We examined whether the patterns of pest and natural enemy abundance were related to physical plant changes associated with rice domestication.

Impacts of Bt transgenic rice on arthropods in rice ecosystem

J Cheng, X Zhu, Y Hu
Institute of Applied Entomology, Zhejiang University, Hangzhou 310029, China, jacheng@zju.edu.cn

Impacts of Bt transgenic rice on community structure of arthropods in rice ecosystem was investigated in isolated rice paddy and the results showed that the abundance and species richness in Bt rice (KMD1) were little higher than those in the control (XS11). Three varieties of Bt rice (KMD1, KMD2 and T7) with the same Bt gene (*Cry*1Ab) and Ubiquitin, but two parents (XS11 and T6) were selected to study the impacts of Bt rice on population parameters and the relevant mechanism in laboratory. The results indicated that the impacts of Bt rice on population parameters of insects varied with insect species and rice variety. The comparisons of free amino acids and plant volatiles among KMD1, KMD2 and XS11 showed that some chemical components in the three varieties were significantly different and the differences might consist with the impacts of Bt rice on biological parameters on the arthropods. Finally, the interactions among main components related to ecological risks in rice ecosystem and the procedures for ecological risk evaluation were discussed.

An overview of citrus IPM in Florida

CC Childers, ME Rogers
University of Florida, Citrus Research and Education Center, 700 Experiment Station Road, Lake Alfred, FL 33850, USA

Florida citrus production includes ca. 323,000 hectares and represents 70+% of the total United States production. Over 90% of the oranges and 40% of grapefruit are grown for processing and the remainder (30 million or more boxes) goes for fresh market. Many citrus species and varieties are grown and production practices differ depending upon their market destination, susceptibility to fungal pathogens, and insect or mite pests. Florida's climate is best characterized by having both moderate temperatures and rainfall and infrequent freezes. Because of environmental conditions, fungal pathogens are among the most important problems facing Florida citrus growers today. Fungicides are regularly applied and their use patterns, in some cases, can exacerbate pest mite pressure in many citrus varieties. In general, the fungal pathogen, *Mycospharella citri* Whiteside and two species of rust mites (e.g. *Phyllocoptruta oleivora* (Ashmead) and *Aculops pelekassi* (Keifer)) are considered key pests on foliage and fruit, respectively. Current management programs for both fresh and process fruit are presented along with their arthropod pests. Within recent years there has been increasing usage of HMO (horticultural mineral oil) programs to reduce production costs. Added benefit of HMO programs provides reduced pest mite pressure on Florida citrus.

Consequences of grass-endophyte associations on insects

SL Clement, AJ Popay
"USDA, ARS, 59 Johnson Hall, Washington State University, Pullman, WA 99164, USA, slclement@wsu.edu"

Fungal endophytes (*Epicholë* and asexual *Neotyphodium* forms) in C_3 grasses have been well studied for 20 years, with many studies focusing on their role in determining the outcome of grass – insect encounters. Research shows that both insect deterrence and toxicity can result from the production of specific alkaloids by grass – endophyte associations, while other research demonstrates that many grass – endophyte interactions have neutral effects on insects. In this symposium talk, we discuss the diverse effects of grass – endophyte associations on insect behavior and survival and our ability to use these associations in agricultural environments. New field research in New Zealand suggests that *Neotyphodium* in meadow fescue deters feeding by root-feeding grass grub (*Costelytra zealandica*). Earlier New Zealand research showed that a chemical (peramine) in endophyte-infected perennial ryegrass acts as a powerful feeding deterrent to adult Argentine stem weevil (*Listronotis bonariensis*). New U.S. research illustrates the toxic and neural effects of endophyte infection in grasses on insects by demonstrating the influence that wild barley species/genotype and endophyte strain can have on the expression of cereal aphid and Hessian fly (*Mayetiola destructor*) resistance.

Susceptibility of blueberry cultivars to the borer *Orthorhinus cylinirostris* (Fabricius)

AD Clift, HA Rose, G Wright
Faculty of Agriculture, McMillan Building A05, University of Sydney NSW 2006, clifta@agric.usyd.edu.au

Subtropical cultivars of blueberries, *Vaccinia* species are cultivated on a 350 hectare site near Corindi, north of Coffs Harbour in New South Wales. Blueberry bushes in this plantation are infested by the larvae of the elephant weevil, *Orthorhinus cylinirostris* (Fabricius), an Australian native weevil. The larvae tunnel in the crown of the bushes, shortening the productive life of the plants from 20 years to less than 7 in the most susceptible cultivars. There are two groups of cultivars, Southern Highbush hybrids and Rabbiteye, with the former the more susceptible. However, both groups show considerable variation and some Rabbiteye cultivars are relatively susceptible. There are two components to the cultivar susceptibility – firstly the level of larval activity and secondly the response of the plant. The most susceptible cultivars are in the Southern Highbush group and the plants show considerable loss of vigour after infestation by a few larvae, the plants dying within 5 years. Susceptible Rabbiteye cultivars may have been infested by up to 20 larvae, but survive for 10-13 years. The tolerant Rabbiteye cultivars can survive for over 15 years and have only been infested by a few larvae. Cultivar selection is discussed in relation to elephant weevil management.

Mass trapping for control of rice and vegetable pests in South Asia

A Cork, SN Alam, M Rahman, NQ Kamal, NS Talekar
Natural Resources Institute, Central Avenue, Chatham Maritime, Kent, ME4 4TB, United Kingdom, a.cork@gre.ac.uk

Farmers in Bangladesh apply insecticides daily on brinjal, at a cost of 1,000 $US per ha, in an attempt to control the brinjal fruit and shoot borer, *Leucinodes orbonalis* but only apply, on average, one application of insecticide on rice to control yellow stem borer, *Scirpophaga incertulas* per season. This reflects both the relative economic importance of the insect pests and the marketable value of the crops. Nevertheless, it can be argued that *L. orbonalis* has only become an economically important pest because of the intensive use of insecticides. In order to prevent the build-up of resistance to insecticides in rice and to overcome the pesticide-abuse problems associated with brinjal production IPM strategies based on mass trapping with sex pheromones has been developed for control of both pest species and are poised for commercial development in India and Bangladesh. The paper will briefly describe the work undertaken to develop the technology and discuss the prospects for implication at the farmer level.

Insects on native and introduced plants: patterns and potential risks

P Dalin, C Björkman
Department of Entomology, Swedish University of Agricultural Sciences, P.O. Box 7044, S-750 07 Uppsala, Sweden.

When a plant species is introduced into a new environment it is colonised by insects. In the Nordic countries, eighty species of forest insects have thus far been recorded on the lodgepole pine (*Pinus contorta* var. latifolia), a species introduced from North America. The list of species includes insects with the native coniferous tree species Scots pine (*P. sylvestris*) and Norway spruce (*Picea abies*) as their main hosts. The most striking pattern is that herbivorous (needle-, bud-, flower- and cone-feeding) insects come from Scots pine, whereas the saproxylic (feeding on the phloem and xylem of dying or dead trees) come from Norway spruce. Only a few of the insect species considered as pests have caused considerable damage in lodgepole pine stands in the Nordic countries. How the introduction of a plant species affects insect colonisation, insect species diversity (biodiversity), the composition of insect communities, and insect population dynamics (e.g. the risk for outbreaks) will be discussed. In addition, a similar study of insects on an introduced willow species (*Salix viminalis*) and on a native willow (*S. cinerea*) will be presented.

Trap crops for managing *Helicoverpa armigera* in Australian cotton

ML Dillon
CSIRO Entomology, Locked Bag 59, Narrabri, NSW, 2390, Australia, martin.dillon@csiro.au

Trap cropping is an established technology within Australian cotton IPM. Farmers using trap crops typically deploy approximately 1% of their cotton area to trap crops with the specific aim of diverting *Helicoverpa armigera* and *H.punctigera* eggs away from their cotton crops. The most commonly used trap crops are spring flowering chickpea (*Cicer arietinum*), summer flowering pigeonpea (*Cajanus cajan*) and late summer sorghum (*Sorghum vulgare*). Trap crops are most effective early in the growing season prior to the cotton flowering, and late in the season when cotton is senescing. During these periods the availability of alternative cultivated and wild hosts is often limited, creating a bottleneck for *Helicoverpa* populations. Trap crops are not harvested, and are usually not sprayed with insecticides. Once a significant population of *Helicoverpa* is present within a trap crop, and before adult moths begin to emerge, trap crops are mechanically slashed and the soil cultivated to kill the larvae and pupae within and beneath the crop. Studies on the optimal layout of trap crops consistently demonstrate that blocks attract higher egg densities per unit area than strips or patches. *Helicoverpa* egg densities in flowering cotton did not appear to change with increasing proximity to trap crops. The minimum effective area that should be sown to trap crops to achieve spatial and temporal suppression of *H.armigera* populations is unknown.

Biological control in mix and match forests

RG Van Driesche
"Dept. Entomology, University of Massachusetts, Fernald Hall, Amherst, MA, 01004, USA, vanies@nre.umass.edu"

Biological control of forest pests occurs in forests that may be natural, modified, or cropped plantations, employing native or exotic tree species. Pest of concern may be native or invasive. These variables generate a set of eight cases that define the variety of circumstances in which biological control of forest insects may be attempted. Biological control options include natural enemy release and establishment (as either classical biological control or new association biological control), habitat enhancement for natural enemies (conservation biological control), and mass releases of artificially reared natural enemies (augmentation biological control). The applicability and the potential economic benefits, costs, and ecological risks of each of these approaches is largely determined by attributes of the pest (native or invasive), the tree species (native or exotic), and the forest context (native forest, modified forest, tree plantations). The categorization scheme discussed allows for quick understanding of the nature of a pest problem and the general nature and associated risks of potential biological control solutions. Examples of each type of forest pest problem are discussed.

Implications of certification on insect pest management in Australian and South African sustainable forestry

JA Elek, P Govender
"Jane Elek, GPO Box 207, Hobart, Tasmania, 7001, Australia Jane.Elek@forestrytas.com.au "

Worldwide markets are demanding that forest products should come from certified forests, which requires compliance with the certification policies for insect pest management. In 2000 the international Forest Stewardship Council (FSC) declared that: "Forest management shall conserve forest diversity… and maintain the ecological functions and the integrity of the forest." To comply with this, "management systems shall promote the development and adoption of environmentally friendly non-chemical methods of pest management and strive to avoid the use of chemical pesticides." The interim Australian Forestry Standard (AFS) in 2003 declared similar intent; that managers must "maintain the productive capacity of forests" but "reduce reliance on chemicals and favour cost-effective methods that minimise adverse impacts on the environment". The FSC has further prohibited the use of genetically modified organisms as well as persistent and toxic chemicals. When FSC standards are applied to 20 insecticides registered or under permits for use in forestry, only *Bacillus thuringiensis* and spinosad products are acceptable, while diflubenzuron, carbaryl, tebufenozide and imidacloprid may be acceptable. Adherence to certification standards presents many challenges in the short term but also provides incentives for minimising the use of toxic chemicals and developing integrated management of insect pests in a sustainable forest industry environment.

Integrated pest management of sunn pest in west and central Asia

M El Bouhssini, BL Parker, M Skinner, B Reid, R Canhilal, A Aw-Hassan, M Nachit, Y Valcun, H Ketata, D Moore, M Maafi, H Kutuk, M Abdel Hay, J El-Haramein
"Mustapha El Bouhssini, International Center for Agricultural Research in the y Areas, ICARDA, M.Bohssini@cgiar.org"

Sunn pest (*Eurygaster integriceps* Puton) is a destructive insect pest of wheat in West and Central Asia and Eastern Europe. Apart from the direct reduction in yield, the insects also inject chemicals into the grain that greatly reduce the baking quality of the dough. If as little as 2-3% of the grain is affected, the whole grain lot might be rendered unacceptable for baking. About US$40 million is spent each year on pesticides in the Sunn pest-prone areas. The present insecticide-based strategies must be replaced with multi-dimensional integrated pest management (IPM) approaches. In collaboration with its partner national agricultural research systems in West and Central Asia, along with the University of Vermont, USA; CABI Bioscience, UK, ICARDA is developing IPM options for the management of Sunn pest making use of adult and egg parasitoids, entomopathogenic fungi, host plant resistance, mechanical control, and cultural practices, such as adjusting planting date and use of early maturing varieties. The IPM options are extended to farmers through a participatory approach using farmer field schools (FFS) formed around IPM pilot sites established in the different countries in the region. Studies assessing the potential impact of IPM options are an integral part of this research.

Level of infestation of transplanted and direct sown cotton seedlings with insect and mite pests

AAM Etman, *AI Yasseen*
El-Fayoum Faculty of Agriculture, University of Cairo, El-Fayoum 63514, Egypt.

Late grown cotton plants are severely attacked by leaf-and boll-worms, aphids, and white flies. Success of growing transplanted cotton would virtually eliminate chemical control of seedling pests. Since very few published work dealt with pests of transplanted cotton, therefore this study was conducted to, mainly, investigate the effect of transplanting on rate of infestation of cotton with seedling pests. Our results revealed that: number of thrips, *Thrips tabaci* Lind; the cotton aphids, *Ahpis gossypii* Glover; and the red spider mites *Tetranychus urticae*(Koch), were significantly lower on cotton seedlings of the nursery beds than that of the permanent field, being 4.6 and 10.7; 1.5 and 5.3; 0.4 and 2.9, in the 2002 season; and 5.7and 13.7; 99.1 and 206.3; 2.7 and 46.2, individual pest/ 6 plants, in the 2003 season , for the nursery beds and permanent field, respectively; and that rate of infestation of direct sown cotton with the cotton leafworm*, Spodoptera littoralis (*Boisduval*), was* significantly higher (number of egg batches increased by 158%) than that of transplanted cotton. Although paper bag seedlings' yield was significantly the highest, labor costs of soil-less seedlings were too much less than paper and plastic bag seedling methods.

Challenges and management requirements for the sustainable use of Bt cotton in IPM systems

GP Fitt, LJ Wilson
CSIRO Entomology and Australian Cotton Cooperative Research Centre Long Pocket Laboratories, 120 Meiers Rd, Indooroopilly, Queensland, 4068, Australia. Gary.Fitt@csiro.au

Insects are a challenge for Australian cotton production, with *Helicoverpa* and a diversity of minor pests. Although many components of IPM have been used, synthetic pesticides have been the main control. Pesticide reliance brings environmental liabilities of resistance, off-target ift, non-target impacts and chemical residues. The introduction of Bt cottons in 1996 produced significant reductions in pesticide, and coincided with a resurgence of industry interest in IPM. The combination of Bt cotton and IPM can bring significant gains provided the transgenic technology is carefully managed. Deployment of INGARD^{TM} cotton varieties expressing only Cry 1Ac was accompanied by a comprehensive, pre-emptive resistance management strategy which included: (i) effective refuges (ii) destruction of volunteers and crop residues (iii) planting windows (iv) defined late-season thresholds (v) monitoring of Bt resistance. Pyramided varieties expressing both Cry1Ac and Cry 2Ab (BOLLGARD II) are now commercially available and will provide even greater efficacy and stability for resistance management. While resistance is the greatest risk for Bt cottons their sustained value in IPM systems also requires focus on the management of other pests. Many of these, particularly the sucking pests, are suppressed in conventional cotton by *Helicoverpa* sprays. An expected 80% reduction in pesticide applications in BGII cotton may see such pests resurge. However, beneficial species are also more abundant in Bt crops and may help suppress secondary pests. Maintaining an appropriate balance and retaining the benefits of Bt cottons requires vigilant resistance management, sustained efforts to enhance beneficial species and non-disruptive, short residual pesticides for key sucking pests.

Citrus leaf-eating weevil IPM using soil applied bifenthrin

CG Freebairn, *D Smith*
Queensland Department of Primary Industries & Fisheries, Maroochy Research Station, PO Box 5083, SCMC, Nambour, 4560; chris.Freebairn@dpi.qld.gov.au

Citrus leafeating weevil numbers exceeded 500 per 20 beating sites, and damaged up to 25% of lower leaves in two orchards in Queensland's Central Burnett area. Peak adult emergence from the soil was from mid-October to mid-December. Bifenthrin (10 % in Talstar®) applied to the leaf litter not only suppressed emergence, but within 24 hours of application also killed the beetles already in the tree. Field trials on rate, application timing and water volume showed that 25 ml product in 10L water/tree effectively suppressed emergence throughout the peak period, but at lower rates did so for less than 4 weeks. Rates of 3, 6 & 12.5 ml in 5L of water reduced adult numbers in foliage by 75, 94 & 92%. Recovery was rate dependant - at 4 weeks numbers were 44, 24 & 8%, and at 9 weeks 116, 93 & 36% of controls. Applications at the same rate/m^2 in 2L of water to only one side of the row reduced numbers by 58, 75 & 83%. Thus management decisions can be based on numbers of beetles in the trees at peak emergence, and options are available to destroy them and suppress emergence using a minimally disruptive soil treatment.

Understanding the hessian fly-wheat interaction: an examination of early larval damage to wheat leaves

TP Freeman, MO Harris, KM Anderson, KM Anderson, O Rohfritsch
Electron Microscopy Center, Northern Crop Science Laboratory, North Dakota State University, Fargo, ND 58105, USA, thomas.freeman@ndsu.nodak.edu

The interactions of the Hessian fly with its host plants are characterized by plant defense via R genes and insect adaptation via avr genes. Because of the simple genetics underlying important aspects of this insect-plant interaction, a unique opportunity exists for integrating plant and insect molecular genetics with coevolutionary ecology. Yet, in spite of the relatively well-studied genetic aspects of this interaction, many fundamental questions remain. For example, little is known about how the virulent Hessian fly larva attacks wheat cells and establishes a feeding site. We will report on recent microscopy studies on the early versus middle stages of larval attack. Within the first day of larval attack on leaves of a susceptible wheat seedling, cell walls and cytoplasm are disrupted. Three to eight days after the onset of larval attack, significant ultrastructural damage is apparent at the base of several leaves. Understanding how virulent Hessian flies establish a parasitic relationship with the host plant will provide a strong foundation for understanding how R-gene-defended plants prevent parasitism.

The impact of farm management practices on naturally occurring biological control

MJ Furlong, ZH Shi, YQ Liu, SJ Guo, YB Lu, SS Liu, MP Zalucki
"School of Life Sciences, The University of Queensland, Brisbane 4072, Australia, m.furlong@uq.edu.au; "

Maximizing the contribution of endemic natural enemies to integrated pest management (IPM) programs requires detailed knowledge of their interactions with the target pest. The impact of the endemic natural enemy complex of the diamondback moth, *Plutella xylostella*, in commercial cabbage crops in southeast Queensland, Australia was evaluated by mechanical exclusion of predators and parasitoids. Pest management practices at experimental sites were scored by analysis of management data and sites categorized as practicing IPM, prophylactic insecticide application or as adopting an intermediate approach. Natural enemy impact was greatest at IPM sites, where insecticide inputs were substantially reduced without decreasing crop yields, and least at sites subject to prophylactic insecticide application. *Plutella xylostella* was attacked by three species of larval parasitoids (*Diadegma semiclausum, Apanteles ippeus* and *Oomyzus sokolowskii*) and one species of pupal parasitoid, *Diaomus collaris*. The most abundant groups of predatory arthropods in pitfall traps were Aranae (Lycosidae) and Coleoptera (Carabidae, Coccinelidae, Staphylinidae). The abundance and diversity of naturally occurring biological control agents was greatest at IPM sites, correlating with the greater *P. xylostella* mortality at these sites. The impact of different pest management regimes on biological control and appropriate strategies to optimize this important natural resource are discussed.

Characterization of *Helicoverpa zea* (Boddie) injury and yield losses in bollgard and bollgard II cotton

J Gore, JJ Adamczyk, BR Leonard
USDA-ARS-SIMRU, PO Box 346, Stoneville, MS 38776 United States

Field experiments were conducted to investigate the impact of bollworms, *Helicoverpa zea* (Boddie), on *Bacillus thuringiensis* (Bollgard® and Bollgard II®) cottons. In the first experiment, individual first instar bollworm larvae were placed into white flowers of conventional, Bollgard, and Bollgard II cottons. Plants were visually examined daily. Bollworm survival and fruiting form injury were recorded. Bollworms injured significantly more squares on conventional cotton than on Bollgard or Bollgard II cotton. The numbers of injured bolls were similar on conventional and Bollgard cotton; however, boll injury was lower on Bollgard II cotton than on conventional or Bollgard cotton. In the second experiment, different levels of white flower infestation by bollworms were established for four durations of infestation. The levels of infestation included 0, 50, and 100 percent of white flowers in 2002. In 2003, the experiment was expanded to also include 10 and 25 percent of white flowers. Bollworms delayed maturity and reduced yields of Bollgard cotton when greater than 10 percent of white flowers were infested for more than one week. Bollworms did not impact maturity or yields of Bollgard II cottons. These data will be important for defining economic injury levels for bollworms on Bollgard and Bollgard II cottons.

Effects of the ecological management of *Acacia mearnsii* plantation residues on soil invertebrate pests in the southern hemisphere

P Govender
Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria, 0002, South Africa; pgovender@zoology.up.ac.za

Limited land for the expansion of wattle plantations in South Africa requires a shift to intensive silviculture of seedlings during regeneration, whereby their survival ensures increased productivity. Indigenous soil invertebrate pests cause noticeable seedling mortality but the effect of different plantation residue management practices on their incidence is unknown. Trials were planted to test different residue management regimes [winowed-burnt-weeded, winowed-burnt-ripped, fallow (mowed, manual weed), winowed-burnt-closer spacing, winowed-'broadcast'-herbicide]. During monthly surveys, damaged seedlings were uprooted to determine the cause of death. Pests included whitegrubs and cutworms that had a higher status than the millipedes, nematodes, grasshoppers, false wireworms, termites and crickets. Cutworm damage was higher in the winowed-burnt-ripped and fallow sites. There was a significantly greater pest infestation on sites where the residue was winowed-burnt-weeded or 'broadcast' (20.34%) than in the winowed-burnt-ripped or fallow (2.36%) treatments. The addition of a rip treatment to the winow and burn regime significantly reduced the pest infestation, especially whitegrubs. Seedlings planted at a closer spacing in winowed and burnt sites also had a lower pest incidence (7.79%). An important management implication is that winow and burn is a standard practice, yet the sustainable silviculture of wattle warrants a move to the broadcasting of plantation residue.

Controlling the lantana bug, *Aconophora compressa* **on fiddlewood trees in Queensland.**

MW Griffiths, J King
Department of Primary Industries and Fisheries, Agency for Food and Fibre Sciences Forestry Research, PO Box 631, Indooroopilly, Queensland, 4068, Australia, manon.griffiths@dpi.qld.gov.au

Aconophora compressa, a sap sucking bug native to Mexico, was released in Queensland and NSW in 1995/96 as a biological control agent for lantana, *Lantana camara*. Within three years of its release the insect was found to have established on lantana, but was also located on a non-target species, fiddlewood, *Citharexylum spinosum*. Fiddlewood is native to Florida and the Caribbean and was widely planted in Queensland in the 1970's and 80's. *Aconophora compressa* numbers were initially low but by 2002-2003 *Aconophora* populations had greatly increased and were causing extensive damage throughout south-east Queensland. The insect continues to spread. Trials of insecticides and application methods have commenced to provide chemical control options to the general public and the arboriculture and horticulture industries. Preliminary results from glasshouse and field trials indicate that imidocloprid provides effective and extended control of this pest. Novel application methods and improved formulations are under consideration to enhance the usability of these chemical treatments for a wider range of tree pests in residential and landscape situations.

Changing relationships among biodiversity, management, and biosecurity in managed and unmanaged forests

LM Hanks
Dept. of Entomology, 320 Morrill Hall, Univ. of Illinois at Urbana-Champaign, Urbana, IL 61801, USA, hanks@life.uiuc.edu

A mounting threat to both natural and managed forests of the world are exotic invasive insects. Several exotic wood-boring insects have colonized North America in recent years, and the rate of introduction will increase with the expansion of international trade. Moreover, the implementation of more stringent shipping rules are unlikely to stem the flow of exotic arthropods into new regions because of the inability of quarantine agencies to keep pace with the volume of transported materials and difficulties in enforcing compliance. Exotic species can not only have severe economic impacts by degrading and killing lumber, crop, and ornamental trees, but also will indirectly influence arthropod biodiversity in natural and managed forests. Exotic wood borers in particular may reduce the abundance and diversity of endemic wood borers, and their natural enemies, by eliminating host plants and by competing for resources. For example, the expected decimation of ash populations by emerald ash borer in North America inevitably will have significant repercussions in communities of wood borers that are ash specialists. The challenge for entomologists now becomes identifying threatening exotic invasive species, developing programs for preventing their introduction and managing established species to minimize their deleterious impact, all in accordance with the activities of national security agencies.

Changes in the driving forces behind pest control strategies in export fruit industries such as the southern African citrus industry

V Hattingh
"Citrus Research International, PO Box 2201, Matieland 7602, South Africa, vh@cri.co.za"

Tree fruits are an important component of international trade in fresh produce and supplying lucrative markets is particularly attractive for farmers in less developed subtropical regions. Production criteria combined with changing demands of sophisticated export markets, represents a unique set of forces that influence the development of pest control strategies in such regions. These driving forces necessitate particularly innovative solutions and consequently the development of pest control in these industries provides valuable direction to the global development of pest control strategies. As an example, southern African is the third largest citrus exporter and 90% of this industry's income is derived from exports to over 60 countries. Whereas pest control developments in this industry used to be driven primarily by IPM principles, this has been replaced by the necessity to find a balance with market demands as diverse as quality assurance and socio-economic responsibility. Additionally, the need to overcome barriers to trade presented by sanitary and phytosanitary regulations affecting international market access, represents the forefront of current and future iving forces behind the development of pest control strategies. Exporting tree fruit industries will again be forced to be at the forefront of developing innovative solutions to these challenges.

Managing a wheat-mite-virus complex: the need to understand the basics

G Hein, R French, B Siriwetwiwat
University of Nebraska, Panhandle Res. & Ext. Center, 4502 Ave. I, Scottsbluff, NE 69361 USA, ghein1@unl.edu

The wheat curl mite, *Aceria tosichella* Keifer, transmits two serious viruses, wheat streak mosaic virus and high plains virus, to wheat throughout the Great Plains of North America. But, just in the last year reports have also been made of wheat streak being found in both Argentina and Australia. This virus-vector relationship has been known since the 1950's; however, the identification of this mite has long been confused with that of the dry bulb mite, *Aceria tulipæ* Keifer. Recent developments are beginning to give us a clue as to the complexity and significance of this mite-vector relationship. To begin to answer questions concerning mite identification, we have carefully characterized several wheat curl mite populations. Through genetic analyses, three major 'haplotypes' of wheat curl mites have been identified. This variability parallels the ability of these mites to transmit high plains virus and the populations' response to mite-resistance genes in winter wheat. As we move closer to the incorporation of WSMV resistant germplasm into commercial use, understanding these basic mite-virus relationships becomes more important because of the need for the long term stability of resistant genes in the wheat germplasm.

Communication of pest management recommendations – experience from Asian rice farmers

KL Heong
"International Rice Research Institute, Dapo 7777 Metro Manila, Philippines, kheong@cgiar.org"

Rice farmers tend to spray for visible damages caused by leaf-feeders. However such damages seldom reduce yields because of plant compensation. Insecticide sprays especially in the early crop stages instead disrupt normal food web formation causing secondary pests, such as brown planthoppers. This misconception problem is widespread among Asian rice farmers. Decision-making and ecology knowledge were "distilled" into a simple rule or "heuristic" - "Spraying for leaf feeders in the first 40 days is not necessary". After extensive farmer evaluations, media materials were created to motivate farmers. The campaign, launched in 1994 as a pilot in Vietnam, eventually reached ~2 million farmers. The campaigns were implemented through a multi-stakeholder participatory process to enhance local ownerships. This methodology was adopted in Thailand in 2001where a 22 % reduction in insecticide was achieved and in northern Vietnam in 2002 to achieve a 30% reduction. In the Mekong, "Three Reductions" campaign in 2003 motivates farmers to further reduce pesticides by reducing seed and fertilizer rates. We learnt three lessons; 1. the importance of understanding farmers' decision making; 2. the importance of developing quality local partnerships through a participatory process and 3. that media resources can be utilized creatively to communicate of pest management to farmers.

Rice stink bug problems in Japan: abundance and control

K Hirai
National Institute of Agrobiological Sciences, Tsukuba 305-8602, Japan, khirai@affrc.go.jp

There are over ten species of rice stink bug (RSB) in Japan. Amongst the most damaging species are *Eysarcoris lewisi* in northern Japan and *Leptocorisa chinensis*, *Cletus punctiger*, *Nezara viridula,* and *Eysarcoris ventralis* in central and western regions. *E. parvus, Trigonotylus coelestialium, Stenotus rubrovittatus,* and various mirid species occur throughout Japan. When grains are badly injured they ripen poorly and develop colored spots called 'peck'. Pecky rice has become serious since 1970 when overproduction of rice became a problem. Since 2000, RSBs have spread to 30-50% of rice growing area of ca. 1.7 million ha. Recent warm winters, hot summers, and an abundance of grassy weeds has accelerated population growth of RSBs. Economic thresholds (ET) have been developed based on field studies of natural populations. ETs of 0.8 adults per 5 sweeps with a 36-cm diameter net during heading and milk stages for *L. chinensis,* or much less for *T. coelestialium,* have been established. A double-strategy of weed control and insecticide applications is recommended for IPM of RSBs. When ETs are exceeded insecticides are applied 1-2 after heading at 10 days intervals, either by ground spray or by aircraft.

Management of *Lygus* spp. (Hemiptera: Miridae) on buckwheat in Manitoba, Canada

NJ Holliday, *AM Mostafa*
Dept Of Entomology, University Of Manitoba, Winnipeg, Mb, Canada R3T 2N2,
Neil_Holliday@umanitoba.ca

In Manitoba, large numbers of *Lygus* bugs have been observed on buckwheat, *Fagopyrum esculentum*, particularly near the end of the growing season. However, there was no information about the effects of these bugs on yield. In 2002 and 2003, the species composition, seasonal pattern, economic implications, and control of *Lygus* bugs in buckwheat were investigated. *Lygus lineolaris* dominated the insect assemblage in buckwheat. A small number of adult bugs arrived in the buckwheat in late July and a generation of nymphs developed in the following month. In early September there were many more adults than had developed as nymphs, presumably indicating migration from early-maturing crops. An application of lambda cyhalothrin in late July suppressed nymphs, and resulted in yield weights averaging 59% higher than in unprotected crops. Insecticidal control of adult bugs in September did not significantly affect yield. *Lygus* bug infestations decreased yield weight and seed number/m^2, and increased the percentage of malformed seeds. In a trial of *Beauveria bassiana* against adults in September, seed yield and fungal infection of bugs were significantly greater in treated plots, although the number of bugs in treated and control plots did not differ.

Landscape structural design and vegetable pest management

CW Hoy, JL Lawrence
Dept. of Entomology, The Ohio State University, Ohio Agricultural Research and Development Center, 1680 Madison Ave., Wooster, Ohio, 44691 USA, hoy.1@osu.edu

Biodiversity is one aspect of spatial pattern that is an important component of agroecosystem health. Although typically considered in terms of rare or endangered organisms, crops themselves can be part of the biodiversity that contributes to agroecosystem health. In fresh vegetable production, the landscape typically is composed of diverse mixtures of crops, each anchoring their own unique food web. The spatial scale and arrangement of vegetable plantings can affect the flow of insects, both pests and beneficial, across the landscape with consequences for insect control. Geostatistical analysis of two different insects suggests that favorable crops decelerate movement of highly mobile insect pests, whereas less favorable crops accelerate their movement within and perhaps out of production areas. Detailed spatially explicit simulation of aster yellows epidemics indicates that highly mobile insect vectors of plant disease are less likely to sustain epidemics if susceptible crops are adequately spaced. Research at two different spatial scales, within and between fields, demonstrates that the diversity within and between vegetable plantings can lead to bottom-up effects that sustain populations of biological control agents of insect pests. Spatial pattern statistics for crop arrangement might be used to design beneficial effects and avoid detrimental effects.

Evaluation of corn hybrids for tolerance to corn rootworm (*Diabrotica virgifera virgifera* LeConte) larval feeding

M Ivezic, JJ Tollefson, E Raspudic, I Brkic, M Brmez, B Hibbard
Univ. of J.J. Strossmayer in Osijek, Faculty of Agriculture, Trg sv. Trojstva 3, 31000 Osijek, Croatia, marija.ivezic@pfos.hr

The western corn rootworm (*Diabrotica virgifera virgifera* LeConte (WCR)) is a major pest of corn. The pest arrived in Croatia in 1995, and today over 250.000 ha are infested. Insecticides are regularly used to control WCR, but the cost is high, can pose environmental risks, and may become ineffective due to resistance. Growing corn that is resistant to corn rootworms would be a valuable alternative to insecticides. Nine Croatian (Institute of Agriculture, Osijek) and two Pioneer Hi-Bred Int. Inc. (Johnston, Iowa, USA) commercial corn hybrids were evaluated for WCR resistance at two locations in 2001, 2002, and 2003 year. One location was in east Croatia (Osijek) and one was in the USA (Iowa). The hybrids' tolerance to larval feeding was rated using root injury, root regrowth and root size. Root injury was rated using the Node-Injury Scale 0-3 and evaluation of root size and root regrowth were done by scale 1-6. In an analysis of variance combined across locations, root injury didn't show any significantly differences among hybrids, but root regrowth and root size were significantly different.

Comparative effects of *Leptocorisa oratorius* (F.) on the yield, grain quality, and seed germination rates of "super rice" and three other rice lines

GC Jahn, I Domingo, LP Almazan, J Pacia
"International Rice Research Institute (IRRI), DAPO Box 7777, Metro Manila, Philippines, g.jahn@cgiar.org"

We studied the effect of *Leptocorisa oratorius* (Fabricius) on the yield, grain quality, and seed viability of four rice (*Oryza sativa*) cultivars. Three of the cultivars, C2, IR64, and PSBRc20 were released in the Philippines. The fourth variety, IR72164-201-1 is an unreleased experimental line of an *O. sativa japonica* X *O. sativa indica* cross, known in the popular press as "super rice". Each variety was exposed to four infestation densities for 21 days. *L. oratorius* feeding produced unfilled and partially filled grains, resulting in a negative correlation of yield to rice bug density. Germination rates were negatively correlated with rice bug densities. The percentage of discolored grains was positively correlated with *L. oratorius* density on all cultivars. Overall, PSBRc20 and IR64 had higher yields, less damaged grain, and higher germination rates than IR72164-201-1 and C2 under high rice bug infestations; suggesting the possibility of host plant resistance to rice bugs. The economic injury levels (EIL) currently used for rice bug management are based solely on yield loss estimates. The results of this study suggest that EIL for rice bugs should be revised to take into account reductions in grain quality and seed germination rates in addition to yield loss.

Preharvest field control as part of systems approaches to quarantine security

EB Jang
"USDA-ARS, USPBARC, P.O. Box 4459, Hilo, Hawaii, 96720, USA, ejang@pbarc.ars.usda.gov"

National and international trade is regulated, in part, by insect quarantine issues that require knowledge of pests that are present or likely to be present in commodities as well as adequate assurances that the "risk" of introduction will meet requirements of the importing country. The development of systems approaches to quarantine security has more recently evolved to take into consideration the impact of preharvest pest control measures that reduce the pest population and therefore the risk that commodities that undergo further inspection or postharvest quarantine treatments are infested. Systems approaches require knowledge of the pest biology in the field, seasonal host phenology, efficacy of specific treatments and the impacts of such on the efficacy of potential quarantine treatments. For fruit flies, the polyphagus nature of many fruit fly species, alternate hosts present in tropical agroecosystems, year-round growing season and internal feeding of immature stages requires particular attention to the preharvest field situation. Areawide integrated pest management systems for fruit fly control have been implemented in many locations and have been shown to be successful in significantly lowering fruit fly populations. Other examples of preharvest methods that could affect postharvest quarantine issues include host prevalence, in-field sanitation and area freedom. Examples of these methodologies and how each may impact pest risk are discussed.

Japanese oak wilt as a newly emerged forest pest in Japan: why does a symbiotic ambrosia fungus kill host trees?

N Kamata, K Esaki, K Kato, H Oana, Y Igeta, R Komura
Graduate School of Natural Science and Technology, Kanazawa University, Kakuma, Kanazawa, Ishikawa 920-1192, Japan, kamatan@kenroku.kanazawa-u.ac.jp

Japanese oak wilt (JOW) has been known since the 1930s, but in the last fifteen years epidemics have intensified and spread to the islands' western coastal areas. The symbiotic ambrosia fungus *Raffaelea quercivora* is the causal agent of JOW, and is vectored by *Platypus quercivorus*. This is the first example of an ambrosia beetle fungus that kills vigorous trees. Mortality of *Quercus crispula* was approximately 40% but much lower for associated species of Fagaceae, even though each species had a similar number of beetle attacks. It is likely that other oaks resistant to the fungus evolved under a stable relationship between the tree, fungus and beetle during a long evolutionary process. *Quercus crispula* was probably not part of this coevolution. *Platypus quercivorus* showed the least preference for *Q. crispula*, yet exhibited highest reproductive success in this species. Therefore, *P. quercivorus* could spread more rapidly in stands with a high composition of *Q. crispula*. *Platypus quercivorus* can reproduce only one year on each *Q. crispula* tree. The relationship among *Q. crispula* – *R. quercivora* – *P. quercivorus* seems evolutionary unstable. JOW seems to be an invasive pest of *Q. crispula*. Concentric patterns of JOW spread also support this hypothesis.

Inducing resistance as a management tool

R Karban
"Department of Entomology, UC Davis, Davis, CA 95616 USA, rkarban@ucdavis.edu"

Induced resistance involving vaccines and drugs that affect the immune response is widely used in western medicine. Similar techniques have been applied recently to manage plant pathogens and hold considerable promise against pest insects. Plants can be successfully vaccinated against herbivores by inoculating them with avirulent species, although these techniques are knowledge intensive and costly. Resistance may also be induced using cultural manipulations or by applying chemical elicitors. These methods do not directly kill the pests but enhance the plant's own defenses. Exogenous applications of methyl jasmonate have been found to induce resistance in many crop species against many insect pests under agricultural conditions. Other chemical elicitors have been identified that are more powerful than naturally occurring methyl jasmonate. Based on the lessons learned by plant pathologists, commercially successful elicitors will likely cause multigenic resistance against a broad spectrum of insects in many diverse crops.

Are island forests vulnerable to invasive defoliators?

M Kay
New Zealand Forest Research Institute, Private Bag 3020, Rotorua, New Zealand,
nod.kay@forestresearch.co.nz

It has become axiomatic to represent oceanic islands as fragile ecosystems, which, because of their evolution in isolation, are particularly susceptible to loss of endemic species. It is patently obvious that simple stable ecosystems do exist (eg bogs, boreal forests and oceanic islands) and remain stable if left undisturbed by man. Risk assessments of the threat posed by invasive Lymantriids to the New Zealand flora, indicate that despite the accepted paradigms, New Zealand's flora is largely resistant to these exotic defoliators. As an explanation of this apparent anomaly, the Island Resource Allocation (*IRA*) hypothesis was developed which states that 'the palatability of plants to invertebrate herbivores is proportional to the geographic range of the plant'. The basis for the *IRA* hypothesis is a redefinition of the fundamental ecological principle of the species: area relationship. Species diversity increases with area, but the relationship is more pronounced at higher trophic levels. The redefined species: area relationship means that islands, or similarly geographically constrained ecosystems, which support lower biodiversity, have fewer trophic levels, and consequently have a lesser regulation of herbivores by natural enemies. The *IRA* hypothesis argues that island ecosystem stability is achieved through bottom-up processes, such as plant defences.

Silicon enhances resistance of sugarcane to African stalk borer *Eldana saccharina* Walker (Lepidoptera: Pyralidae)

MG Keeping, JH Meyer, P Brenchley
South African Sugar Association Experiment Station, P/Bag X02, Mount Edgecombe 4300, South Africa, malcolm.keeping@sugar.org.za

Soil amendments with silicon (Si) can increase crop resistance to insect pests, including that of South African sugarcane to its major pest, *Eldana saccharina*. This study examined the effect of six sources of Si, incorporated into the growing medium at low (T_1) and high (T_2) levels (controls = no Si), on resistance to *E. saccharina* of seven sugarcane varieties in a pot and a field trial. In pots (4 varieties, 4 Si sources), treatment T_1 (1200 kg/ha pure Si) reduced mean borer damage and borer survival by 34.4% and 30.8%, respectively, in the two susceptible varieties and by 25.7% and 13.2%, respectively, in the two resistant varieties. Effects were significant only at T_2. In the field (3 varieties, 2 Si sources), mean borer damage was reduced by 20.5% in the two susceptible varieties at T_2 (480 kg/ha pure Si) and by 21.5% at T_1 (960 kg/ha pure Si); in the resistant variety damage was reduced by 10.6% (T_1) and 16.7% (T_2). Borer survival was reduced only in the susceptible variety (T_1: by 14.3%; T_2: by 26.7%). The results support the argument that Si amendments in Si-deficient soils, can substantially reduce sugarcane stalk damage and yield loss due to *E. saccharina*, especially in susceptible varieties.

Salt mixture - an IPM option for managing sucking pests in cotton

M Khan, D Murray
DPI&F, FS and Australian Cotton CRC PO Box 23, Kingaroy, Queensland 4610, Australia, moazzem.khan@dpi.qld.gov.au

Green vegetable bug (GVB), *Nezara viridula* (L.) and green and brown mirids, *Creontiades spp.* have emerged as important mid to late season sucking pests in cotton in Australia. The insecticides currently registered for the control of these pests are mostly non-selective and are highly disruptive to a wide range of beneficial species. To increase selectivity of the existing chemicals we are using common salt (NaCl) to mix with reduced rates of chemicals. The mixture provided good control of GVB and mirids. They also decreased the impact of treatments on beneficial insects and spiders. Trials were carried out to evaluate Regent® (fipronil) plus salt against mirids and GVB, Steward® (indoxacarb) plus salt against mirids and Affirm® (emamectin) plus salt against GVB. Trials were also conducted to determine the effect of salt rate on the mixture and to find out the reason for salt mixture working. The results indicate that salt mixture increased mortality by 20 to 40% compared to reduced rates of chemicals alone and were as effective as full rates of chemicals. The results also indicate that effectiveness of the mixture did not vary with salt rate and salt mixture encouraged insects to probe 30 – 35% more compared to chemical treatment alone. The implication of this finding for management of GVB and mirids in the context of cotton IPM will be discussed.

Synthetic hexaploid wheat: increasing diversity for resistance to Russian wheat aphid and greenbug

J Lage, B Skovmand
International Maize and Wheat Improvement Center (CIMMYT), Apdo. Postal 6-641, 06600 México D.F., Mexico, jacob_lage@hotmail.com

Fifty-eight different *Triticum dicoccum* x *Aegilops tauschii* synthetic hexaploid wheats were evaluated for resistance to Russian wheat aphid (RWA) (*Diuraphis noxia*) and greenbug (*Schizaphis graminum*) under field and greenhouse conditions. In the field, plants were grown in one-meter long, paired plots, one plot infested with RWA while adjacent plot treated with insecticide. Resistance observed in the *T. dicoccum* parents was expressed in the synthetics, although variation occurred. All *Ae. tauschii* parents were susceptible indicating that any RWA resistance present in the synthetics must be located on the A and/or B-genomes, whereas all other previous located RWA resistance genes are located on the D-genome. Greenhouse evaluation for greenbug resistance revealed resistance in 9 out of 15 randomly selected *Ae. tauschii* parents, while all *T. dicoccum* parents were susceptible. Resistance was expressed in 75% of the synthetics derived form resistant *Ae. tauschii* parents. However, both positive and negative epistatic interactions was also observed. These results show that: 1) synthetic hexaploid wheat can act as "genetic bridge" for RWA and greenbug resistance, 2) novel genetic diversity for RWA resistance can be derived from *T. dicoccum*, 3) *Ae. tauschii* is an important source of greenbug resistance, 4) epistatic interactions can occur in synthetic hexaploids.

Assessing the susceptibility of plantation *Pinus* spp. in Queensland to pine wilt nematodes

SA Lawson, H Kosaka, T Aikawa, I Okochi, G Nikles, R Aigner, JM McDonald
Department of Primary Industries and Fisheries, Agency for Food and Fibre Sciences, Forestry Research, PO Box 631, Indooroopilly, Queensland, 4068, Australia, Simon.Lawson@dpi.qld.gov.au

In 2001 an incursion of *Monochamus alternatus* (Coleoptera: Cerambycidae) was detected in Brisbane in pallets imported from China. This beetle is the primary vector of pine wilt nematode (*Bursaphelenchus xylophilus*) a devastating pest of *Pinus* spp. in northeast Asia (Japan, China and Taiwan). The susceptibility of the major pine species grown in Queensland (predominantly *Pinus caribaea* var. *hondurensis* and its hybrids with *Pinus elliottii* var. *elliottii*) to this nematode was unknown. To test relative susceptibilities of both the parent species and the six best performing hybrids, one-year old seedlings were sent to Japan in 2002 and 2003 and planted out in a nursery at the Forestry and Forest Products Research Institute, Tsukuba. These were later inoculated with either distilled water, *B. xylophilus* or *B. mucronatus,* as dispersal stage adults. *B. mucronatus* is endemic to Eurasia and is not pathological to *Pinus* species there, but its pathogenicity against southern USA and Caribbean pines was unknown. Additionally, stems of all eight pines were presented to captive adult *M. alternatus* beetles to test for maturation feeding acceptability. The results of this research will be commented on in relation to risk management and proactive breeding programs for exotic pest resistance in Queensland.

Susceptibility of *Eucalyptus* taxa to attack by giant wood moths (*Endoxyla cinerea*) and longicorn beetles (*Phoracantha* spp.) in Queensland

SA Lawson, R Aigner, JM McDonald

Department of Primary Industries and Fisheries, Agency for Food and Fibre Sciences, Forestry Research, PO Box 631, Indooroopilly, Queensland, 4068, Australia, Simon. Lawson@dpi.qld.gov.au

Since 1997 more than 500 hectares of trials of eucalypt taxa have been established in Queensland to evaluate their potential as commercial plantation species. Plantings of eucalypt species in northern New South Wales and southeast Queensland between the 1960s and the early 1990s confirmed that a number of stem boring insects were potentially important pests limiting plantation productivity. The giant wood moth *Endoxyla cinerea* and longicorn beetles in the genus *Phoracantha* were the most important of these. To evaluate the susceptibility of eucalypt taxa to these stem borers, 25 eucalypt taxa were assessed at 19 trial sites across southeast and north Queensland by visual inspection of external damage to 2.5 to 3 y.o. trees. Priority solid timber species planted in southeast Queensland, *C. citriodora* ssp. *variegata*, *E. cloeziana* and *E. argophloia*, generally showed low incidences of attack. In contrast, the three main species being grown in Queensland for pulp purposes, *E. grandis*, *E. dunnii* and an *E. grandis* x *E. camaldulensis* hybrid all showed moderate to high rates of attack. Our results are commented on in relation to the future management of these insects and the expansion of the hardwood plantation industry in Queensland.

Thiamethoxam as a drench application for the control of scale insects and mealy bugs on mangoes in South Africa

MD Le Lagadec
"Merensky Technological Services, Private bag X3009, Hoedspruit 1380, South Africa, danielle@hansmerensky.co.za"

The control of the scale insect ***Aulacaspis tubercularis*** & various mealy bug species on mangoes in South Africa has become problematic due to the withdrawal of several products. To address this problem, imidacloprid, acetamiprid and thiamethoxam (neo-nicotinoids) were tested over three seasons in large field trials. During the 2001/02 season all three products produced promising results with thiamethoxam being the most efficacious. In 2002/03 dosage verification trials were conducted on the three products. The level of insect control achieved by imidacloprid and acetamiprid was not cost effective. However, thiamethoxam proved to be cost effective. Further development trials with thiamethoxam commenced in 2003/04 in three mango growing areas of South Africa. In all three regions it was shown that the placement of the drench application was important. Application at the point of drip irrigation was most effective, resulting in approximately 90% of the crop being of export quality and free of insect pests. The untreated control plots yielded 20% - 50% export quality fruit.

Integrating crop resistance and biocontrol for sustainable protection against wheat midge

RJ Lamb, MAH Smith, IL Wise, OO Olfert
"Agriculture & Agri-Food Canada, 195 Dafoe Road, Winnipeg, MB, R3T 2M9, Canada, rlamb@agr.gc.ca"

An antibiotic resistance gene *Sm*1 will be deployed against larvae of the wheat midge, *Sitodiplosis mosellana* (Géhin) (Diptera: Cecidomyiidae), an important pest of wheat in the Northern Hemisphere. This resistance kills over 95% of larvae in the field, but its efficacy is likely to decline as virulence to *Sm*1evolves. Oviposition deterrence, probably conferred by two genes, has also been identified, but no other antibiosis genes are available. Hymenopteran egg parasitoids and insecticide applications now contribute to pest management, although imperfectly. An interspersed refuge of 5-10% susceptible plants within the resistant crop could slow or prevent the evolution of virulence and preserve parasitoid populations, while maintaining damage below economic thresholds. The refuge is greatly enhanced by pyramiding *Sm*1 with oviposition deterrence. This integrated resistance strategy has been assessed in multi-year field trials of the refuge, by investigating the prevalence of virulence in the midge population, and by computer simulation. The critical features of the insect-plant interaction that require an interspersed refuge and contribute to the success of the strategy are: a sedentary feeding stage, sedentary male midges, post-mating dispersal by female midges, dispersed oviposition which stabilizes local sex ratio, and density-independent searching by the parasitoid.

Host tree resistance to insects in changing forest communities

F Lieutier
Université d'Orléans, rue de Chartres, BP 6759, 45067 Orléans Cedex, France, francois.lieutier@univ-orleans.fr

Tree resistance to insects can condition the nature and establishment of invasive insect and introduced tree species, as well as the moving direction of the invaders, in various ways. Effects of resistance of indigenous or introduced tree species on invasion processes of exotic or indigenous insect species, respectively, are first considered. Factors involved can be: - botanical diversity; - phenological coincidence and host plant distribution; - resemblance between defence mechanisms of new hosts and those of the original host species or resemblance of the introduced tree species with local species; - capacity of native or introduced trees to adapt to new aggressors (role of previously encountered selective pressures); - capacity of invasive insects to adapt to resistance of new hosts (role of selective pressures existing in the original habitat and role of the presence of original host trees). Climate change can also affect resistance of indigenous trees, then influencing invasion processes of insect populations. The effects of introducing exotic tree or insect species on resistance of indigenous trees are then discussed. These factors can act through: - modification of forest biodiversity, tree competition, vigour and growth; modifications of microclimatic and soil conditions; modification of tree attraction; interactions between insect species.

Compatibility of biopesticides and reduced-risk products with biological control agents of *Plutella xylostella* in cabbage: problems and perspectives

TX Liu, M Haseeb, YY Xu
Vegetable Ipm Laboratory, Department Of Entomology, Texas Agricultural Research And Extension Center, Texas A&M University, 2415 E. Highway 83, Weslaco, TX 78596 USA, tx-liu@tamu.edu

Biopesticides, including Bt-products and azadirachtin-based insecticides, have been extensively used for management of *Plutella xylostella* and other lepidopteran pests in crucifer vegetables in the US. Spinosad and indoxacarb are two relatively newer insecticides with distinct modes of action and chemistries from other conventional insecticides, and have been considered as reduced-risk insecticides by the USEPA. However, our laboratory bioassays (contact and ingestion) indicate that both spinosad and indoxacarb can be destructive or exhibit significant effects to pupae and adults of *Diadegma insulare* and *Cotesia plutellae,* parasitoids of *P. xylostella*. In contrast, all Bt-products and azadirachtin-insecticides had no or little effects to the two parasitoid species. Our field studies also reveal that parasitism of *P. xylostella* by *D. insulare* on cabbage in the treatments of Bt- and azadirachtin-insecticides are generally greater than in the treatments of spinosad, indoxacarb, and l-cyhalothrin, indicating that the latter three had negative effects to the parasitoids and other natural enemies. We conclude that all Bt- and azadirachtin-insecticides are compatible with the parasitoids in IPM programs against *P. xylostella* in crucifer vegetables, whereas spinosad and indoxacarb need to be used with caution when *D. insulare* and *C. plutellae* are dominant in the cabbage fields.

Biological impact of the exotic diamondback moth parasitoid *Diadegma semiclausum* (Hellen) in Kenya

B Löhr, R Gathu, C Momanyi
International Centre of Insect Physiology and Ecology, P.O. Box 30772, Nairobi, Kenya.

Pre and post-release studies were conducted in farmer-managed crucifer fields to assess the biological impact of the parasitoid. Fortnightly, diamondback moth (DBM) populations and damage were assessed in fifteen farmers' fields. Larvae and pupae were collected to assess parasitism and 7 and 12 months after release, exclusion experiments were conducted to assess parasitoid contribution to mortality. Before release, populations peaks were 15.8 DBM/plant (Oct.-Nov.) and 7.9/plant (Jan.-Feb.), average annual population was 5.8 and the damage score was 1.9.Most farmers applied insecticide weekly. The first year after release, peaks declined to 5.5 and 1.9/plant, annual average was 3.9. The damage score remained similar but farmers stopped pesticide application. Parasitism in exclusion experiments increased from 18.0% to 65.0% at Werugha and from 9.2% to 18.1% at Limuru, 7 and 12 months after release. Data from exclusion experiments and field collections indicate displacement of indigenous parasitoids. In field simulation experiments with different parasitoid densities, parasitoids increased unexplained loss of larvae. Most larvae collected off-plant (68-75%) were parasitised. We conclude that field parasitation rates measure less than half of the killing power of the parasitoid. All results indicate high impact of the parasitoid and justify releases all over East African highlands.

Development of an IPM program for cotton production in Arkansas, 1997-2003

GM Lorenz, DR Johnson, JG Greene, G Studebaker
University of Arkansas Cooperative Extension Service, P.O. Box 391, Little Rock, AR 72203, glorenz@uaex.edu.

There have been numerous IPM projects and programs in Arkansas over the years, many achieving great successes in reduction of pesticide usage within particular crops and increased economic benefits to growers. In response to the National Initiative and in an effort to increase and better coordinate actual farm implementation, a county-based IPM program was initiated in 1997. This program offers financial and specialized support to participating counties. Counties submit project proposals, which are screened and approved (or not) by an IPM Program Committee. Documentation of program efforts and results is required. Arkansas farmers have traditionally used many IPM methods but largely in an unfocused way. Similarly, researchers and extension personnel have developed pest management recommendations using many biological, cultural, and chemical techniques but more often than not, have failed to integrate them into a single, cohesive system for growers to use. The need for IPM education is obvious today, with increasing challenges to crop production for Arkansas growers. In Arkansas, the success of implementing any IPM Program will rest logically and predominately on the County Extension Agents. This is as it should be, since local education efforts are generally the most successful in the short and long term. The county agent system has obvious close contact with the farmer, but also works closely with consultants and industry representatives at the local level. The results of this program have shown great success in the implementation of IPM in Arkansas agriculture.

Successful suppression of melon fly, *Bactrocera cucurbitae*, on Oahu and Maui, Hawaii

RFL Mau, R Pandey, MY Chou, R Vargas, E Jang
Department of Plant and Environmental Protection Sciences, University of Hawaii at Manoa, 3050 Maile Way, Honolulu, Hawaii 96822, maur@ctahr.hawaii.edu

The melon fly, *Bactrocera cucurbitae* is the most harmful pest of cucurbit and melon crops in Hawaii. Before the area wide program was implemented, growers reported losses 40-60 percent and occasional complete losses. We implemented a science-based integrated pest management (IPM) philosophy and a comprehensive grower education program. In addition to establishing a monitoring program, step-wise implementation of the following technologies was implemented. The tactics were: 1) field sanitation; 2) environmentally safe spinosad bait sprays; 3) male annihilation. Geographical positioning systems (GPS) and geographical information systems (GIS) tools were used to determine the impact of the IPM tactics on fruit fly densities throughout the implementation zones. As a result of the program, melon fly populations are at an all-time low. Peak male populations at the start of the program in 2000 were 100, and 135 flies/trap/day, respectively at Kula, Maui and Ewa, Oahu implementation zones. Fly population densities at each of the implementation zones were reduced to about 5 and 25 flies/trap/day, respectively. Melon fly percent infestation rates were reduced from >30 percent on Oahu to less than 5 percent at in 2003. Organophosphate usage as crop sprays for melon fly control was practically eliminated.

An evaluation of reduced risk pesticides for control of lepidopterous pests of cole crops

EM Maxwell, HY Fadamiro
Auburn University; 301 Funchess Hall; Auburn, AL 36830; maxweem@auburn.edu

The major pests of cole crops are three caterpillars; diamondback moth, *Plutella xylostella* (L.) (DBM), imported cabbageworm, *Pieris rapae* (L.), (ICW), and cabbage looper, *Trichopulsia ni* (Hubner). These insects are all pests in the larval stage, as eggs are laid on the surface of the leaves and the caterpillars feed on the foliage as they develop. They are generally viewed as a single caterpillar complex and controlled as such. Traditionally broad-spectrum insecticides have been used to control these pests. However in recent years there is growing concern of food safety, resistance, environmental protection, and conservation of the natural enemy guild. Therefore, the pressure to find new control methods that are safer for humans and the environment and that maximize the efficacy of natural enemies for control of these caterpillars is increasing. This study looks at *Bacillus thuringiensis* (Bt) and specifically compares Dipel DF, Xentari and a combination of the two for control of these pests. In addition, the efficacy of EnTrust (a microbial product) is compared to the *Bt* sprays to get a good comparison of an array of reduced risk pesticides.

Evaluation of petroleum spray oils for integrated pest management program against cotton pests in Australian cotton agro-ecosystems

RK Mensah, W Liang, B Frerot

"Australian Cotton Research Institute, NSW Agriculture, Locked Bag 1000, Narrabri, NSW 2390, Australia, robert.mensah@agric.nsw.gov.au"

Petroleum spray oils (PSOS) have been used to control a wide range of crop pests and are now an essential part of many integrated pest management (IPM) programs. We determined the efficacy of an nC27 based oil (Caltex Australia Canopy®) oil) against *Helicoverpa* spp. on cotton crops in the field and mesh house. The results of the study showed that application of 2% v/v of the PSO was efficacious against *Helicoverpa* spp. larvae, reduced oviposition by *Helicoverpa* adult moths and enhanced the efficacy of nuclear polyhedrosis virus (NPV) and *Bacillus thuringiensis* (Bt) against *Helicoverpa* larvae with no symptoms of phytotoxicity to cotton plants. A comparison of plants treated with PSO at various times showed that only 50% of tested females settled on plants 4-5 days after treatment (DAT) whereas none settled on plants 0-2 DAT. A solid phase micro-extraction (SPME) test to determine the effect of the PSO on volatiles released by the cotton plants showed that the quantity of volatiles released by the cotton plants treated with PSO was relatively lower than water treated plants. This indicates that the PSO sprays may be suppressing or masking the leaf surface volatiles of the cotton plants, thereby deterring oviposition of *H. armigera*. PSOs may have the potential to be integrated into IPM programs against cotton pests to minimise synthethetic insecticide use on cotton crops.

Reducing the threat of Russian wheat aphid on wheat and barley in Australia

S Migui, *J Vitou, O Edwards, J Ridsdill-Smith*
CSIRO European Laboratory, International de Baillarguet, 34980 Montferrier-sur-Lez, France,
samuel.migui@csiro-europe.org.

The Russian wheat aphid (RWA) *Diuraphis noxia* (Mordvilko) occurs in all major cereal-growing regions worldwide except Australia. As a preparedness strategy against RWA, GRDC and CSIRO funded research to develop RWA-resistant Australian germplasm. Research at the CSIRO laboratory in Montpellier, France investigated the performance of four RWA populations (United States (US), South Africa (SA), Hungary (HU) and France (FR)) on five wheat lines (PI 137739 (Dn1), PI 372129 (Dn4), Halt (Dn4), Arminda (S) and Wichita (S)) and one susceptible barley. Seedlings at the two-leaf stage were infested with aphids of each of the four populations. Three weeks later, several plant damage symptoms were recorded. Overall, HU significantly differed from the other three populations ($P<0.0001$) by causing the most damage on all plants, and there were no significant differences ($P>0.05$) among US, SA and FR populations. Comparisons among plants showed that Dn1 exhibited the best resistance against the aphids. Dn4 was as good as Dn1 when subjected to three populations, FR, SA, and US. Research is ongoing to test additional Dn and Dbn genes, and will hopefully incorporate other virulent RWA clones. These and other findings will provide a basis for crossing effective Dn genes into Australian germplasm.

Population dynamics and efficacy of ULV aerial application of diflubenzuron against the cedar web spinning sawfly, *Cephalcia tannourinensis* Chevin, in Lebanon.

N Nemer, L Kfoury, G Demolin, B Frerot, N Kawar
"American University of Beirut, PO Box 11-0236, Riad El Solh 11072020, Beirut, Lebanon, nn04@aub.edu.lb"

The cedar web-spinning sawfly *Cephalcia tannourinensis* Chevin is a pest that has been causing serious damage to cedar forest of Lebanon since 1990. The populations of the pest is composed of individuals characterized by a different length of the life cycle, annual and multi years individuals. The two parts of the population differ as to the distribution of their larvae (prepupae) in the soil; long term diapausing larvae being deeply distributed in the soil. The ULV air-application technology was conducted from 1999 until 2002 with the insect growth regulator diflubenzuron. Evaluation methods were done by sampling prepupae in the soil, catching adults with yellow sticky traps and direct observation of larvae on branches. The results ranged from 60 to 85% mortality of the larval stages present on randomly selected branches depending on years. One-year diapausing prepupae population decreased up to 70% in treated areas compared to 52% decrease with multiple years diapausing prepupae. A significant linear relationship between estimates of adult catches and number of prepupae ready to emerge was found. The variability in the diapause length makes it difficult to predict future attacks and the phenology.

Real-time prediction of planthopper migrations in East Asia by three-dimensional computer simulations

A Otuka, T Watanabe, M Matsumura, Y Suzuki, A Furuno, M Chino
3-1-1, Kannondai, Tsukuba, Ibaraki, 305-8666, Japan, aotuka@affrc.go.jp

The white-backed planthopper and the brown planthopper are insect pests of rice and migrate from southern China to Japan in the rainy season. In order to develop a high-precision migration prediction system, an advanced numerical weather prediction model, MM5, and a particle random-walk model, GEARN, were employed. The real-time meteorological data are supplied online to MM5 which can forecast three-dimensional atmospheric fields at one-hour intervals. GEARN calculates the movement of a number of planthoppers and predicts relative aerial density. The forecasting results are provided as geographical maps on the Internet. The changes of the relative aerial density show the timing and area of migrations over the next two days. An evaluation was conducted using daily catch data collected in the south-western Japan in 2003. The result showed the prediction system worked as required throughout the migration season and the prediction quality was comparable to that of rainfall forecast by the Japanese Meteorological Agency.

Changing the mix: new rules in regulating herbivore populations

TD Paine
"Department of Entomology, University of California, Riverside, California 92521. USA.
timothy.paine@ucr.edu"

Populations of herbivores in native or endemic environments are regulated by a broad range of factors that can include abiotic conditions and both top-down and bottom-up factors. It is possible to characterize the relative importance of each factor and the conditions where the balance among regulating factors can change. However, when those herbivores become established in novel environments, the factors regulating the populations and the balance among those forces can be astically altered. The host plants are growing under very different conditions, often in association with very different communities with different composition and structure. These differences can change the bottom-up regulation of the herbivore populations. The herbivore may also be part of a very different community, either more simplified with fewer potential competitors, or more complex. The community of natural enemies may also be simplified or more complex. Consequently, the impact of top-down regulation on the population may be very different from what is observed in the native range. The differences in the impact of individual components that contribute to population regulation need to be carefully assessed in the context of the novel environment, host tree community, other herbivores, and complex of natural enemies.

Aphids associated with papaya plants in Puerto Rico

A Pantoja, W Robles, E Abreu, JE Peña, S Halbert, E Hernandez, J Ortiz
"USDA, ARS, PO Box 757200, Fairbanks, Alaska 99775, ffap2@uaf.edu"

In Puerto Rico, papaya (*Carica papaya* L) is the most extensively grown fruit. The crop is severely affected by the papaya ringspot virus (PRV), causing severe economic losses. With all the interest in the commercialization of papaya in Puerto Rico, there is a paucity of information on the vectors of the PRV in the island. Field trials were conducted at the Agricultural Experimental Station, University of Puerto Rico, Isabela and Corozal to identify aphids associated with papaya. Ten species of aphids were identified: *Toxoptera citricida* (Kirkardy), *Toxoptera aurantii* (Boyer de Fonscolombe), *Pentalonia nigronervosa* Coquerel, *Tetraneura nigriabdominalis* (Sasaki), *Uroleucon ambrosiae* (Thomas), *Aphis spiraecola* Patch, *Aphis gossypii* Glover, *Aphis craccivora* Koch, *Aphis illinoisensis* Shimer and *Picturaphis sp.* All species were present at Corozal, while only six species were collected from Isabela. The difference in species composition between localities is associated with the crops present in each location. Plantains and papaya are common in both localities; however commercial papaya plantings are common in Isabela, while plantains and citrus are predominat crops in Corozal. The presence of weeds in fields could be an important factor. The plantings at Corozal were almost weed free, while at Isabela weeds were common and abundant between papaya rows.

Biological control of *Pulvinaria urbicola* (Cockerell) in a *Pisonia grandis* forest on North East Herald Cay in the Coral Sea

D Smith, D Papacek, M Hallam, J Smith
Citrus Consultant, 28 Orton Street, Mundubbera, Queensland 4626

During 1993-2000, *Pulvinaria urbicola* (Cockerell) completely destroyed a 16 ha *Pisonia grandis* forest on Coringa South West Islet, 400 km off the coast of Queensland in the Coral Sea. Surveys on nearby North East Herald Cay, with a similar area of Pisonia, showed a worrying increase in scale infestation in December 2000. A survey in March 2001 revealed no natural enemies and five months later, the mealybug ladybird *Cryptolaemus montrouzieri* (Mulsant), and three parasitioids, *Coccophagus ceroplastae* (Howard), *Euryischomyia flavithorax* (Girault), and *Metaphycus luteolus* (Timberlake), were released. *C. montrouzieri* multiplied and within six months reduced the scale population by 60%. Percent infested leaves dropped from 25% to 8%, and the scale average per cm of midrib from 0.34 to 0.18. One year after release of the natural enemies, the scale average dropped to 0.03. Two years after release, only 0.01% of leaves were infested. The ants, *Tetramorium* sp., and *Monomorium* sp., feeding on the scale honeydew, declined by 99%. All three parasitoids established, and parasitism was evident on 30% of infested leaves after nine months. The parasitoids, particularly *C. ceroplastae*, are expected to play a important role in maintaining the scale population at its current low level.

Biological control of cotton aphids, *Aphis gossypii*, **in cotton: effectiveness of** *Hippodamia convergens* **and** *Chrysoperla carnea*

MN Parajulee, RB Shrestha
"Texas Agricultural Experiment Station Cotton Entomology Program, Rt. 3, Box 219, Lubbock, Texas 79403,USA, m-parajulee@tamu.edu"

"The predation rates of *Hippodamia convergens* (adult and larva) and *Chrysoperla carnea* were quantified at fixed prey density (100 aphids/leaf) in the laboratory. *Hippodamia convergens* adult showed the highest rate of consumption (91 aphids/12 h) followed by *C. carnea* (75 aphids/12 h), *H. convergens* medium larva (56 aphids/12 h), and *H. convergens* small larva (13 aphids/12 h). Predation rates were also examined temporally for variable prey densities. Laboratory prey suppression trial and field cage study showed that *H. convergens* adult can suppress *Aphis gossypii* populations more efficiently at lower prey density and the suppression rate decreased when prey populations exceeded 100 aphids per leaf. In a field cage study, one *H. convergens* adult per plant released at the prey density of one aphid per leaf kept the aphid population below economic threshold for the entire growing season. Three *H. convergens* adults per plant released at 25 aphids per leaf or six adults per plant released at 50 aphids per leaf could not prevent aphid populations from exceeding the economic threshold. Field experiments showed strongly positive temporal and spatial distributions of *H. convergens* with that of *A. gossypii*, suggesting a significant potential of *H. convergens* for *A. gossypii* suppression in cotton.
"

Development of banana entomology in north Queensland, Australia: progress towards an IPM system.

B Pinese, R Piper, D Astridge
"PO Box 1054, Mareeba, Queensland, 4880, Australia, bruno.pinese@dpi.qld.gov.au"

Over 80% of the Australian banana production is concentrated on a narrow strip of Queensland's tropical coastline from Cardwell in the south to Innisfail in the north. This paper presents the changes in pesticide use and the new developments that have occurred in application methodology against the five major pests of commercial bananas in north Queensland. Other minor pests and quarantine threats are also discussed. Chlorinated hydrocarbons had been used since the 1960s primarily for control of the two major pests, the banana scab moth, *Nacoleia octasema* and the banana weevil borer, *Cosmopolites sordidus.* Legislative bans placed on these in 1985 resulted in a switch to organophosphates and other less disruptive and shorter residual insecticides. The universal adoption of targeted injection into the emerging bunch has resulted in a 95% reduction in pesticide use. Controlled release pesticide technology and, more recently, biopesticides, are further reducing off-target impacts for the control of bunch pests. The changes in pesticides and development of the new application technologies are discussed in relation to IPM.

Unraveling the etiology of aphid-elicited desistance to improve aphid resistance in wheat

S Quisenberry, X Ni, T Wang, V Tolmay
104 Hutcheson Hall, MC 0402, Virginia Tech, Blacksburg, VA 24061, USA

The etiology of aphid-elicited desistance on wheat (*Triticum aestivum*) was studied using 'Tugela' and three near-isogenic lines and two cereal aphids (chlorosis-eliciting *Diuraphis noxia* and non-chlorosis-eliciting *Rhopalosiphum padi*). The mechanisms of aphid-elicited chlorosis will be discussed in the context of photosynthetic pigments (chlorophylls *a* and *b* and carotenoids) and chlorophyll degradation enzyme (chlorophylase, oxidative bleaching, and Mg-decheltase) activities. Concentrations of chlorophyll *a* and *b* and carotenoids were lower in *D. noxia*-infested wheat lines compared with *R. padi*-infested plants. Chlorophyllase activities were higher in *R. padi*-infested plants and lower in *D. noxia*-infested plants, while reverse mg-decheltase activities were observed. *Diuraphis noxia*-induced chlorosis was most likely driven by unbalanced chlorophyll biosynthesis and catabolism processes.

Targeted control of *Myzus persicae* (Sulzer) in North American seed potato production

EB Radcliffe, MW Carroll, IV MacRae, DW Ragsdale, KD Olson, RA Suranyi
Department of Entomology, Univ. Minnesota, 219 Hodson Hall, ST. PAUL, MN 55108, USA, radcl001@umn.edu

Mid-summer colonization of seed potato fields in the northern plains of North America by *Myzus persicae* (Sulzer), the key PLRV vector, is concentrated on field edges, particularly at the crop interface with fallow or owned out areas, but especially along headlands. This colonization behavior combined with the fact that apterae move <2 m per day within the field provides a spatial and temporal window for site-specific pest management. In 2003, large-scale on farm experiments (25 seed potato fields, each >20 acres) evaluated the effectiveness of targeting spray treatments for *M. persicae* on field edges. When *M. persicae* flight activity spiked (~July 30), an 18 m wide spray swath of methamidophos insecticide was applied by airplane to field edges abutting headlands. Pretreatment densities of *M. persicae* were 16 times higher on field edges than mid-field. Three days post-treatment, *M. persicae* densities on field edges were reduced 92% from pretreatment levels. Seven days post-treatment, *M. persicae* densities in untreated field interiors were still not significantly different than in sprayed edges. Treating only 94 of 1804 acres saved 85% in control costs ($23.85 per acre, application included) compared to treating all acres.

Aphids and blueberry scorch virus – a multifaceted problem

DA Raworth
"Agriculture and Agri-Food Canada, P.O. Box 1000 – 6947 #7 Highway, Agassiz, British Columbia, Canada V0M 1A0, raworthd@agr.gc.ca"

Ericaphis fimbriata (Richards) (Homoptera: Aphididae) is the predominant aphid on blueberry, *Vaccinium corymbosum* L. (Ericaceae), in British Columbia, Canada, and a vector of *Blueberry scorch virus* (BlScV). BlScV may reduce yield by more than 85% depending on virus strain and plant cultivar. Virus transmission is non-persistent so resident aphids on blueberry, as well as winged morphs of other species that frequent blueberry fields, may transmit the virus. Our studies suggest that local spread of BlScV is facilitated by the life history and behaviour of *E. fimbriata*: egg hatch is timed with bud break; a high proportion of alatae are produced in the second generation – production is dependent on plant tissue type and local aphid density; populations grow exponentially through the spring; and apterae move frequently. Population simulations based on our life-history data for *E. fimbriata* show that about 45% of population decline during summer is caused by reduced plant quality. Growers normally apply chemical aphid controls in June. Our studies suggest that the appropriate timing for an IPM program is April, before bloom.

Resistance to hunting billbug, *Sphenophorus venatus vestitus* **among** *Zoysia*

JA Reinert, MC Engelke, JE McCoy, JJ Heitholt
Texas A&M Univ., 17360 Coit Road, Dallas, TX, USA 75252-6599 j-reinert@tamu.edu

Hunting billbugs (*Sphenophorus venatus vestitus*) damage *Zoysia* and *Cynodon* but it is often misdiagnosed as drought, insect or disease damage. Plants of nine *Zoysia* cultivars were established and adult billbugs were confined on them in field cages in a paired cage split-plot experiment with four reps in June 2000, so infested and uninfested paired plants could be compared. Billbug damage was measured in late Sept. 2000. Shoot and leaf necrosis was evaluated by ranking each test plant on a scale of 1 to 9. Total rhizome and stolon length were measured and total plant biomass was oven ied and weighed. Resistance was identified in the four cultivars of *Z. matrella* ('Diamond', 'Cavalier', 'Royal' and 'Zorro') while the five *Z. japonica* cultivars ('Crowne', 'De Anza', 'El Toro', 'Meyer,' 'Palisades') were susceptible. Meyer, the industry standard, has now been documented as highly susceptible to zoysiagrass mite, fall armyworm, tropical sod webworm, tawny mole cricket, differential grasshopper and hunting billbug. The data provides the first report of *Zoysia* resistance to the hunting billbug.

Management of thrips in Florida citrus

ME Rogers, DS Achor, CC Childers
"Citrus Research and Education Center, University of Florida, 700 Experiment Station Road, Lake Alfred, FL 33850-2299, USA, mrogers@crec.ifas.ufl.edu"

Several thrips species are known to be pests of citrus in one or more parts of the world. Depending on the species of thrips, feeding injury may occur on the twigs, leaves, flowers or fruit of citrus. In Florida, *Frankliniella bispinosa* (Morgan) is the prevalent thrips species feeding on the flowers of citrus. Infestation of citrus flowers with high numbers of *F. bispinosa* can lead to reduced fruit set but is not known to cause damage to developing fruit after petal fall. Another thrips species not associated with Florida citrus, *Scirtothrips citri* (Moulton), feeds on the rind of developing fruit causing ring scarring that results in the fruit receiving a lower grade at the packing house. Within recent years, localized problems on 'Murcott' tangors in Florida have shown somewhat similar rind blemish damage. Some growers have attempted insecticide applications during bloom to reduce this injury. In this paper, we provide a summary of thrips management in Florida citrus and preliminary results of a study examining the cause of ring scarring on 'Murcott' tangors in Florida.

Best management practices to control the cotton aphid, *Aphis gossypii* Glover, in strawberry grown under protected culture

SI Rondon, DJ Cantliffe, JF Price
"1301 Hull Road, Fifield Hall, Gainesville, FL 32611, srondon@mail2.ifas.ufl.edu"

In the greenhouse, the cotton or melon aphid, *Aphis gossypii* Glover, is one of the most important pests worldwide. In order to determine the susceptibility of different strawberry cultivars, *Fragaria x ananassa* Duch to natural infestations of the cotton aphid, seven cultivars were grown and evaluated. Treatments were arranged in a randomized complete block with three replications per treatment (cultivar). No insecticides or fungicides were used at any time. Five releases of *Aphidius colemani* at a rate of 10 wasps per m^2 per month were made to control aphids. 'Banker plants' were introduced in the greenhouse to ensure the permanence of the parasitic wasps throughout the season. The effectiveness of the control was measure by selecting ten strawberry leaflets at random and by counting the total number of aphids and parasitized aphids ('mummies') per leaflet. Early releases of *A. colemani* can guarantee the effective control of the cotton aphid.

Cereal aphid expert system and the glance 'n go sequential sampling system for managing of greenbug (*Schizaphis graminum* Rondani) in winter wheat.

TA Royer, IL Giles, NC Elliott
"127 NRC, Stillwater, OK 74078, USA, rtom@okstate.edu"

An Expert System was developed to help wheat producers and agri-business essionals manage greenbug, *Schizaphis graminum* Rondani and other cereal aphids in winter wheat. The system has four components. Two components help the user identify common cereal aphids and their natural enemies. A third component allows the user to calculate a treatment threshold for greenbugs, based on control costs and grain yield potential. This component uses a yield loss model and a temperature-dependent development model for greenbug that links to a regional historical weather database. Once a treatment threshold is calculated, the user can select and print the appropriate presence/absence sequential sampling "*Glance 'n Go"* form to quickly and accurately determine if greenbug treatment thresholds have been exceeded in that field. The fourth component helps the user select the appropriate pesticide for corrective control of a greenbug outbreak using various criteria listed on the label. This system is designed to incorporate new research results as they become available. Future improvements will include incorporating the impact of aphids on forage yield and the inclusion of a presence/absence sampling tool for simultaneously assessing the potential impact of the aphid parasitoid, *Lysiphlebus testaceipes* on greenbug populations.

Successful mass-trapping in a bark beetle: effect estimation by 22-year time series

M Cappucci, A Battisti, M Faccoli, G Birgersson, Y Hillbur, F Schlyter
Chem. Ecol., SLU, P. O. Box 44, SE-230 53 ALNARP, Sweden, freik.schlyter@vv.slu.se

Thaumetopoea pityocampa (Den. & Schiff.) (Lep.: Thaumetopoeidae) is one of the most destructive defoliators of natural and artificially established *Pinus* spp in the Mediterranean region. Infestation rates differ dramatically among species and tree individuals, suggesting female choice of hosts during egg-laying. We have identified two main factors affecting the host selection process: - Tree silhouette, suggested as a dominant factor in the litterature. In a rearing room we offered to moths several *Pinus nigra* trees, a preferred species, of different sizes. A significant positive correlation was found between the number of egg masses laid on each tree and both tree height and silhouette. - Volatiles of host plant may play an important role in habitat selection. We investigated the olfactory host recognition mechanisms of females by the gas chromatographic-electroantennographic technique (GC-EAD). We tested natural volatile blends and a synthetic mixture of monoterpenes present in pine needles. Repeatable responses were among others to minor compounds like *E*-ocimene, b-terpinol and neodihydrocarveol. In addition, the identification of suitable needles through contact sensilla on tarsi is evaluated as an additional input for the host choice by females.

Bemisia and *Liriomyza* complexes: implications for management on vegetables

DJ Schuster, JT Trumble
University of Florida, Gulf Coast Research & Education Center, 5007 60th Street East, Bradenton, FL 34203 USA, dschuster@ifas.ufl.edu

The whitefly *Bemisia tabaci* (Genn.) and the leafminers *Liriomyza huidobrensis* (Blanchard) and *Liriomyza trifolii* (Burgess) are globally distributed. *B. tabaci* has been a major pest in arid regions of the world for at least 70 years, particularly on agronomic crops. A worldwide outbreak of the pest that began in the late 1980s on vegetables and other crops was attributed to a new strain or even a new species, although this latter view is not accepted universally. Numerous strains have been identified since the outbreak using electrophoresis and RAPD PCR techniques. Differences in host suitability and insecticide resistance of some strains have been demonstrated. Throughout the late 1970s and 1980s, *L. trifolii* was a major pest on vegetables while *L. huidobrensis* was a minor pest on just a few crops. In the early 1990s, reports indicated that *L. huidobrensis* was becoming the dominant species in many areas, suddenly developing a much wider host range and tolerance to pesticides. Classical mating studies showed that the more destructive *L. huidobrensis* was genetically dominant, resulting in rapid spread through populations. Subsequent molecular studies have suggested the presence of cryptic *Liriomyza* species. Correct strain/species identification is important in determining appropriate biological and chemical control strategies.

Advances in wheat stem sawfly management

TG Shanower, WL Morrill, DK Weaver, KA Hoelmer, WA Berzonsky.
"USDA-ARS, 1500 N. Central Ave., Sidney, MT 59270, USA, tshanower@sidney.ars.usda.gov"

Wheat stem sawflies (Hymenoptera: Cephidae) are key pests of wheat in the northern hemisphere. At least seven species of sawfly attack wheat in different parts of the world. Yield losses of more than 30% have been reported from North America, Europe, North Africa, and Asia. Current management practices include the use of resistant wheat cultivars, various cultural control practices, and biological control. Chemical control is not cost effective in North America and Europe, and is not widely practiced in other wheat production areas. We review the status and impact of wheat stems sawflies in different global regions, and current pest management alternatives. Several new sawfly resistant wheat cultivars have been released in the past few years. Recent research on cultural practices, particularly integrating tillage and biological control, is also highlighted. Finally, progress in finding and importing new exotic biological control agents for *Cephus cintus*, a pest species in western North America, is also summarized.

Getting help from the wild: exploitation of wild relatives of crops as source of novel genes for resistance to insect pests

HC Sharma, SL Clement, J Ridsdill-Smith
"International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), Patancheru 502 324, Andhra Pradesh, India, h.sharma@cgiar.org"

Identification and utilisation of germplasm with insect resistance is key for sustainable crop protection. Evaluation of germplasm for resistance to insects has revealed the presence of low to moderate levels of resistance against the key pests such as bollworms, pod borers, aphids, shoot flies, jassids, and white flies. Thus, progress in developing insect-resistant cultivars has been slow. Therefore, there is a need to find resistance genes in wild crop relatives. Resistance to specific pests in wild relatives has been found, as follows: *Heliothis/Helicoverpa* in cotton, pigeonpea, chickpea, and tomato; *Atherigona*, *Chilo*, and *Stenodiplosis* in sorghum; *Maruca* in cowpea; *Orseolia* and *Scirpophaga* in rice; *Amrasca*, *Aproaerema* and *Spodoptera* in groundnut; Hessian fly in wheat. Considerable information has also been generated on the physico-chemical mechanisms of resistance to the target insect species. The genes from wild relatives can be tapped through wide hybridisation, marker assisted selection, and sequencing and cloning of resistance genes for use in genetic transformation to increase the levels and diversify the bases of resistance to insect pests.

The status and challenges of insecticide resistance in vegetables

AM Shelton, JZ Zhao
"Dept. of Entomology, Cornell University, New York State Agricultural Experiment Station, 630 W. North St., Geneva, New York, 14456 USA.
Ams5@cornell.edu"

Insecticide resistance represents an important challenge to the continued production of high quality vegetables for local and international markets. Some insect species have demonstrated an amazing propensity to develop resistance to synthetic, organic and microbial insecticides. A current database lists a total of 543 cases of arthropods that have developed resistance, and this list contains many important species attacking vegetable crops. Elevated crop losses can be incurred even before resistance is detected and continued reliance on the pesticide will often result in increased dosages or applications, thus leading to economic losses and increased hazards to human and environmental health. Vegetables tend to have high insecticidal inputs because of their diverse insect pest complexes and high cosmetic standards. However, because of environmental and human health concerns, some older, broad spectrum insecticide classes are no longer being registered and this presents new challenges for insect pest management. To cope with these challenges there have been new advances in monitoring methods for detecting resistance and development of new insecticides with novel target sites. However, there has been limited success in implementing insecticide resistance management programs in vegetables. The reasons for this problem and potential strategies to overcome it will be discussed.

Transgenic crops for managing insect pests on vegetables: prospects and problems

AM Shelton, JZ Zhao
"Dept. of Entomology, Cornell University, New York State Agricultural Experiment Station, 630 W. North St., Geneva, New York, 14456 USA.
Ams5@cornell.edu"

The area grown to transgenic crops for insect control was 18 million ha worldwide in 2003. However, only a small proportion of this total was grown to a vegetable crop- sweet corn. In contrast to field crops, development, commercialization, and deployment of biotech vegetable crops has taken dramatically different trajectories, including sharp declines in acreage, differential trajectories for fresh- and processing markets, and successful deployment of cultivars aimed at insect-transmitted pathogens. Biotech vegetables will present new challenges and opportunities for those involved in crop protection, marketing and consumption of insect- and insect-vectored pathogen protected plants. Much has already been learned about food safety, environmental and regulatory issues, and influence of adoption on pesticide use patterns from work with Bt corn, cotton, and potato, and from biotech papaya and squash. This may help pave the way for the development and deployment of biotech insect- or insect-vector pathogen - protected vegetables.

Cultural management of cotton aphids

JE Slosser
"Texas Agricultural Experiment Station, PO Box 1658, Vernon, Texas, 76385,USA,j-slosser@tamu.edu"

Studies were conducted in the Texas Rolling Plains from 1988 to 1994 to determine the influence of planting date on cotton aphid management. Dryland cotton was planted in late April, late May, and late June, and aphid numbers were consistently highest during August in cotton that was planted in late June. Percentage leaf nitrogen was highest during August in cotton planted in late June, but yields were lowest in cotton planted in late June. Nitrogen fertility rates should be adjusted in each planting date to minimize aphid numbers and to optimize yield. Aphid numbers were significantly reduced by dicrotophos applications during August in cotton planted in late April and late May, but control was inefficient in cotton planted in late June. Efficacy was influenced by leaf nitrogen and temperature conditions. Studies were conducted from 1997 to 2000 to evaluate date of irrigation termination on aphid populations during boll opening in September. Aphid numbers were lower in cotton that received a final irrigation in mid-August compared with numbers in cotton that received a final irrigation in late August. Aphids were more difficult to control with an insecticide in cotton that was irrigated in late August.

Studies on the flatid *Jamella australiae* Kirkaldy causing dieback in *Pandanus tectorius* var. *pedunculatus* (A.Br.) Domin on the Sunshine and Gold Coasts in southeast Queensland

NJ Smith, D Smith
Queensland Parks and Wildlife Service, School Rd. Pomona, Queensland 4568, Australia

The flatid, *Jamella australiae* Kirkaldy, has caused extensive dieback in pandanus, *Pandanus tectorius* var. *pedunculatus,* on the Queensland Sunshine and Gold Coasts. *J.australiae* is a native species that has spread to these areas from north Queensland within the last 10-15 years. Flatid populations in North Queensland are low and non-damaging. A survey of 3200 pandanus in Noosa National Park during 1995 showed a high correlation between tree health and flatid numbers ($P<0.001$). The percentage of dead or poorly growing trees increased from 45.8% to 66.4% to 75% from 1995- 1997. By March 1998, 45% of trees had died. Predatory syrphids and lacewings, and an egg parasitoid, *Aphanomerus* sp.were ineffective. At Dimbulah in north Queensland, two other species, *Aphanomerus* sp.nr *pusillus* Perkins, and *Oencyrtus sp.,*were recorded parasitising up to 80% of the egg rafts and 80% of eggs within a raft. The Dimbulah parasitoids were released in southeast Queensland in 1996-97. *Ooencyrtus* sp established but wasn't effective. *A.* sp. nr. *pusillus* established at 20 release sites from where it dispersed throughout the Sunshine and Gold Coasts. In most instances, parasitism is at similar high levels to those at Dimbulah, and there has been an 80% reduction in flatid numbers.

Grower adoption of integrated pest management systems in tree crops in northern Australia

ESC Smith, D Chin
"GPO Box 3000, Darwin, NT, 0801, Australia, stuart.smith@nt.gov.au"

There are few reports in the world-wide literature on the grower adoption of Integrated Pest Management (IPM) principles in tropical and subtropical tree crops. An email survey was conducted to determine the level of grower adoption of IPM in the most economically important tree crops in six regions across northern Australia. Recipients were experienced agricultural practitioners both in the private and government sectors and involved in the fields of plant health or pest management. In descending order, the six most important crops were mango, banana, citrus, avocado, macadamia and rambutan. The mean IPM adoption level (rated Low, Medium, High; 1-3 respectively) for the crops was 1.98. The highest adoption level of 2.67 was reported in rambutan while mango had the lowest with 1.53. Respondents considered that the IPM components most adopted by growers were 'soft' pesticides, regular monitoring, and plant health/nutrition in that order. The most important reason for adopting IPM was the growers' concerns about over-use of pesticides. Respondents indicated that the growers' main source of IPM information was from government departments and other growers. Various strategies that may assist in increasing grower adoption of IPM principles in these and other tree crops in northern Australia will be discussed.

Advances in managing Russian wheat aphid (*Diuraphis noxia* Mordvilko)

CM Smith, M El Bouhssini, D Porter, S Lhaloui, H Ketata, M Nachit, M Mosaad
"Department of Entomology, Kansas State University, Manhattan, KS 66506-4004 USA, cmsmith@ksu.edu"

The Russian wheat aphid (RWA), *Diuraphis noxia* (Mordvilko), has become one of the most damaging pests of wheat and barley globally, since its discovery in Russia in 1900. Characteristic RWA damage symptoms include leaf rolling, leaf folding, intervenal chlorosis and grain panicle trapping in the leaf sheath. Systemic insecticides have provided acceptable RWA control, but contact insecticides are ineffective against RWA colonies in rolled leaves. Cultural practices for RWA control include eliminating over-summering reservoirs, delayed planting in the fall, and early spring planting. Several RWA predators and parasites are abundant in the northwest U. S. and South Africa, and appear to have substantially reduced the incidence of RWA damage. Diverse complexes of entomopathic fungi lower RWA incidence on irrigated wheat in the U. S. (Colorado) and South Africa but not in dryland wheat. Resistant wheat cultivars have proven useful in managing RWA on wheat in Colorado and in South Africa. However, RWA field populations in several countries have developed virulence to different resistance genes, necessitating the identification of sources wheat resistance to the virulent populations. Data from successful RWA - IPM programs in different countries will be reviewed and discussed.

Molecular mapping of cereal aphid resistance genes in wheat

CM Smith
Department of Entomology, Kansas State University, Manhattan, KS 66506-4004 USA, cmsmith@ksu.edu

Segregating wheat populations with different genes for resistance to greenbug *Schizaphis graminum* Rondani, biotype I or Russian wheat aphid *Diuraphis noxia* Mordvilko, (RWA) biotype A have been evaluated to identify molecular markers linked to resistance genes. The *Gbx, Gby* and *Gbz* genes express resistance to greenbug and are linked to molecular markers that provide selection accuracy for these genes ranging from 93.2% to 100%. Cytogenetic and physical maps indicate that *Gby* is located on the short arm of wheat chromosome 7A, while *Gbx* and *Gbz* are part of a resistance gene family located on the long arm of wheat chromosome 7D. In contrast, RWA resistance genes occur on the short arm of wheat chromosomes 7D or chromosome 1D. A gene family consisting of the allelic or tightly linked genes *Dn1*, *Dn2*, *Dn5*, *Dn6*, *Dnx,* and four uncharacterized *Dn* genes, is tightly linked to microsatellite marker *Xgwm111* on wheat 7DS. *Dn4* and an uncharacterized *Dn* gene, linked to *Xgwm106* and *Xgwm337* on chromosome 1DS, are either allelic or linked. A marker assisted selection system to identify aphid resistance genes in germplasm as well as in resistant plants under RWA attack is currently being developed.

Solanum viarum **Dunal. – a potential trap crop against tomato fruitworm (TFW),** *Helicoverpa armigera* **Hubner (Lepidoptera : Noctuidae)**

R Srinivasan, NS Talekar, S Uthamasamy
"Department of Entomology, Tamil Nadu Agricultural University, Coimbatore 641 003, Tamil Nadu, India, amrasca@yahoo.com Asian Vegetable Research and Development Center, Shanhua, Tainan 741, Taiwan"

Solanum viarum, a wild solanaceous plant was heavily infested by tomato fruitworm, *Helicoverpa armigera,* which opened the possibility of using this plant as a trap crop. Host plant selection in TFW is primarily a function of ovipositing female as newly emerged larvae are limited in their dispersal abilities. Hence, we aimed to explore the ovipositional cues of this plant and n-alkanes were identified as a major group. Though *S. viarum* was highly attractive to ovipositing females and young larvae, the later instars failed to develop, which ultimately resulted in death. In our experiments, the larvae did not feed on pure rice diet (check) and 60% of them died within a week. In diet fortified with *S. viarum* aqueous extract, only 20% could feed and survive up to four weeks. The larval duration was 25.60 days in diet fortified with hexane fraction of steam distillate (SD). The percent pupation (70.00) and pupal weight (0.139g) were significantly different in diet fortified with residual water fraction of SD. The adult emergence was only 20% where the larvae were fed with *S. viarum* extracts. The adults were unable to emerge completely. Hence, *S. viarum* can be used as a potential trap crop for managing TFW.

Impacts of insects on forest landscapes: implications for forest health management

FM Stephen, *RN Coulson*
Department of Entomology, A-317, University of Arkansas, Fayetteville, AR 72701, USA, fstephen@uark.edu

Change in forest landscapes occurs as a result the activities of humans and through natural disturbances. As human activities and intervention increase in frequency and impact, the consequences may be visualized in terms of deforestation and reforestation, corridors such as roads and powerlines, conversion of forested lands for agriculture, urban and suburban development, recreation and/or preservation, plus effects of atmospheric pollution and climate change. Humans may also modify natural rhythms of forest succession by lengthening normal cycles of fire or harvesting and replanting forests to select for individual species or age class structure. The resulting forest conditions affect population dynamics of native and introduced insects and may stimulate insect epidemics of amatic proportions. Although primarily aimed at reducing risk of fire, recently enacted legislation by the United States Congress, the Healthy Forests Restoration Act of 2003, is also aimed at ameliorating forest conditions that favor wide-scale insect epidemics. Examples of such outbreaks from North American forests currently abound. We discuss their causes, and examine the impacts of insects on resources and conditions of managed forest landscapes through examples that include red oak borer and southern pine beetle.

Selective control of chironomids and the preservation of biodiversity in Australian rice crops.

MM Stevens, AL Wilson
"NSW Agriculture and the Cooperative Research Centre for Sustainable Rice Production, Yanco Agricultural Institute, PMB, Yanco, NSW, 2703, Australia, mark.stevens@agric.nsw.gov.au "

The root-feeding larvae of chironomid midges cause major problems for Australian rice farmers. Chemical control is used in aerial sown crops on a routine basis during plant establishment, and often no other insecticides are applied to the crop for the remainder of the season. Chironomids are rarely a problem in drill sown crops, which are only intermittently flooded during crop establishment. Field studies have shown that aerial sown crops treated for chironomid control support lower levels of aquatic invertebrate biodiversity than drill sown crops. Despite major reductions in chemical use for chironomid control (> 90% in the last decade), these chemicals continue to be a threat to aquatic biodiversity. Recent studies show that *Bacillus thuringiensis israelensis* (BTI) has good potential for the control of *Chironomus tepperi*, which is known to be the principal pest species in rice. BTI shows a high degree of selectivity between different chironomid groups, and its potential use requires that we develop a better understanding of the feeding habits of other chironomid taxa (particularly *Polypedilum*, *Cryptochironomus* and *Tanytarsus*) present in the rice field environment. We are currently developing molecular techniques for investigating food preferences in chironomid larvae.

Hemipteran pests and their management in the US cotton belt

SD Stewart
"West TN Experiment Station, 605 Airways Blvd, Jackson, TN 38301 USA, sdstewart@utk.edu"

Several hemipteran pests including *Lygus* species, clouded plant bug, cotton fleahoppers, and stink bugs are significant pests of cotton grown in the US Cotton Belt. These pests have increasing importance owing to a reduction in use of broad spectrum insecticides. This reduction is the result of boll weevil eradication efforts, the use of Bt technology, and greater reliance on relatively selective insecticides. This paper will review the basic biology of "bug" pests, with special emphasis on the mid-southern and southeastern US cotton production regions. The injury caused by these pests and experimental evaluation of various management approaches (such as insecticide applications, area-wide destruction of alternate hosts, and the use of trap crops) will be addressed.

The use of plant resistance for management of the rice water weevil in Louisiana

MJ Stout

"Dept. of Entomology, 402 Life Sciences Bldg., Louisiana State University, Baton Rouge, LA 70803, mstout@agctr.lsu.edu"

The rice water weevil, *Lissorhoptrus oryzophilus* Kuschel, is the most destructive insect pest of rice in the United States, and has recently become a global threat to rice production through its introduction into major rice-producing regions of Asia. Current research on the use of host-plant resistance against this pest focuses not only on genotypic-specific resistance but also on the increases in resistance that occur as rice plants develop, irrespective of genotype. Variation in the tolerance of rice genotypes to feeding by weevils has been demonstrated in commonly-grown commercial cultivars and in a number of additional rice genotypes. Similarly, variation in the resistance of rice genotypes to infestation by weevils has been demonstrated in commercial cultivars and other rice genotypes. A breeding program for weevil resistance has been initiated. Furthermore, plant age-dependent increases in both the tolerance and resistance to infestation of rice plants have been shown. The efficacy of cultural strategies such as delayed flooding and early planting may be explained, in part, by these age-related increases in rice plant resistance.

Biology and management of *Batocera rufomaculata* De Geer (Coleoptera: Cerambycidae) in Jammu region of J&K State, India.

JS Tara
"Department of Zoology, University of Jammu, Jammu-180 006, J&K, India: 1. jstara@indiatimes.com, 2. jstara@rediffmail.com "

The longicorn a long-horned beetle *Batocera rufomaculata* has been recorded as serious pest of large number of horticultural and forest trees. The author has made detailed observations on the biology and management of this pest on mulberry plantation. The salient observations revealed that adult beetles start emerging from the pupal chamber after the first monsoon shower and their number increases as the monsoon progresses. Adults feed by gnawing the bark or the green tips of the mulberry branches. During this period the male and female copulates and start deposition after carefully selecting suitable sites. Before deposition of an egg the gravid female makes a girdle around the selected twig, beyond which normally the branch falls with the action of the wind or it may subsequently y. Incubation period varies between 6-12 days. Newly hatched grub starts tunneling the twig/plant in a distinct pattern. In the process a large amount of frass is thrown out through a series of ejection holes, the number of which increases as the larva goes deeper in the branch. These ejection holes also serve as aeration holes. As the larvae grows, type of the frass changes. Distinct period of rest and the number of larval instars in two years life cycle of the beetle have been recorded. Based on the biological studies and screening of various chemicals, insecticides, different combinations and their effectiveness for the control of this pest at larval stage have been suggested.

Environmental risk associated with plant resistance to insects

BJ Todd, RKD Peterson, AH Arthur
PO Box 6051, St Kilda Rd Central, Melbourne, Vic, 8008, Australia, bethwyn.j.todd@monsanto.com

Insect-resistant crops represent a growing sector of the global agricultural scene, delivering economic and environmental benefits to growers and communities in diverse geographies around the world. Environmental benefits of Bt crops, such as reduced use of conventional broad-spectrum insecticides, can lead to more sustainable farming practices. These environmental benefits cannot be realised, however, until the technologies complete extensive regulatory review. Monsanto Australia achieved regulatory approval of Bollgard II® cotton in 2003, after years of research, development and regulatory activities in the US and Australia. This achievement, while significant, represents one milestone in the entire product stewardship lifecycle applied by Monsanto for its biotech products. Environmental risk assessment and management processes feature throughout the Bollgard II stewardship lifecycle: from early regulatory studies in the laboratory and glasshouse that determined safety to non-target organisms, to environmental impact studies in the field, and post-marketing stewardship such as the effective implementation of the Bollgard II resistance management plan. Moreover, after two commercial seasons of Bollgard II, the benefits of the technology to the Australian environment have also been demonstrated, with significant reductions in conventional pesticide use, leading to increased numbers and diversity of insects within the biotech crop.

Optional strategies for management of the sucking bug complex in US Cotton

SG Turnipseed
"Clemson University, Edisto REC, 64 Research Rd., Blackville, SC. 298178, USA, strnpsd@clemson.edu"

Historically, insecticide use has been heavy throughout the southern cotton belt. Following the USDA Boll Weevil eradication program and the introduction of B.t. cotton varieties, insecticide use decreased dramatically. New,"low-insecticide-input" cotton production systems are threatened by the rising importance of a complex of sucking bugs (e.g., tarnished plant bugs and southern green, brown, and green stink bugs), all of which were previously controlled by insecticides applied for boll weevil and lepidopteran pests. Growers report frustration that despite rising expenditures for bug control, yield and quality continue to decline because of bug damage. Current methods used to assess and quantify bug densities and associated damage are ineffective; thus, insecticide use seldom matches the actual need. Farmers are inclined to either over-treat with insecticides to protect their investment in B.t. cotton or revert back to non-B.t. production. Discussion will include bugs involved, their distribution, the need for dynamic treatment thresholds, and how bug and boll sampling can be simplified through application of technology. We will also examine the feasibility of site-specific applications to control bugs in cotton.

GM insect-resistance: pest management or mis-management?

HF van Emden
Department of Agriculture, The University of Reading, Earley Gate, Reading, RG6 6AR, U. K., h.f.vanemden@reading.ac.uk

Host plant resistance (HPR) can be used as the central pivot of true IPM. It can synergise with biocontrol by a variety of routes, including the exploitation of the inherent selectivity of reduced-dose pesticide applications. The kinds of interactions between HPR, biocontrol and chemical control (the 'Pest Management Triad') can prevent or delay the development of pest tolerance to any of the three component control methods However, these valuable synergisms depend on the resistance being partial, and not based on allelochemicals, particularly single ones that are highly toxic. HPR based on high expression of a single toxin, the principle of current GM insect-resistance, has all the characteristics of pest mis-management inherent in the early insecticides such as DDT. Yet GM insect-resistance, although comparing badly with partial and broadly-based HPR, nevertheless compares rather favourably with insecticides, perhaps the fairest comparison. Surely GM is more often alternative technology to pesticides than to HPR?

Pesticide-free vegetables: commercially successful biological control in greenhouses

JC van Lenteren
Laboratory of Entomology, Wageningen University, PO Box 8031, 6700 EH Wageningen, The Netherlands, Joop.vanLenteren@wur.nl

Development of pesticide resistance in greenhouses initiated biocontrol research. The first natural enemies became available in the 1960s. A change from pure chemical control to advanced Integrated Pest Management took place in 20 years. Nowadays, growers annually introduce billions of natural enemies in greenhouses, and 125 species are commercially available for control of all important insect and mite pests. In the main vegetable crops in northern Europe, most if not all insect problems can be solved without the use of insecticides. The change to biocontrol was rooted on clear advantages for the grower. Integrated management of pests and diseases without conventional chemical pesticides is a goal that will be realized in Europe within a decade. Plant-breeding activities contribute to these IPM programmes by (1) combining host-plant resistance with biological control, (2) selecting plant cultivars that stronger attract natural enemies, and (3) selecting plant cultivars that produce a better "working environment" for biological control agents. Recently, the development of so called "closed system" greenhouses with strongly optimized energy management and nutrient recycling, resulted in improved biological control of pests and diseases due to a more stable greenhouse climate. (van Lenteren 2000 A greenhouse without pesticides. Crop Protection 19:375-384)

Semiochemicals – their role in the management of tropical tree fruit pests

RA Vickers
"CSIRO Entomology, 120 Meiers Rd Indooroopilly, Queensland 4068 Australia Richard.Vickers@csiro.au"

Semiochemicals are now in common use as pest management tools. They have application as a means of monitoring fluctuations in pest populations and so assist in the timing of control measures, and as control measures in their own right, in which they are released as mating disruptants or as attractants in 'attract and kill' formulations. But have they lived up to expectations? Interpretation of trap catch is notoriously difficult and mating disruption is not suited to all pests and situations. The impact of attract and kill formulations that attract only males may be limited, whereas those that attract females should, in theory at least, have better prospects of success. The various techniques are reviewed in the context of managing tropical tree fruit pests.

Cotton IPM in South America – progress and challenges

GW Videla

Dorrego 487 (2700) Pergamino, Argentina, guillermo.w.videla@la2.monsanto.com

IPM strategy to manage pests of cotton is broadly accepted and practiced throughout South America. The main cotton producing countries in the region are Brazil, Argentina, Paraguay, Bolivia, Perú, and Colombia. Few pests are common to most of the countries (e.g., cotton leaf feeder, *Alabama argillacea*, and pink bollworm, *Pectinophora gossypiella*). Other insects are restricted to some areas of few countries. Some countries have developed erradication programs against boll weevil, *Anthonomus grandis*. Lepidoptera resistant transgenic cotton is commercially available in Argentina and Colombia. Details on its efficacy, and level of acceptance from farmers will be presented, along with the IRM program in each of these South American countries. The progress made in the areas of pest management decision-making, evaluation of economic thresholds, and research on new chemicals, cultural control, biological agents, and biotechnology will be discussed with case studies from major cotton areas of South America. Information presented will be obtained from published papers, personal communications with researchers and extension specialists, and personal experience. Cotton arthropod pest complex, pesticide resistance issues, and specific pest management practices for different sizes of farms in each of these countries will be discussed, with special emphasis in Argentina situations.

Physical control methods for managing vegetable insect pests

C Vincent, B Vernon, G Boiteau, P Weintraub
"Horticultural Research and Development Centre, Agriculture and Agri-Food Canada, 430 Gouin Blvd., Saint-Jean-sur-Richelieu, QC Canada J3B 3E6
e.mail: vincentch@agr.gc.ca"

Physical control may offer innovative alternative to insecticides. After a brief review of the theory of physical control methods, we will discuss case studies from Canada (Quebec, New Brunswick and British Columbia) and Israel. Eastern Canada has played a significant role in the development of new physical control methods against agricultural insect pests since the mid 80s. Successful designs of plastic lined trenches, vacuums, propane flamers and others to control insect pests of the potato crop were achieved by combining entomological and engineering research interests. Reliance on chemical control methods has slowed down the adoption of physical control methods in traditional agriculture but the increasing place taken by organic production is creating opportunities. Israel has long been at the forefront of research on the use of physical control methods for agricultural pests. Major developments include: insect exclusion screens in the 1970s, which are now found covering greenhouses world-wide; colored plastic mulches, utilized since the early 1980s; and, recently, ultraviolet absorbing plastics, shown to be effective against several pests. Research is on-going in these and other areas. Future directions for research will be discussed.

Manipulating the phenotypic expression of resistance in young conifers

D Wainhouse, *S Brough*
Entomology Dept. Forest Research, Alice Holt Lodge, Wrecclesham, Farnham, Surrey, GU10 4LH, UK, david.wainhouse@forestry.gsi.gov.uk.

Seedling conifers must grow fast enough to establish successfully in competition with other plants yet allocate adequate resource to defence against pests and pathogens. Environmental conditions that affect the growth of trees can alter the absolute and relative concentration of nutrients and carbon-based secondary chemicals and can also influence the physical characteristics of different parts of the tree. It is however, difficult to generalise about environmental influences on the phenotypic expression of resistance because the significance of these changes for different pests and pathogens will depend on their particular adaptations. The manipulation of plant growth to produce a range of phenotypes can, however, be a useful tool in the experimental investigation of 'quantitative' resistance traits and in determining the extent to which resistance expression could be manipulated in pest management. In this paper, the physical and physiological limitations on the phenotypic expression of resistance in seedling pine and spruce are discussed in relation to defence against the stem-feeding weevil, *Hylobius abietis*. Results are presented of the effect of light and nitrogen treatments of young trees on the resin duct system and consequences for feeding and reproductive behaviour of adult weevils.

Exclusion nets - a viable management option for vertebrate and invertebrate pests of tree crops

GK Waite, AC Lloyd, E Hamacek, RJ Nissen, AP George
Queensland Department Of Primary Industries, Maroochy Research Station, Po Box 5083 Scmc, Nambour 4560 Queensland, Australia, Geoff.Waite@Dpi.Qld.Gov.Au

Vertebrate pests have become a chronic problem for the expanding areas of mono-cultured tree fruit crops, especially in tropical and subtropical Australia. Birds and bats have multiplied under environmental protection legislation in Australia, despite a reduction in some natural habitats. Protected populations require more food than native sources can provide to sustain increasing numbers, and fruit crops provide a bountiful source that is easily accessed. Various counter measures have been used to mitigate vertebrate pest damage. Flashing lights, noise, high voltage electrical grids, and shooting, have all been tried. Some of these are now illegal, and increasing urbanisation limits the use of most. Exclusion netting is the only viable option remaining, and is being used successfully in commercial orchards. The development of new technology in net manufacture and erection has initiated interest among entomologists with respect to the potential exclusion of many insect pests. Some pests are excluded by nets used to protect crops from hail, and total exclusion of fruit flies from stone fruit has been achieved in Queensland trials, using finely woven nets. In addition to achieving effective pest exclusion, the physiological effects on the crop of shading, reduced wind movement and elevated temperatures must also be considered.

Improving vegetable IPM with introduced parasitoids: successes and challenges

GP Walker, PJ Cameron
"New Zealand Institute for Crop & Food Research Limited, Private Bag 92169, Auckland, New Zealand, walkerg@crop.cri.nz"

IPM programmes for process tomatoes and vegetable brassicas in New Zealand are based on cost-effective monitoring systems, validated action thresholds and strategic use of selective insecticides to maximise the impact of introduced larval parasitoids. *Cotesia kazak,* the dominant parasitoid of tomato fruitworm in tomatoes, is well synchronised with its host and kills larvae while still small, preventing major fruit damage. Other introduced parasitoids complement *C. kazak*, and when combined with use of an adjustable action threshold using estimated larval parasitism, have led to a 90% reduction in insecticide use. In vegetable brassicas the recently introduced parasitoid of white butterfly, *Cotesia rubecula*, is displacing the earlier introduced *Cotesia glomerata*. *C. rubecula* is the superior competitor and better synchronised with host populations. Along with *Diadegma semiclausum* attacking diamondback moth, these two parasitoids can attain high levels of parasitism. In combination with well-timed larvicides, insecticide applications may be reduced by 75%. Challenges include selecting effective parasitoids, minimising non-target effects, integrating parasitoids with insecticide use, and maintaining adequate support systems for the IPM programmes.

Apparent genotypic resistance in Norway spruce to feeding by the weevil *Hydrobius abietis*.

J Weslien

"The Forestry Research Institute of Sweden (Skogforsk) SE 75183, Uppsala, Sweden.
jan.weslien@skogforsk.se "

The large pine weevil *Hylobius abietis* L. is a major pest in conifer plantations in the palearctic region. Field studies in Sweden on 52 clones of Norway spruce *Picea abies* L. (Karst.) indicate that there is a genetic factor involved in tree resistance/tolerance. At present growth parameters are used for genotype selection in the Swedish spruce breeding program. The results suggest that it is important to study trade-offs between these growth parameters and resistance to pine weevils

Recent stem borer research on rice in the United States

MO Way, TE Reagan, FPF Reay-Jones
Texas A&M University, Agricultural Research and Extension Center, 1509 Aggie Drive Beaumont, TX 77713. moway@aesrg.tamu.edu

Stem borers, primarily sugarcane borer (*Diatraea saccharalis*) and Mexican rice borer (*Eoreuma loftini*), are becoming increasingly problematic in the southern United States. Recent investigations in Texas have shown that *E. loftini*, introduced from Mexico into Texas in 1980, is spreading north and east towards Louisiana where production of rice and sugarcane is threatened by this exotic pest. Cooperative research between Texas A&M University and Louisiana State University is aimed at developing a pro-active IPM program for stem borers attacking both rice and sugarcane. The program includes studies on host plant resistance and cultural and chemical control of stem borers. In regards to rice, results of studies have demonstrated that 1) Cocoie, the most commonly grown rice variety in the southern United States, is very susceptible while hybrid rice cultivars are least susceptible to stem borers; 2) stem borers do not attack rice before panicle differentiation; and 3) transgenic rice shows great promise as a genetic method of control. In addition, research results have led to the registration of lambda-cyhalothrin for stem borer control. Recommended rate is 0.034 kg (AI)/ha applied twice at approximately panicle differentiation and late boot.

Compensation for pest damage – linking pest and damage based thresholds

LJ Wilson, TT Lei, A Takenaka
CSIRO Plant Industry, Locked Bag 59, Narrabri, NSW, 2390, Australia, lewis.wilson@csiro.au

Cotton compensates for pest damage, often with little effect on yield or maturity. Damage thresholds, if developed, combined with pest thresholds, would account for both plant recovery and potential pest damage thereby avoiding control of non-economic pest densities or damage. Experiments using leaf removal to simulate pest damage found young cotton plants could tolerate >80% early leaf loss without affecting yield or maturity. Similarly, manual removal of apical meristems from 100% of plants three times or of the apical meristem plus two nodes from 100% of plants did not effect yield and delayed maturity <5d. Flower bud removal from the first 4 fruiting branches did not affect yield but caused a delay of 7d. Effects of leaf and terminal damage on yield and maturity were additive and reasonably predicted by multiple regression equations. These have been used to develop tentative damage thresholds. Distribution of damage between plants was less important than amount of damage in determining recovery. When leaf damage was inflicted on 0%, 25%, 50%, 75% or 100% of plants the performance of undamaged plants changed, allowing compensation. Modelling compensation has begun using the CSIRO OZCOT cotton crop simulation model to provide greater flexibility for exploring and predicting compensation.

Southern hemisphere exotic pine plantations threatened by insect pests and their associated fungal pathogens

MJ Wingfield, B Slippers, BP Hurley, S Gebeyehu, R Ahumada, BD Wingfield
Forestry And Agricultural Biotechnology Institute (Fabi), University Of Pretoria, Pretoria, 0002, South Africa, mike.wingfield@fabi.up.ac.za

Plantations of exotic *Pinus* spp. in the Southern Hemisphere cover many millions of hectares and represent a major industrial resource. The success of these plantations is commonly attributed to the fact that the trees have been separated from their natural enemies, including insect pests and pathogens. Recent trends show clearly that introductions of new pine pests and pathogens are increasing. This is a situation that seems likely to continue as the movement of people and products increases. Trends also suggest that once an insect pest or pathogen has become established in a new Southern Hemisphere environment, the likelihood of movement to adjacent countries and continents increases. Here, patterns of movement of the Sirex woodwasp *Sirex noctilio* provide an interesting example. Interactions between fungal pathogens and introduced insect pests are also appearing. For example, the damaging pitch canker pathogen *Fusarium circinatum* has been introduced into nurseries in various southern hemisphere countries. Associations between this pathogen and various insect pests are emerging and these are likely to heighten an already serious impediment to pine propagation. Future forest management practices will need to incorporate a clear understanding of these threats, if profitable exotic pine propagation is to be sustained in the long term.

Long-term benefits of the integrated management of rice insect pests in Dasha Town of Sihui City, Guangdong Province, China.

WQ Zhang, DX Gu, GR Zhang
State Key Laboratory for Biocontrol, School of Life Sciences, Sun Yat-sen University, Guangzhou 510275, China, Ls37@zsu.edu.cn

A biocontrol-based IPM program has been conducted since 1973 in the rice ecosystem in Dasha Town of Sihui City of Guangdong Province, China. Experimental areas of the program were extended from 1.6 ha in 1973 to about 4000 ha in 1975. Experts from the university passed on IPM knowledge and measures to farmers through Farmer Field School (FFS) in intervals. IPM measures have since then been adopted conscientiously by the farmers. The program resulted in significantly ecological, social and economic benefits, including (1) the population of major insect pests in the rice field obviously decreased; natural enemies had successfully restored and kept the dominant position, which play a key role in the control of rice insect pests; (2) the amount of pesticides used in the rice field was decreased dramatically; and the pesticide residue of the rice and soil in Dasha, measured in 1983, 1993 and 1997, has showed very low and met the State Criteria for "Green Food". As a result, the rice product in Dasha Town was allowed in 1998 to be labeled "Green Food" (LB-18-9801190913).

Paradigm shift in pest management in rice in southeastern China newly invaded by the rice water weevil *Lissorhoptrus oryzophilus* Kuschel (Coleoptera: Curculionidae)

ZR Zhu, JA Cheng, HW Shang, BP Zhai
Institute of Applied Entomology, Zhejiang University, 268 Kaixuan Lu, Hangzhou, Zhejiang, 310029, China. zrzhu@zju.edu.cn

The alien rice water weevil (RWW) has been severely threatened to the rice production in the SE coaster Zhejiang, China. There was only one generation in one season of rice. Most of the adults emerged from 1st-season rice was in reproductive diapause and migrated to hills for oversummering and overwintering, while only minors migrated into newly grown rice of 2nd-season rice and developed 2nd-generation. Species and age of host plant, and adult density may change the proportion of reproductive females. Compared with the management measures for insect pests before RWW invasion, nowadays two extra insecticide applications are implemented by farmers: control of the overwintered adult weevils by triazophos, fipronil or fenvalerate in late April to early May in seedling beds or early transplanted fields, and control of 1st-generation adults by triazophos, trebon in late June to early July. The larval populations of 1st-generation RWW and stem borers can be controlled by triazophos in mid - late May simultaneously. Because of the risk of resurgence of planthoppers resulted from triazophos and pyrathroids via killing of natural enemies and stimulation of reproduction, conflict between loss of ecological function and efficient of control of RWW must be solved in a balanced way.

Integrated Pest Management of Hessian fly (*Mayetiola destructor* Say)

S Lhaloui, M. El Bouhssini, N. Nachit, N. Nsarellah, M. Jlibene and S. Clement
Saadia Lhaloui, INRA, CRRA-Settat. P o Box 589. Settat. MOROCCO. E-mail: lhaloui@hotmail.com

Hessian fly, *Mayetiola destructor* (Say), is the most destructive insect of wheat throughout the world. It is an economical pest in Morocco, Tunisia, Algeria, Kazakhstan, Spain and the USA. When heavy infestations occur on young tillers, damage can result in total yield loss. In Morocco, losses were estimated to 36% and 32% of bread and durum wheat yields, respectively. Integrated pest management uses a variety of methods to keep crop damage below an economic threshold without causing adverse effects on the environment. It reduces the selection pressure and enhances the durability of resistance. Several methods of control are being integrated to manage hessian fly. Host plant resistance is the most practical and economic method of control. Sources of resistance are continuously sought and incorporated into high yielding wheat cultivars. Thirty one genes of resistance have been identified in the usa, out of which 10 (*h5*, *h11*, *h13*, *h14h15*, *h21*, *h22*, *h23*, *h25* and *h26*) are effective in morocco, two (*h25* and *h26)* and three (*h13*, *h25* and *h26*) confer resistance to the syrian and the kazakh hessian fly populations, respectively. The genetic interaction between wheat and hessian fly is highly specific and consistent with a gene-for-gene relationship. Therefore, biotypes evolve, like it has happened in the usa. Other methods of control such as chemical control, rotation, planting dates, and nitrogen top dressing are also practiced to reduce the fly damage.

Laboratory rearing techniques for the giant wood moth (*Endoxyla cinerea*) and a longicorn beetle (*Phoracantha solida*) in Queensland.

R Aigner, SA Lawson
Department of Primary Industries and Fisheries, Agency for Food and Fibre Sciences, Forestry Research, PO Box 631, Indooroopilly, QLD, 4068, Australia.
Aigner@dpi.qld.gov.au

In eucalypt plantations in southeast Queensland a number of key insect pests have been identified causing damage. Among the most important of these are two stem boring insects, giant wood moth (*Endoxyla cinerea*) and longicorn beetle (*Phoracantha solida*). Basic biological information on the lifecycles of these insects is limited but was required to support research into identifying effective management methods. Cultures of both these species were established in 2001. Wood moth larvae were initially sourced as relatively mature larvae extracted from infested trees and reared on an artificial diet based on wheatgerm blended with host bark. Later, first instar larvae reared from eggs were also established on the same diet. Generally, late instars did not accept the diet well and suffered considerable fungal mortality. Early instar larvae accepted the diet but there was limited success in rearing them through to later instars. However for both groups the process was labour intensive and was not an economically viable method for obtaining adults for experimentation. In contrast, longicorn larvae reared from eggs accepted the diet well, had fast growth rates, low later instar mortality, and required less frequent handling. *P. solida* have now been reared for three generations in the laboratory.

Managing leaf beetles in eucalypt plantations: non-target impacts, biocontrol and natural enemy recolonisation

GR Allen, JA Elek, M Matsuki
"Geoff Allen, School of Agricultural Science, Private Bag 54, University of Tasmania, Hobart 7001, Australia. Geoff.Allen@utas.edu.au "

A field trial examined the impact of chemical spraying on leaf beetle (*Chrysophtharta agricola*: Chrysomelidae) control by natural enemies in *Eucalyptus nitens* plantations. We compared the impact of the Naturalyte insecticide Success$^{\text{Ò}}$ with the broad-spectrum pyrethroid Dominex$^{\text{Ò}}$. In addition to reducing natural enemy loss to insecticides we hypothesised that we would enhance natural enemy effectiveness and residency in the plantation. Non-target impacts were monitored using op sheets during aerial spraying, sticky traps, malaise traps and visual searches of branches before and at intervals after spraying. The efficacy of natural enemies was assessed by protecting sentinel cohorts of beetle larvae during spraying and monitoring their disappearance due to predation or levels of parasitism. As anticipated, Dominex$^{\text{Ò}}$ reduced levels of non-target species, including natural enemies, more than Success$^{\text{Ò}}$. However, predation rates were higher following Dominex$^{\text{Ò}}$ spraying with the few recolonising and remaining resident predators targeting the sentinel larvae. By contrast, predation rates following Success$^{\text{Ò}}$ spraying mirrored that of unsprayed plantations. Parasitism rates of sentinel larvae by tachinid flies were severely impacted by either spray, though less so under Success$^{\text{Ò}}$. The return to pre-spray levels of natural enemies varied according to species but was often at least two months following broad-spectrum spraying.

Investigations into the effect of four insecticides on taro beetle (*Papuana Uninodis* Prell) infestation on taro (*Colocasia Esculenta*) in two selected sites in Fiji

ML Autar, SN Lal, T Vasuieketi, F Atumurirawa
Ministry of Agriculture, Sugar & Land Resettlement, Koronivia Research Station, P.O Box 77, Nausori, Fiji Islands.

Taro beetle (*Papuana uninodis* Prell) was first recorded near Suva in 1984. *P.uninodis* creates tunnels on taro corms and severely reduces its quality. The beetle has spread to taro growing areas in most parts of the Southern side of Vitilevu, Ovalau Island and was recently found in Vanualevu, poses a very serious threat to taro production in Fiji. Field trials to determine the effect of Suscon Indigo, Confidor and Chlorpyrifos insecticides were conducted in taro beetle infested sites in Ovalau and Navua in 2002-2003. In addition, Nutri-gro-plus insecticide was tested only in Navua. Each insecticide treatment was replicated five and six times in Ovalau and Navua respectively and the trials were laid out using the Randomised Complete Block Design. The highest total corm weights from both field trials were observed in the Confidor-treated plants, which out yielded ($P<0.05$) the Chlorpyrifos-treated and Suscon Indigo-treated plants and Nutri-gro-plus in Navua only. In both field trials, the Suscon Indigo insecticide did not perform well in minimizing the damage caused by the beetle as compared with the untreated-plants at ($P<0.05$). Therefore, treating taro plants with the recommended rate of Confidor insecticide resulted in higher market corm weights.

Adapting and validating spatially variable insect control programs for cotton

R D Bagwell, BR Leonard, J Temple, R Downer, D Magoun, K Paxton, R Price
"212B Macon Ridge Rd. Winnsboro, LA 71295, USA. rbagwell@agcenter.lsu.edu"

Geographic information system data are being correlated with in-field densities of cotton insect pests and evaluated as a basis for variable rate pest control strategies. Insect pest densities are being correlated with remotely sensed images of variable plant biomass (Normalized Difference Vegetative Index or NDVI) and NDVI based spatially variable insect control programs evaluated. Insect pest populations that have reached sufficient density for evaluation include the cotton aphid (Hemiptera: Aphididae), tarnished plant bug (Heteroptera: Miridae) and bollworm/tobacco budworm (Lepidoptera: Noctuidae) complex. Correlations between tarnished plant bug densities and NDVI appear very transient. That is, good correlations are observed on some dates while correlations on other dates correlations appear negative. No apparent correlations between cotton aphid or cotton bollworm/tobacco budworm complex densities have been observed on any sampling dates. Yield impact of NDVI based insect control programs is still being evaluated. Historical crop yields from yield monitors are also being evaluated as a method to base variable rate insect control programs. No significant impact on crop yield has been observed when spatially variable treatments are based on historical crop yield or itability. Historical crop yields appear to be viable basis for spatially variable cotton IPM.

Field observations of the pasture mealybug, *Balanococcus poae* **(Maskell) in New Zealand**

FP Baxendale, CGL Pennell, AJ Popay, TR Glare, TA Jackson.
"Department of Entomology, University of Nebraska-Lincoln, 202 Plant Industry Bldg., Lincoln, NE, 68583-0816, USA, fbaxendale1@unl.edu"

The pasture mealybug, *Balanococcus poae* (Hemiptera: Pseudococcidae) was originally identified on common tussock grass, but is now known to be endemic on a wide range of pasture grasses in Canterbury, Nelson, Manawatu, and other regions in New Zealand. *B. poae* feeds in the crown and upper root zone where it withdraws sap from plant tissues causing a general browning of the paddock which is often misidentified as drought stress. Damage can first become apparent in January during dry periods, but is usually most severe in autumn and early winter. A preliminary report published in 1988 by W.D. Pearson suggested that *B. poae* was univoltine with parthenogenetically produced offspring. Recent field studies conducted at AgResearch in Lincoln, NZ, however, revealed that *B. poae* has at least two generations per year. First and second generation crawlers reached maximum numbers in mid-November 2003 and mid-January 2004, respectively. Male mealybugs were present beginning in mid-December 2003, and reached peak abundance on 31 December. DNA analysis confirmed that collected males were *B. poae*. Further research is needed to fully understand the biology and develop effective management strategies for this hidden threat to New Zealand pastures.

Thrips and their management in the Mississippi River Delta cotton region

ML Boyd
University of Missouri Delta Center, 147 St. Hwy T, Portageville , MO 63873 USA. boydm@missouri.edu

Several thrips species, including *Frankliniella* species, are annually significant pests of cotton grown in the Mississippi River Delta Cotton Region. These insects are important early-season pests that can slow plant growth, and thus increase the crop's exposure to later-season pests and an early fall frost. This paper will review the species composition of thrips complex in cotton, with a special emphasis on the US Mississippi River Delta cotton production region. The injury caused by these insects and experimental evaluation of the various insecticide management programs (i.e. seed, in-furrow, and foliar treatments) will be compared and discussed.

Plant incorporated Bt resistance in maize for control of *Spodoptera frugiperda* and *Helicoverpa zea* in the southeastern United States

GD Buntin, JN All, RD Lee, DM Wilson
Department of Entomology, University of Georgia, Georgia Station, Griffin, GA 30223, USA, gbuntin@griffin.uga.edu

Fall armyworm, *Spodoptera frugiperda* (J. E. Smith), and corn earworm, *Helicoverpa zea* Boddie, perennially cause leaf and ear damage to maize in the southeastern United States. Transgenic Bt hybrids with the Bt11, MON810, or 176 events expressing the Cry1Ab insecticidal endotoxin from *Bacillus thuringiensis* (Bt) were evaluated for control fall armyworm and corn earworm on 2-3 planting dates at seven locations in Georgia during 1999 and 2000. All Bt events consistently reduced whorl infestation and damage. Hybrids containing Bt11 and MON810 events reduced ear infestations in all trials, although reductions were small in later plantings. Because of lack of toxin expression, the hybrid containing Event 176 did not reduce ear infestations and damage. Total grain aflatoxin concentrations were not significantly affected by Bt resistance in any trial (N=17). Yield responses were variable with the prevention of yield loss being proportional to the severity of insect damage. Although Bt resistance did not consistently benefit recommended time plantings, Bt11 and MON810 events were effective in preventing significant losses to field maize when damaging infestations occurred. The Bt11 and MON810 events mitigated the risk of severe lepidopteran damage to maize, thereby making later plantings of maize feasible in double-cropping systems.

Extrinsic resistance potential for biologically-based turfgrass pest management

SK Braman
Department of Entomology, University of Georgia, 1109 Experiment St., Griffin, GA 30223-1797 USA. kbraman@griffin.uga.edu

Interactions between host plant resistance and biological control may benefit or hinder pest management. Turfgrasses have rarely been tested for extrinsic resistance characteristics -occurrence and performance of beneficial arthropods on plant genotypes with resistance to known turf pests. Among six turfgrass genotypes tested, the braconid wasp *Aleiodes laphygmae* Viereck, varied in percent parasitism of fall armyworm, *Spodoptera frugiperda* (J. E. Smith), larvae A total of 20,400 first instar larvae were placed in the field; 2,368 were recovered; 468 parasitoids were subsequently reared; 92.2% were *A. laphygmae*. The consistent dominance of *A. laphygmae* in the turfgrass environment is a departure from the minor role observed for this species in agricultural crops such as corn and sorghum. Parasitism by *A. laphygmae* was consistently highest on paspalum followed by bermudagrass and then zoysiagrass. Percent parasitism of *S. frugiperda* in this field study decreased with increasing resistance levels to the host insect. However, substantial parasitism on TifSport, a cultivar of bermudagrass demonstrating intermediate levels of resistance to fall armyworm, suggests a promising potential synergy between modest levels of host resistance and pest suppression by natural enemies. Additional studies demonstrated that turf taxa also roundly influences predator occurrence and performance and armyworm susceptibility to insecticides.

Development and parasitism of *Aphidius colemani* and *Lysiphlebus testaceipes* (Hym.: Aphidiidae) on *Aphis gossypii* (Hem.: Aphididae)

VHP Bueno, MV Sampaio, SMM Rodrigues, MCM Soglia
"Departament of Entomology, Federal University of Lavras, P.O. Box 37, 37200-000 Lavras, MG, Brazil. vhpbueno@ufla.br"

The parasitoids *Aphidius colemani* and *Lysiphlebus testaceipes* are the most frequent natural enemies of *Aphis gossypii* under greenhouse conditions. The temperature directly affects the development time and behavior of insects. The adaptability to climatic conditions is a key point for the success of mass rearing and parasitoids establishment in biological control programs. The objective this study was to evaluate the development and parasitism of *A. colemani* and *L. testaceipes* on *A. gossypii* as a host, in controlled climatic chambers. *L. testaceipes* development on *A. gossypii* at different temperatures (15, 20, 25 and 30ºC) showed the shortest development time (11.3 days) and the highest percentage of parasitism and emergence (> 60%) at 25ºC. The rates of mummies and the emergence of *A. colemani* and its longevity decreased with the increase of the temperature (16, 19, 22, 25, 28 and 31ºC), and no mummy's formation at 31ºC. The results indicate that the temperatures 22ºC and 25ºC, respectively, for *A. colemani* and *L. testaceipes*, could be the most adequate for reproduction and establishment of each parasitoid as a biological control agent of *A. gossypii* in protected cultivation.

Olive lace bug *Froggatia olivinia* Froggatt (Hemiptera: Tingidae) – an Australian native pest of cultivated olives

MP Cannard, R Spooner-Hart, GAC Beattie
Centre for Horticulture and Plant Sciences, University of Western Sydney, Locked Bag 1797, Penrith South DC, NSW, 1797, Australia,
m.cannard@uws.edu.au

The olive industry has been the fastest growing horticultural activity in Australia over the past decade, with more than 8 million trees now in the ground. The native phytophagous tingid, olive lace bug, *Froggattia olivinia* has moved from its original host *Notelaea longifolia* to become an important pest of cultivated olives, *Olea europea*. Infestations of nymphs and adults suck sap from undersides of leaves, often resulting in severe damage or the death of host plants. *F. olivinia* was originally reported by Froggatt, in the only published paper on this species, from coastal and tableland regions of the eastern mainland, but it has since spread to inland areas of the eastern states as well as to Victoria and South Australia. An incursion of *F. olivinia* was detected in Western Australia in 2002, where a successful eradication campaign was conducted. This poster paper will present descriptions and images of *F. olivinia* adults and nymphs together with their damage.

"Seasonal fluctuations in crop damage of hemipteran pests in California pistachio"

R Krugner, KM Daane,
"Center for Biological Control, Division of Insect Biology, University of California, Berkeley, CA, 94720, USA, daane@uckac.edu"

California pistachios are attacked by a variety Hemiptera, most notably stink bugs such as the *Thyanta pallidovirens* and *Acrosternum hilare*, and a leaffooted bug (*Leptoglossus clypealis*). We clarified seasonal changes in nut damage using cages that isolated adult hemipterans on pistachio clusters for 7 day periods (fruit set – harvest). Results show early-season feeding does not result in crop loss because the pistachio compensates for opped nuts. For example, pistachio clusters naturally declines from 80 to 20 nuts during the season. There are critical mid- and late-season periods when damage (epicarp lesions) because the natural nut op has been completed and Hemiptera feeding impacts the cash crop. For example, in late-May and early-June trials, a single stink bug feeding for 7 days caused about 40 – 50% damage of the available nuts (opped nuts or epicarp lesion) of cages nuts. Trials conducted later in the season, June to August, show fewer opped nuts and epicarp lesion. Finally, after August, it was difficult to determine damage levels by examining nuts for epicarp lesions because feeding wounds did not form for many weeks or months while the internally-damaged nuts remained in the cluster. Results have been used to improve seasonal insecticide applications.

Effect of temperature on activity of insecticides to the differential grasshopper – (Orthoptera: Acrididae)

JV Edelson, KG Amarasekare
"OSU/WWAREC, P.O. Box 128, Lane, OK, 74555, USA, jedelson-okstate@lane-ag.org"

We evaluated insecticides for activity to third instar *Melanoplus differentialis* (Thomas) at temperatures from 10° to 35°C. In the laboratory, treatment with esfenvalerate resulted in 100% mortality and activity was not temperature dependent. Treatment with spinosad resulted in similar mortality as esfenvalerate at all temperatures except 10°C. The activity of *B. bassiana* was greatest at 25°C, and was adversely affected by high and low temperatures. Treatment with diflubenzuron resulted in increased mortality at high temperatures. Activity of azadirachtin was not influenced by temperature. In field studies, spinosad, diflubenzuron, endosulfan and esfenvalerate provided significant levels of mortality both at-application and when nymphs were exposed to 1-h old residues. Spinosad and diflubenzuron provided similar levels of mortality when nymphs were exposed to 24-h old residues. Residual activity of endosulfan, naled, esfenvalerate, and spinosad decreased with increasing time (0 to 24 hours) after exposure to sunlight and high summer temperatures. Compared to other insecticides, naled had a short residual activity period and activity was dependent upon immediate contact with the nymphs. *Beauveria bassiana* was inactive under high temperatures and intense sunlight as occurs in summer.

Identification and characterization of peroxidases in resistant sorghums

TE Eickhoff, D Novak, TM Heng-Moss, FP Baxendale, G Sarath
"Department of Entomology, University of Nebraska-Lincoln, 202 Plant Industry Bldg. Lincoln, NE, 68583-0816 USA.
teickhof@unlserve.unl.edu"

Greenbugs, *Schizaphis graminum*, are important insect pests of sorghums in the United States. The identification of sorghums with resistant traits to greenbugs has provided a sustainable, economical and environmental responsible approach for managing this serious pest. However, information regarding the mechanisms of the resistance remains unknown. Previous research investigated the role of several oxidative enzymes (catalase, polyphenol oxidase and peroxidase) in the defense response of sorghum to greenbug feeding. This research documented no change in the activity levels of catalase and polyphenol oxidase levels in control and greenbug infested sorghum plants. However, there was an increase in peroxidase activity in resistant sorghums being fed upon by greenbugs. These results suggest that increases in peroxidases may accompany insect feeding in resistant genotypes and could be an important marker for selecting resistant germplasm. Our current research focuses on purifying the peroxidases present in resistant sorghums and characterizing their role in the defense response of sorghum to greenbugs. Results from this research will be presented at the International Congress of Entomology.

SuccessÒ is an alternative to DominexÒ for managing leaf beetles in eucalypt plantations

JA Elek, GR Allen, M Matsuki
"Jane Elek, GPO Box 207, Hobart, Tasmania, 7001, Australia. Jane.Elek@forestrytas.com.au "

A field trial compared the efficacy of the Naturalyte insecticide SuccessÒ (a.i. spinosad) with the pyrethroid DominexÒ (a.i. cypermethrin) for managing the eucalyptus leaf beetles, *Chrysophtharta bimaculata* (Olivier) and *C. agricola* (Chapuis) (Coleoptera: Chrysomelidae), attacking *Eucalyptus nitens* plantations. Larval and adult populations were monitored before and at intervals after aerial spraying using tagged shoots, sticky traps and visual assessments. Defoliation levels were assessed at the end of the summer. Non-target species were also assessed (see Allen *et al.* Poster). Both DominexÒ and SuccessÒ reduced egg and larval populations of *C. agricola* immediately following spraying and reduced the level of defoliation by larvae during the summer months. In the field, effective control of young beetle larvae from the spray residue on the foliage lasted approximately one week longer for DominexÒ than for SuccessÒ. Both DominexÒ and SuccessÒ were equally effective against the 1st instar larvae, while SuccessÒ was less effective than DominexÒagainst the 2nd instar larvae. Leaf beetles recolonised and laid more eggs within one month after spraying with SuccessÒ and within two months after spraying with DominexÒ. For maximum efficacy, application of SuccessÒ should be timed immediately after egg hatch when the 1st instar larvae are most abundant.

Insect management in litchi orchards: a tool for sustainable land use

D Euler, *K Martin*
"Hohenheim Office, Faculty of Agriculture, Chiang Mai University, Chiang Mai 50200, Thailand, dirk_euler@web.de"

In litchi growing systems in northern Thailand frequent use of pesticides is the common farmers practice to prevent negative impacts of pest arthropods. Considering the ecology of the major pests it seems doubtful that they can be effectively controlled by this measure. However, it is well-known that the massive use of broad-spectrum insecticides leads to shifts in the composition of the arthropod community, i.e. not only pests are reduced, but also beneficial organisms such as pollinators, predators and parasitoids. To establish a sustainable land use management and to increase in arthropod biodiversity, which can also help to suppress pest populations, a reduction of pesticide application and a suitable vegetation management are required. In the present study the spatial and temporal patterns of the major pest and beneficial species are analyzed on landscape level. In a litchi orchard four different treatments including pesticide application (yes/no) in combination with mowing (yes/no) of the underground vegetation are conducted. Effects of the different treatments on the presence and diversity of beneficial insects are studied. Detailed knowledge of the seasonal dynamics and the insect antagonist-complex are expected results. In addition an analysis of relationships between the diversity of beneficial insects and the underground vegetation will be conducted.

Development of a numerical simulation model for long-range migration of rice planthoppers

A Furuno, M Chino, A Otuka, T Watanabe, M Matsumura, Y Suzuki
Japan Atomic Energy Research Institute, Tokai, Ibaraki, 319-1195 Japan, furuno@sakura.tokai.jaeri.go.jp

Trans-oceanic migration of rice planthoppers was precisely simulated by incorporating some parameters related to the flight behavior with a high performance atmospheric dispersion model. The model consists of an atmospheric dynamic submodel for calculating meteorological fields and a particle random-walk submodel for atmospheric dispersion. The model also functions in specifying source term information such as the source area, take-off time and the relative amount of the planthoppers. We carried out a case study of source term estimation for the migration of planthoppers to western Japan with net-trap catches obtained at nine locations in mid-June 1998. In the simulation, 56 areas each with the width of two degrees of latitude and longitude were set as the take-off area. Take-off duration time was assumed as one hour at dawn and dusk. Relative immigrant density originated from take-off area was calculated for each observation site, and rank correlation coefficients were used for the model evaluation. Possible migration source areas were distributed around 23-27N, including Fujian and Taiwan. Air temperature that allows the planthopper to fly continuously, and flight duration are critical parameters for the simulation results.

Managing stink bugs in cotton in southeastern USA

JK Greene, GM Lorenz, GE Studebaker, RG Luttrell
"P.O. Box 3508, University of Arkansas, Monticello, AR 71656 USA, greene@uamont.edu"

Because stink bugs continue to pose a challenge to current and future efforts concerning cotton insect management, we continued investigations into alternative monitoring strategies and management tactics for the pest complex. Pheromone trapping of stink bugs was useful in following in-field populations of stink bugs, but the reduced availability and considerable expense of currently available lures and unavailability of lures for other important species continues to make potential pheromone trapping prohibitive. Research with treatment thresholds for stink bugs, based on monitoring internal feeding injury to bolls, supported treatment at the 10-20% injury to mid-sized (ca. 14-d-old) bolls. In laboratory bioassays, methyl parathion and dicrotophos provided superior control (94-100% mortality) of field-collected fifth instars and adults of the green stink bug (GSB), *Acrosternum hilare* (Say) and the brown stink bug (BSB), *Euschistus servus* (Say), at 0.5 lb (AI)/A. Pyrethroid insecticides provided variable results (11-100% 24-hr mortality) due to considerable tolerance by BSB. Results from studies addressing simulated mechanical injury to bolls suggested that losses from bug feeding injury to small-to-medium-sized bolls could be significant under certain circumstances. In caging experiments, the ability of GSB to damage cotton bolls and reduce yield decreased as bolls aged, and yields from bolls that accumulated 583 HU at 27 d following anthesis were not significantly reduced.

Biology and behavior of western leaf-footed bug on satsuma orange in USA

SJ Johnson, M Zhang
"Dept. of Entomology, Life Sci., Bld., LSU AgCenter, Baton Rouge, LA, 70810, USA, sjohnson@agcenter.lsu.edu"

The western leaf-footed bug, *Leptoglossus zonatus* (Dallas) was first noticed attacking Satsuma oranges in Plaquemines Parish, Louisiana in autumn 1997 and since then has become a serious pest. This species typically begins feeding on Satsuma in mid-August and continues feeding through harvest. It causes concealed damage to Satsuma through transmission of the yeast, *Nematospora coryli* Peglion. Studies were conducted to find an optimum diet for rearing this insect in the laboratory. Results indicated that the combination of fresh raw peanuts, potatoes and Satsumas was the most suitable diet. When given a choice of green beans, potatoes, sweet potatoes, fresh raw peanuts, Satsumas, and carrots first instar nymphs preferred to feed on Satsumas. Second through fifth instars and adults fed frequently on fresh raw peanuts, Satsumas and potatoes. Field observations in October 2003 revealed that adults moved around the tree during the day in order to remain in full sunlight. Fifty six percent of adults under observation in the field did not move during the night from their afternoon location. In the laboratory, both sexes fed more during scotophase than photophase. Females fed longer than males but males moved between fruits more often during a 24 hr study period.

Bioefficacy of azadirachtin against *Scirtothrips dorsalis* **infesting tea crop**

NK Joshi, SS Bisht, A Shukla
New Hope, the Nilgiris District, Tamilnadu, Department of Entomology, G. B. Pant University of Agriculture and Technology, Pantnagar, U.S. Nagar, U.A., India, 263 145. neeleshjoshi@hotmail.com

India is the world's largest producer of tea, having 507200 hectares of land under cultivation. At field, several pests nestled on the tea crop canopy, affecting the production and quality of the made tea. One among them is *Scirtorthrips dorsalis* infesting two leaves and a bud as well as three leaves and a bud crop.

The present study was conducted to know the bio efficacy of Azadiractin 0.15EC (NEEMGOLD) against *Scirtorthrips dorsalis* at Hope Tea Estate, the Nilgiris district, Tamilnadu. Azadirachtin 0.15EC (NEEMGOLD) which is environmentally safe formulation, have the ingredient Azadirachtin-A, which is a tetranortiterpenoid and most active limonoid with insect growth regulating and antifeedant properties. The spray of Azadiractin 0.15EC (NEEMGOLD) at the rate 1.25 lit. per hectare at the first sight of *Scirtorthrips dorsalis* was found most effective for its control. Whereas, minimum thrips incidence was recorded with continuous three spray round. Besides thrips control, zero phytotoxicity was also observed on tea crop canopy, during the spray schedule.

Management of *Scirpophaga nivella* F. (Lepidoptera: Pyralidae) in sugarcane (Punjab, Pakistan)

J-J Lee, A Khaliq, M Ashfaq, W Akram
Department of Agri-Entomology, University of Agriculture, Faisalabad, Pakistan Faculty of Bio-Resources Science, College of Agriculture and Life Science, Chonbuk National University, Chonju 561-756, South Korea. jjlee@chonbuk.ac.kr

Ten varieties of sugarcane were screened with CP-43/33 and L-118 as susceptible, BF-162 and SPSG-26 resis-tant while CP-72/2086 as intermediate, for management studies of *Scirpophaga nivella*. Morpho-physio chemi-cal plant factors as well as quality of sugar were determined to see their affects on the pest infestation. Leaf thickness and moisture contents showed positive/significant correlation with the pest infestation at tillering stage. Total mineral, manganese and copper contents did not show significant correlation with the pest infesta-tion, whereas nitrogen, potassium, calcium, magnesium and ferrous contents manifested positive and sig-nificant contribution with the pest infestation. Phosphorous, carbohydrates, fats and zinc produced significant and ad-verse effect on the pest infestation at tillering stage. Zinc contents with contrasting behaviors appeared to be the most important character with co-efficient value of 0.764 followed by ferrous with positive sign. The effect of borer infestation was significantly negative on POL, Brix contents CCS. The coefficient of determination value was 0.821, obtained by computing fiber content, POL, Brix and CCS factors together for multivariate regression models. Application of trash mulching at the time of sowing proved to be the most effective treatment followed by Furadon, removal of dead hearts+spike trust, hand collection of egg masses and cutting of shoots at 15 days interval.

Evaluating Bollgard 2, WideStrike, and VipCot against lepidopteran pests in mid-southern U.S. Cotton Fields

BR Leonard, DR Cook, KD Emfinger, G Lorenz
Louisiana State University AgCenter, Macon Ridge Research Station, 212A Macon Ridge Rd, Winnsboro, LA 71295, USA, rleonard@agcenter.lsu.edu

Bollgard$^{\text{Ò}}$ cotton cultivars produce the Cry1Ac protein from *Bacillus thuringiensis* Berliner var. *kurstaki* (Bt), which exhibits toxicity to larvae of many lepidopteran cotton pests. The Bollgard$^{\text{Ò}}$ technology has been very effective against tobacco budworm, *Heliothis virescens* (F.). However, Bollgard demonstrates limited activity against other lepidopteran pests including bollworm, *Helicoverpa zea* (Boddie); armyworms, *Spodoptera* spp.; and soybean looper, *Pseudoplusia includens* (Walker). Monsanto's new Bt cotton (Bollgard 2) was derived by incorporating the Cry2Ab protein into Bollgard cotton cultivars. Transgenic cotton lines (WideStrike) from Dow AgroSciences express the Cry1Ac and Cry1F Bt proteins. Syngenta's lines (VipCot) express a Bt protein that is different in structure and mode of action than proteins in other transgenic cottons. The objectives of these studies were to document technology efficacy against a spectrum of caterpillar pests and to determine their role in a cotton IPM system. The Bollgard, Bollgard 2, WideStrike, and VipCot technologies demonstrated satisfactory control of tobacco budworm. Bollgard 2, WideStrike, and VipCot generally provided acceptable control of bollworm and other defoliating pests, including beet armyworm, *Spodoptera exigua* (Hubner), and soybean looper. These technologies will further reduce, and in some instances, eliminate a requirement of supplemental control of caterpillar pests with foliar applications of insecticides.

Characterization of bruchid resistance in the mungbean variety VC6089A and the resistance-associated protein VrD1

C Lin, SB Horng, CS Chen
"Department of Entomology, National Taiwan University, No.1, Sec. 4, Roosevelt Road, Taipei, Taiwan, sbhorng@ntu.edu.tw"

A novel bruchid-resistant protein, VrD1, was identified in the mungbean variety VC6089A, which was bred from a wild accession TC1966. In the present study, the resistance of VC6089A variety and the toxic-related protein VrD1 was investigated against the cowpea weevil, *Callosobruchus maculatus*. We found that the seeds of VC6089A showed great resistance by causing more than 96% mortality to the bruchid population. The survival bruchid individuals were kept on the VC6089A seeds consecutively for five generations, and it revealed that the mortality of bruchid larvae remained higher than 96%; however, female adults maintained higher fecundity with generations. The toxic-related protein VrD1 purified from VC6089A seed also showed marked resistance to *C. maculatus* under artificial seed bioassays. Thorough inhibition of development was observed when larvae were fed on artificial seeds containing merely 0.2% VrD1, which could be concluded it was one of the most potent anti-bruchid protein discovered from plant so far. Our findings demonstrated the insecticidal activity of VC6089A seeds and VrD1 protein against *C. maculatus*. These results may facilitate pest control corresponding to bruchid infestation, but the potential of bruchids evolving resistance to the resistant mungbean variety through maintaining higher fecundity should be carefully monitored as well.

Productivity and factors associated with arthropod pest abundance in a 2-Year survey of watermelon (*Citrullus lanatus*) production

Wenhua Lu, W Roberts, M Taylor, JV Edelson
Oklahoma State University, P. O. Box 128, Lane, OK 74555, USA, wenhua@lane-ag.org

We conducted a statewide survey of watermelon production during 1998 and 1999 with 39 and 62 fields (or growers), respectively. The striped cucumber beetle, the squash bug, the melon aphid, and the spider mite were monitored weekly during the growing season. A pest index was developed based on mean densities of these 4 arthropod pests. Among 25 other variables surveyed, plant density, row bedding, presence of windbreaks, hoeing, cultivation rate, rainfall, planting date, and harvest date were strongly associated with this index. High cultivation rates were accompanied with greater arthropod pest abundance. Early planting dates were affiliated with greater abundance of arthropod pests and weeds. However, greater arthropod pest abundance was also correlated with greater productivity in terms of harvest frequency and number of marketable fruit. We partitioned 4 economic categories as machinery, labor, supply, and risk for each survey variable, and then assigned weight scores to each. Management intensity was measured by summing weight scores across the categories for all factors involved in each field and found to be the key for increased productivity. Differences in climatic conditions and sample size may explain the variation in association of factors with pest index and watermelon yield between years.

Effects of vetiver oil and nootkatone on *Myzus persicae* infesting eggplants in a controlled environment

L Maistrello, L Cigarini, D Galli, M Ferrari, P Medeghini Bonatti
Dipartimento di Scienze Agrarie – Università di Modena e Reggio Emilia, Via J.F. Kennedy 17, Reggio Emilia, 42100, Italy, maistrello.lara@unimore.it

The essential oil of vetiver (*Vetiveria zizanioides* (L.) Nash.) and the sesquiterpenoid nootkatone, commonly used in the perfume and flavour industries, were reported to show repellent, feeding deterrent and toxic effects to *Coptotermes formosanus* Shiraki, one of major pests of structural wood. The present investigation aimed to study the effects of the two substances on a serious pest of agricultural systems, the green peach aphid *Myzus persicae* (Sulzer), which was maintained in a controlled environment on eggplants (*Solanum melongena* L.), representing one of its most important herbaceous hosts. Preliminary tests were performed to verify the phytotoxicity of formulations of the two substances, using fluorescence microscopy. The activity on *M. persicae* was tested by means of different experiments: a) using foliar disks, and, b) spraying the plants before and after aphid colonization. Evaluations of aphid behaviour and observations on the number of colonizing individuals and of nymphs generated parthenogenetically were performed. The results suggest that, in spite of the problems emerged with the used formulations, both substances could represent potentially good candidates as active ingredients for the control of this aphid.

Effects of spurge flax (*Daphne gnidium* L., Thymelaeaceae) extracts on the development and mortality of the elm leaf beetle (Coleoptera: Chrysomelidae)

MA Lopez, FJ Soria, L Maistrello, R Ocete
Dipartimento di Scienze Agrarie – Università di Modena e Reggio Emilia, Via J.F. Kennedy 17, Reggio Emilia, 42100, Italy, maistrello.lara@unimore.it

Spurge flax (*Daphne gnidium* L., Thymelaeaceae) is an evergreen shrub typical of the Mediterranean flora. It has been traditionally used for centuries in Spain as a control agent of invertebrate pests of crops and cattle. Previuos bioassays performed in our laboratory demonstrated that leaves and ethanolic extracts of *D. gnidium* showed antifeedant activity on pest species belonging to the orders Heteroptera, Isoptera, Lepidoptera and Coleoptera. The elm leaf beetle, *Galerucella luteola* Müller (Coleoptera, Chrysomelidae), in Spain represents one of the most important pests of elms (*Ulmus spp.*) in both river bank forests and urban areas, being responsible for partial or total defoliation of the tree tops. In order to study the effects of spurge flax on *G. luteola*, different doses of an ethanolic extract of *D. gnidium* were added to the natural diet (elm leaves) of young larvae. During the development, weight changes, phase durations and mortality rates of each stage were recorded. Results showed that the addition of spurge flax extract to the diet of *G. luteola* induced: a) a significant increase in the duration of the larval period; b) greater mortality rates for all stages; c) weight reduction of individuals of all stages, including imagoes.

Termites in the vines: *Kalotermes flavicollis* is one of the main pests of sherry vineyards in Andalusia, Spain

L Maistrello, MA Lopez, R Ocete.
Dipartimento di Scienze Agrarie – Università di Modena e Reggio Emilia, Via J.F. Kennedy 17, Reggio Emilia, 42100, Italy, maistrello.lara@unimore.it

Sherry vineyards, located in Andalusia (SW Spain) yield important registered designation of origin wines. These vines are affected by important sanitary problems caused by the termite *Kalotermes flavicollis* (Isoptera: Kalotermitidae) and the fungus *Eutypa lata.* A detailed investigation was performed during 15 months in nine districts of the Sherry area on differently aged vines of the "Palomino fino" variety. Samples were collected twice a month, cutting randomly selected vines into six sections, which were examined to detect the living status and the presence of arthropods (*K. flavicollis, Reticulitermes lucifugus*, ants) and fungi (*Eutypa* dieback disease, wood fungi). The results showed that among the 44% unhealthy vines, always aged more than 15 years old, *K. flavicollis*, found in almost 84% of cases, and often in contemporary presence with dead vine areas, represented the major pest of sherry vineyards, followed by *Eutypa* symptoms (14%), whereas *Reticulitermes lucifugus*, ants and wood fungi were found only sporadically. The characterization of the infestations, their trend over the seasons and their location in different sectors of the vines will be shown and discussed.

Direct and correlated responses to selection for varietal resistance in the whitebacked planthopper, *Sogatella furcifera* (Delphacidae)

M Matsumura
National Agricultural Research Center for Kyushu Okinawa Region, 2421 Suya, Nishigoshi, Kumamoto 861-1192, Japan, mmasa@affrc.go.jp

Performance of the whitebacked planthopper *Sogatella furcifera* (Delphacidae) was examined on the resistant rice variety IR-58032-1-1 (IR) carrying the resistance gene *Wbph 1*. Nymphal survivorship on IR was as high as those feeding on susceptible rice varieties. In contrast, adult survivorship within 5 days after emergence on IR was only 10-25%. To elucidate whether a planthopper biotype that can attack the resistant IR rice variety can develop, artificial selection for varietal resistance on IR was conducted for 5 generations. A control planthopper line was selected on the susceptible rice variety TN1. Adult survivorship on IR was increased to 40% after 5 generations of selection. However, realised heritability was low (h^2=0.098 for females), suggesting that the biotype may not develop rapidly. Selection on the resistant line not only increased adult survivorship directly but also led to a correlated change in honeydew production (a measure of feeding amount) in two ways. The amount of honeydew in the resistant-selected planthopper line increased on IR, but it decreased on TN1. The results suggest that selection for varietal resistance not only improves feeding ability but also decreases the minimum food requirement to survive. The mechanism of varietal resistance in *S. furcifera* will be discussed.

Detecting new and emerging pests of eucalypt plantations in Queensland: the value of systematised forest health surveillance

JM McDonald, SA Lawson
Department of Primary Industries and Fisheries, Agency for Food and Fibre Sciences, Forestry Research, Indooroopilly, Queensland, 4068, Australia, Janet.McDonald@dpi.qld.gov.au

Systematised forest health surveillance has been carried out in eucalypt plantations in southeast Queensland since 2000. Surveys are carried out using two main methods - drive through and walk through. When severe problems are detected intensive monitoring of pest damage and their effects on growth in targeted plantations is carried out by establishing medium-term monitoring plots in which crown damage index (CDI) and growth parameters are assessed, and by using the newly established national standard for CDI assessment. These results feed directly into hardwoods research programs. Call outs from plantation managers and operational staff also form part of the surveillance. The disparate nature of the plantation resource in southeast Queensland means that not all plantations can be visited. Since surveys have been carried out a number of new and emerging pests have been detected. These include an eriophyoid mite (*Rhombacus* sp.) causing severe damage to spotted gums, a plate-galling wasp (*Ophelimus* sp.) on western white gum, *Creiiis lituratus* psyllids on Dunn's white gum and leafblister sawfly (*Phylacteophaga* spp.) on a number of hosts. Spatial analysis of the distribution and severity of damage by the eriophyoid mite is illustrated and data on damage caused by the other emerging pests provided.

Susceptibility of upland cotton *G. hirsutum* to silverleaf whitefly colonization compared to the cotton relative, *Gossypium thurberi*

ET Natwick, GP Walker
University of California Coop. Ext., 1050 E Holton Rd, Holtville, CA 92250, USA etnatwick@ucdavis.edu

Three cotton, *Gossypium hirsutum* L., cultivars and the cotton relative, *G. thurberi,* were evaluated in the field, during 2001, 2002 and 2003, for susceptibility to infestation by the silverleaf whitefly, *Bemisia argentifolii* Bellows and Perring, also known as *B. tabaci* biotype B, in Imperial Valley, CA. The upland cotton cultivars included DP 5415, Siokra L23 and Stoneville 474. Entries were evaluated for colonization by silverleaf whitefly as numbers of adult, eggs and nymphs. In the field studies, *G. thurberi* had very low numbers whitefly adults, eggs and nymphs, followed by Siokra L23, DP 5415 and Stoneville 474. In contrast, in greenhouse studies on potted plants, silverleaf whitefly had higher nymphal survival and shorter development time on *G. thurberi* compared to DP 5415. Low field numbers of *B. argentifolii* on *G. thurberi* does not appear to be explained by poor nymphal survival. The stage-specific survival data from the 2001 greenhouse test, the 2002 data on mature field-hardened potted plants, and the 2003 field survival data support the conclusion that *G. thurberi* is a suitable host for nymphal development.

The change of target thrips and their insecticide susceptibility in Japan

T Nishimori, K Imai, M Yamada, N Miki, S Kobayashi, M Kobayashi
Pesticide Research Department, Zen-noh Agricultural R&D Center, 5-5-1 Higashi-Yahata, Hiratsuka, Kanagawa 254-0016, Japan,
nishimori@zk.zennoh.or.jp

Melon thrips, *Thrips palmi* Karny, invaded Japan in 1978. Neonicotinoid insecticides were highly active on *T. palmi*, and thus neonicotinoids were used as the main insecticides for thrips control. However, when western flower thrips, *Frankliniella occidentalis* (Pergande), invaded Japan in 1990, the effectiveness of neonicotinoid insecticides on that species was low. The main insecticides to control thrips then changed to emamectin benzoate, spinosad and chlorfenapyr because of their effectiveness in controlling *F. occidentals*. Though onion thrips, *thrips tabaci* (Linderman), have been known as one of the main pests on Welsh onion and onion from the old days in Japan, they were largely ignored owing to the invasion of *T. palmi* and *F. occidentalis.* In recent years, the damage of *T. tabaci* has expanded to other vegetables, fruit trees and flowers, thus raising serious problems in several regions. In order to establish control methods on *T. tabaci*, insecticide susceptibility of *T. tabaci* was investigated. The results showed that the activity of Acephate and Spinosad was outstanding. Neonicotinoids and emamectin benzoate were also active on *T. tabaci*. It suggested that the recent expansion of *T. tabaci* has been caused by several factors beyond just the change of insecticides used on thrips.

New aphid pest of seashore Paspalum turf grass: greenbug, *Schizaphis graminum*

GS Nuessly, RT Nagata, MG Hentz, A Carroll
"Everglades Research and Education Center, UF/IFAS, 3200 E. Palm Beach Rd., Belle Glade, FL, USA, 33430-4702, GSN@IFAS.UFL.EDU"

Greenbug (*Schizaphis graminum*) was first found feeding and damaging seashore Paspalum (*P. vaginatum*) turf grass in October 2003 in Belle Glade, Florida, USA. Feeding by this aphid causes rapid chlorosis and necrosis. Water soaked green spots appear on leaves within 24 h of feeding, followed within 24 hours by yellowing. Leaf death follows within 48 to 72 hours. The use of this turf grass, made popular by its rapid growth, fine short blades and salt tolerance, is increasing internationally in coastal temperate through tropical zones. Greenbug is spreading into golf courses and sod farms in southern Florida and a currently distribution map will be presented. Results of biotype, insecticide efficacy and host plant resistance trials will be shown and discussed in relation to short and long term pest management goals.

The monitoring activity of *Diabrotica virgifera virgifera*, in center part of Romania

F Muresan, C Popov
"915200 Fundulea-Calarasi, ICDA Fundulea, Romania, fundulea@ricic.ro"

In the maize crop from Romania, about 20 pest species with a great economical importance were identified. In Transylvania, center part of Romania, at maize crop there are recorded pest species on seed and during vegetation, which could induce significant damages by their attack, causing big yield losses and crop compromising. Since 1996, western corn rootworm (*Diabrotica virgifera virgifera)* was registered in western part of Romania, and later, in 2002, in the center part. The monitoring was performed by using feromone sexual traps. Based on the obtained data during these two years of experimentation, the flying curve has been established. In 2002, only six adults were recorded but in 2003, the abundance of adults increased over 400 individuals. The massive appearance of adults (50-60 adults/week) was recorded during flowering stage (July, 15- August, 15). At the present, in Romania, western corn rootworm is identified in 17 districts from 41, but the level of the population does not assure damage area yet.

Wireworms management by seed treatment in Romania

C Popov, S Vasilescu, E Trotus, AA Alexani, S Rarancuc
"915200 Fundulea-Calarasi, ICDA Fundulea, Romania, fundulea@ricic.ro"

In Romania, the main species of *Elateridae* are: *Agriotes ustulatus* (40.1%), *A. obscurus* (17.3%), *A. sputator* (11.3%), *A. flavicornis* (10.9%), *A. pilosus* (6.9%), *A. lineatus* (3.8%), *Limonius pilosus* (1.8%), *Synaptus filiformis* (1.6%), *Selatosomus latus* (1.5%). Annually, the wireworms attack 800,000 ha approximately. The recorded densities in field crops vary from 5-10 larvae/sq m up to 70-100 larvae/sq m which determine attack levels up to 25-30% in wheat and barley crops and up to 40-65% in maize and sunflower crops. At present, the seed chemical treatment method is the most important, efficacy, economic and little pollutant measure for the control of wireworms in field crops. At the spring row-crops (maize and sunflower), different products based on the following active ingredients: *acetamiprid, bifentrin, carbofuran, fipronyl, furatiocarb, imidachlopride, thiamethoxam,* have been used. At the winter spiked cereals, the seed treatment was made with products based on *lindan* and one or more fungicides (*carbendazim, carboxine, diniconazol, miclobuthanil, prochloraz, tebuconazol, tiophanat methyl, thiram, triadimenol*). In this case, a good simultaneous protection to both wireworms and some specific pathogens (*Tilletia spp., Fusarium spp., Ustilago nuda, Pyrenophora graminea*) was assured. The efficacy, up to 80% permitted their registration and promoting in production in Romania.

Methods to increase efficiency of releasing *Phytoseiulus persimilis* Athias-Henriot (Acari: Phytoseiidae) predators of twospotted spider mites (*Tetranychus urticae* Koch (Acari: Tetranychidae)) in strawberry

JF Price, KA Sorensen
Gulf Coast Research and Education Center, 5007 60th Street East, Bradenton, FL, 34203 USA jprice@mail.ifas.ufl.edu

Florida produces about 2,800 ha. of strawberries for wintertime, fresh market sales valued at about $170 million. Numerous arthropod pests affect the production including strawberry root aphid, melon aphid, fall armyworm, southern armyworm, flower thrips, sap beetles, and *osophila* and fruit flies. No arthropod pest of Florida's strawberry production is more damaging, however, than the twospotted spider mite, *Tetranychus urticae* Koch (Acari: Tetranychidae). Strawberry producers control this pest by collecting weekly ecological information through scouting and applying miticides or *Phytoseiulus persimilis* (Acari: Phytoseiidae) predatory mites at predetermined thresholds. The predators cost about $300/ha. and are shipped in mixtures with dry carriers and are applied by on-farm, hand labor. Experiments were performed to maximize the efficiency of and probability of successful predator releases by the laborers. These data lead to the conclusions that laborers must remix predators and dry carrier material in the shipping containers frequently in order to avoid inefficient releases.

Innovative farm practices for sustainable white grub management in sugarcane

GM Quimio, FA Ceballo
The National Crop Protection Center, University of the Philippines, Los Baños, Philippines 4031; greg_quimio@yahoo.com

An integrated management approach was suggested for sustained reduction in grub population of *Leucopholis irrorata* Chevrolat and its damage to sugarcane in the Philippines. The strategy calls for conservation of natural biological control agents through field population enhancement of native grub Scoliid parasites and predators and potential use of *Beauveria bassiana* fungus. Removal of alternate weed hosts, exposure of grubs to solar radiation and predators by thorough soil cultivation, and flooding infested fields reduced grub population. Area-wide collection and burning of collected beetles from harboring trees, before the beetles breed, significantly reduced grub population and the cost of control. Baits and traps using indigenous materials augmented and facilitated beetle collection from large trees. Judicious use of insecticides registered for sugarcane in exceptional cases. Regular monitoring and sustained application of any of these control options, in conjunction with area-wide beetle collection, effectively reduced grub population in infested areas.

Large-scale biological control of cone pests in spruce seed orchards

O Rosenberg, J Weslien
"The Forestry Research Institute of Sweden, Uppsala Science Park SE-751 83 Uppsala, Sweden. olle.rosenberg@skogforsk.se"

We have investigated large-scale application of the biological insecticide *Bacillus thuringiensis* var. k*urstaki*/ *aizawai* (Btk) on damage levels of three lepidopteran species (*Dioryctria abietella* Den et. Schiff. (Pyralidae), *Eupithecia abietaria* Götze, (Geometridae) and *Cydia strobilella* (L.) (Tortricidae)) in a Swedish spruce (*Picea abies* L. (Karst.) seed orchard. To discover the number and timing of sprayings as well as dosage of Btk necessary for control of the lepidopterans, spraying was conducted at different phases of flowering and cone development. The Btk treatment reduced damages caused by *D. abietella* and *Eupithecia* spp. by 65% of that in control treatments. The damage by *C. strobilella* was however not affected by the treatment. Dosage and repeated spraying had no effect on insect damage levels.

Small-scale industrial production of Thai neem-based extracts: RIT-pilot plant and contribution in vegetable insect pests control in Thailand

U Sanguanpong, J Kanobdee, A Sotatikul, S Chaitungchit, C Paengwangthong, K Boonyaretniran, K Lawtong, L Kongsombat, S. Bureepakdi
Department of Postharvest Technology and Processing Engineering, Faculty of Agricultural Engineering and Technology, Rajamangala Institute of Technology, Patumtani 12110, Thailand unchalee@rit.ac.th

By moving-bed contacting extraction technique, defatted cake of Thai neem seeds (*Azadirachta indica* var. *siamensis* (Valeton)) was extracted with methanol at RIT-Pilot Plant (Rajamangala Institute of Technology) in Patumtani province, central part of Thailand. After sedimentation of crude cake, the neem solution was ained out, then filtered and evaporated until a specific volume, the so-called-concentrated alcoholic neem-based extract. Before packing in containers, the content of azadiracthin is monitored per batch by using HPLC. Furthermore the concentrate is also formulated for specific purpose as 3 different "Ready-To-Use" products named- RITNEEM, RITNEEM-O I, RITNEEM-O II. The capacity of pilot plant is 25 ton/year within 250 working days. In contribution to vegetable production, many field experiments on insecticidal toxicity against *Hellula undalis, Lipaphis erysimi, Spodoptera litura* and *Pleutella xylostella* in chinese kale were conducted. Overall, it was observed that similar trend of population suppression were noted between all formulations at dose of 25 cc/20 L. In particular, they could be considered to give effective control against *H. undalis* and *S. litura*, whereas *P. xylostella* was the least susceptible. However, all formulations did not result in significantly greater yields than control with chemical and water spraying.

Non-host anti-feedants in *Hylobius* pine weevils: from lab to field applications

F Schlyter, P Månsson, J Löfqvist, C Eriksson, K Sjödin, H-E Högberg
Chem. Ecol., SLU, P. O. Box 44, SE-230 53 Alnarp, Sweden, freik.schlyter@vv.slu.se

Anti-feedants as a protection against herbivores is known in many plants, like in the 'neem' tree *Azadiractica indica.* In conifers, defence is quantitative, based on less toxic oleoresin compounds. In small, stressed conifers like the ones planted on clear-cuts in forestry, the quantitative defence is weak. These seedlings have been defended by insecticides like DDT and pyrethroids against the feeding by adult pine weevils *Hylobius abietis* but use of insecticides will be banned. Our work follows two lines: 1) The screening of synthetically available anti-feedant compounds and related structures. 2) The search for antifeedants in non-host plants (presented elsewhere). The development of laboratory bioassays has been a prerequisite for both. The screening of synthetic antifeedant candidates has given a dozen field test candidates. Three groups of interest, the carvone-analogues, the arylaldehydes, and the bark alkaloids, show a high activity for some structures. Field-tests in 1997 and 2001-2003 have confirmed the activity in lab-bioassays, but the molecular activity itself is here interwoven with effects of stability and evaporation. The three factors compound, dose, and formulation and all affect protection efficacy. New types of formulations in development, like thicker coatings or discrete or provoked-release principles show promising first results.

Sweetpotato weevil, *Cylas formicarius elegantulus* (Summer) (Coleoptera: Curculionidae): a worldwide pest of sweetpotato and sustainable management

KA Sorensen
"Department of Entomology, North Carolina State University, Box 7626, Raleigh, NC 27695-7626, USA, kenneth_sorensen@ncsu.edu"

Sweetpotato weevil (SPW) is the most destructive insect pest of sweetpotato in the world. Native to Asia, SPW was discovered in India in 1792 and in US in 1875, near New Orleans, LA. Occurrence on five continents and 11 US southern states attests to weevil's adaptive potential and impact. Weevil dissemination has historical ties to people and commerce. Sweetpotatoes, *Ipomoea batattas*, and related yams, *Dioscorea* sp., are the seventh largest crop (FAO world crop statistics). Weevil hosts include seaside morning glory, *Ipomoea sagittata* and related species. Sweetpotato production and marketing offer constant weevil spread. Direct damage by this quarantined pest, control costs and regulatory action conservatively exceed $20 M annually in USA. SPW management is sustained through an educational program, through development and worldwide use of sex pheromone trapping, tolerant varieties, effective insecticides, sound cultural practices, micropropagation techniques and regulatory programs. To contain weevil movement and control or successfully manage weevils requires cooperation, synchronization and application of any and all IPM tactics and strategies. Research efforts with breeding, DNA finger printing in combination with host plant resistance, pathways of movement and detection, insecticidal control in field and storage, cultural and biological control, in concert with eradication and educational programs should improve understanding of SPW behavior, ecology and management.

A tractor mounted device for collecting live arthropods in cotton crops.

TL Staines, ML Dillon, MEA Whitehouse, T Murphy
CSIRO Entomology, Locked Bag 59, Narrabri, NSW, 2390, Australia. trudy.staines@csiro.au

Efficient and precise arthropod sampling methods are important components of integrated pest management in Australian cotton crops. Here we describe a tractor-mounted device for sampling and collecting live insects and spiders from cotton crops, and we present the results of a single experiment quantifying the effectiveness and precision of the device. The number and diversity of insects and spiders captured per metre of row by the device were significantly lower than the average results from beat-sheets that sample individual metres. However the device can sample much greater distances per unit time. The total number of individual arthropods captured by the device increased as tractor-run length increased from 20 to 40 and 80 metres. However the increase was not linear, and variance increased substantially with run length. The total number of distinct taxa collected peaked at tractor-run lengths of 40 metres. Overall the device is less efficient and less precise than manual beat-sheet sampling for the purposes of crop protection decisions. However the device does provide an efficient and effective method for the collection of live insects and spiders from cotton crops.

Advances in IPM for citrus in New Zealand

P Stevens, *K Pyle*.
HortResearch, Private Bag 92169, Auckland, New Zealand. pstevens@hortresearch.co.nz

The citrus industry in New Zealand is relatively small (approximately 2000 ha) compared to other New Zealand grown fruit crops such as apples (approx. 14200ha) and kiwifruit (approx. 11500ha). Because of the small size, the citrus industry has historically received little research attention and has fallen behind with respect to IPM developments in other crops. However, in 2002, a three-year programme was initiated to develop an IPM programme for New Zealand citrus. The citrus IPM programme builds on past experiences gained from other IPM programmes developed in New Zealand, especially those developed for pipfruit and kiwifruit. Successful models for analysis of industry data have been applied to citrus to determine current industry practices and monitor changes over time. Knowledge of successful IPM approaches for generic horticultural pests and diseases have also been included. However, many of the pests and diseases are unique to citrus and there is a limited ability to easily transfer technology and approaches from one crop to another. For example, thrips, especially *Pezothrips kellyanus*, is one of the key pests iving the pest management programme in citrus, whereas thrips are not a major pest of kiwifruit or pipfruit. Specific research to identify IPM-compatible methods for controlling thrips, scale insects and mites is underway. Determining the role of grower practices on natural enemies is a key component of the project.

Dependence of biotype development on life history traits of pests

Y Suzuki, *T Yamanaka*
National Agricultural Research Center, Tsukuba 305-8666, Japan, pa8422@affrc.go.jp

Biotype management is crucial for both the breeding and sustainable use of pest-resistant crops. We developed simulation models accounting for a wide range of pests to evaluate the effects of life history traits on the developmental velocity of a new biotype. Parameters such as the proportion of land cultivated with a resistant variety, migration rate among patches, reproductive potential and degree of density dependence in population growth, initial frequency and dominance of a biotype gene, and fitness cost of a biotype on susceptible varieties were incorporated into 1-locus 2-allele models. The simulation results revealed that life history traits promoting assortive mating have prominent effects on biotype development in general. The frequency of a biotype gene remains at a negligible level for more than 25 generations in holometabolous pests that mate after migration, provided that the biotype gene is recessive and less than 0.1% in initial frequency. Migration rate does not greatly affect biotype development, while high reproductive potential and strong density dependence in population growth of pests facilitates biotype development. On these results we discuss desirable strategies for breeding durable resistant varieties.

Ripening stages of rice spikelets selectively damaged by four species of rice bugs, *Leptocorisa chinensis* Dallas (Hemiptera: Alydidae), *Lagynotomus elongatus* (Dallas) (Hemiptera: Pentatomidae), *Cletus punctiger* (Dallas) (Hemiptera: Coreidae), and *Stenotus rubrovittatus* (Matsumura) (Hemiptera: Miridae).

H Takeuchi, T Watanabe, Y Suzuki
National Agricultural Research Center; Tsukuba, 305-8666, Japan, thiroaki@affrc.go.jp

The rice bugs *Leptocorisa chinensis*, *Lagynotomus elongatus*, *Cletus punctiger*, and *Stenotus rubrovittatus* are serious economic pests of rice crops in Japan. To clarify the ripening stages of spikelets preferentially attacked by those bugs in paddy fields, rice bugs were individually released for three days onto a rice panicle at the following stages of maturation: 7, 14, 21, and 28 days after heading. The spikelets were classified into three groups according to the flowering order in a panicle. The spikelets in Group A (early flowering) and B (mid flowering) were selected by the bugs to feed on at 7 DAH; that is, earlier than those in Group C (late flowering). At 14 and 21 DAH, however, bugs preferred the spikelets in Group C to those in the other two groups. In *L. chinensis*, *L. elongatus*, and *S. rubrovittatus*, the total number of damaged spikelets decreased with maturing of the panicle, whereas there was no remarkable change in the number of spikelets damaged by *C. punctiger*. These results suggested that all species of rice bugs except *C. punctiger* selectively damage the spikelets whose ovaries are developing from lengthwise to sidewise elongation, whereas *C. punctiger* mainly attacks the spikelets whose ovaries are developing from lengthwise to thickness elongation.

WideStrike™ a stacked Bt cotton for improved lepidopteran pest control and resistance management

GD Thompson, JW Pellow, LB Braxton, JL Sernyk, P Downard, R Annetts
Dow AgroSciences, 9330 Zionsville Rd, Indianapolis, IN 46268, gdthompson@dow.com

Dow AgroSciences is a major supplier of pest management, biotechnology and seed products that improve the quality and quantity of the earth's food supply and contribute to the health and quality of life of the world's growing population. One of the more prominent developments in insect control has been the development and rapid adoption of Bt cotton which brought significant advantages to the cotton producer. Dow AgroSciences has had a long commitment to biotechnology which is bearing fruit with a highly efficacious stacked transgenic trait that express both the Cry1F and Cry1A lepidopteran active Bt proteins in cotton plants. The combined trait stack results in higher levels of efficacy and a broader lepidopteran pest spectrum than previously available in single Bt cotton improving the overall value to the grower and providing selection diversity to slow resistance development in target insects. Additionally, improved promoters provide expression throughout the growing season. Dow AgroSciences anticipates that WideStrike will be available commercially in the U.S. via PhytoGen cotton varieties in 2005. Dow AgroSciences is supporting licensing of WideStrike to additional seed companies and geographies where all environmental safety and stewardship requirements can be met. Performance data and information on pest spectrum will be presented.

Impact of artificial shelters on arthropod complex in agroecosystem

W Tshernyshev, V Afonina, A Timokhov, R Seyfulina, A Sujazov, E Bokhovko
Dept. of Entomology, Faculty of Biology, Moscow State University, 119992, Russia; tshern@yandex.ru

Artificial shelters were made of straw as long banks in large fields of winter wheat. The most pronounced positive effect was observed in active predators using these shelters. Abundance of some beetles (*Carabus*, aleocharine staphylinids) and Lycosidae spiders were increased in some times in close vicinity to the shelters. The same increase takes place in herpetobiont beetles Anthicidae which also hid under straw. Other mass herpetobiont beetles of Dermestidae and Silphidae did not use these shelters. The abundance of *Dermestes laniarius* does not depend on the presence of shelters while the beetles of *Silpha obscura* avoided the field zones with shelters. Parasites and herbivores were observed in shelters very seldom. Catches of hortobionts (aphids, bugs, thripses and hymenopterans) by entomological net as well as the parasitization of eggs of a harmful bug, *Eurygaster integriceps*, were not influenced by shelters. However the number of eggs that yielded neither bug larvae nor their parasites (killed by predators?) increased twice as many at the parts of field with shelters.

Imidacloprid treatment of seedling roots as a component of an integrated pest management strategy for insect pests in *Brassica* crops.

B Walsh, MJ Furlong,
"Queensland Department of Primary Industries and Fisheries, Gatton Research Station, Gatton, 4343, Queensland, Australia,
Bronwyn.Walsh@dpi.qld.gov.au "

In Queensland, Australia *Brassica* crops are attacked by a suite of insect pests. In the early months of the growing season (February- April), crops are attacked by *Bemisia tabaci* type B and the major lepidopterous pests are *Hellula hydralis* and *Crocidolomia pavonana*. Later in the season (May- September) the diamondback moth, *Plutella xylostella*, poses the greatest threat to the successful cultivation of *Brassica* crops. Disruption of the agro-ecosystem by the frequent foliar application of synthetic chemical insecticides to control these early season pests can seriously diminish the success of subsequent integrated pest management programmes developed for the diamondback moth. In field studies, root treatment of early season cabbage seedlings with imidacloprid prior to transplanting significantly reduced *H. hydralis* infestation for up to four weeks post transplantation and *B. tabaci* infestation for up to five weeks after transplantation. *Crocidolomia pavonana* infestation was not affected by imidacloprid treatment of seedlings. Root treatment of seedlings with imidacloprid can reduce the number of foliar sprays required for the management of some early season *Brassica* pests and has the potential to be incorporated into existing pest management programmes without disrupting the successful management of the diamondback moth.

Yearly fluctuations in the immigrant density of the rice planthoppers into Japan

T Watanabe, M Matsumura, Y Suzuki
National Agricultural Research Center, Tsukuba, 305-8666 Japan, tomonari.watanabe@affrc.go.jp

Since the mid 1990s, the immigrant densities of the migratory planthoppers, *Sogatella furcifera* and *Nilaparvata lugens* from south China to Japan have been decreased compared with those in the 1980s. Light trap catches obtained in southern part of Japan in June and July were used for detailed analyses. No correlation was observed in the number of catches between *N. lugens* and *S. furcifera* for the period from 1997 to 2002, whereas high correlation was observed in the trap catches between *N. lugens* and *S. furcifera* during 1989 to 1993. Only 5 to 20% of the total catches of *S. furcifera* were obtained in June early in the 1990's, but the proportion increased 30 to 70% during 1997 to 2002. The mean cumulative days of low-level jet stream (LLJ) development observed during June and July decreased from 15.0 days/year in 1980-1990 to 8.4 days/year in 1997-2002. The differences between the two periods was due to much lower frequency of LLJ development in July in 1997-2002. This indicates that the absence of meteorological conditions for migration accounts for the recent decrease in immigrant planthoppers in Japan, though low population densities in the migrant source area is another possible reason.

No adverse effect of YieldGard® rootworm on ground beetles (Coleoptera: Carabidae)

A Ahmad, M Al-Deeb, GE Wilde
"Department of Entomology, Waters Hall, Kansas State University, Manhattan, KS, 66506, gwilde@ksu.edu"

The effect of transgenic corn ground beetles was studied under laboratory and field conditions. No differences in ground beetle populations occurred in transgenic and non-transgenic corn in the field. No differences in longevity and fecundity occurred in laboratory tests where two ground beetle species were fed dog food sprinkled with pollen from transgenic and non-transgenic plants.

Spatial and temporal features and social composition of vine-infesting colonies of Kalotermes flavicollis in Sherry vineyards (Spain)

Research on the environmental impacts of GM plants in New Zealand

L Malone, J Todd, E Burgess, M O'Callaghan, T Glare
HortResearch, Mt Albert Research Centre, Private Bag 92169, AUCKLAND, NEW ZEALAND, LMalone@hortresearch.co.nz

In 2001 New Zealand's Royal Commission on Genetic Modification (GM) gave a recommendation to "proceed with caution" and to undertake more research on the potential environmental impacts of this technology. Studies to develop methods in containment for assessing impacts on non-target organisms (bees, predators and soil biota) were already underway. This effort was expanded with new research programmes on horizontal gene transfer in NZ soils, gene flow to indigenous and naturalized plants, native pollinators of crop plants, persistence of gene products (recombinant proteins) in soil and in insect frass, criteria for selecting non-target invertebrate species for biosafety testing, and specific environmental impact studies with GM vegetable crops and forest trees. Recent results from a honey bee project suggest that three different insecticidal gene products (a Bt toxin, a proteinase inhibitor and a biotin-binding protein) are not likely to affect the development of hypopharyngeal glands in adult bees that have consumed each protein with their pollen food. Recent results from a project to examine the effects of GM plants on soil biota suggest that proteinase inhibitor-expressing plants have little impact on life cycle parameters in one species of Collembola.

The Silkworm Genome Project in China: a 6X draft sequence of the domesticated silkworm (Bombyx mori) genome

*Q.-Y. Xia, Z.-Y. Zhou, C. Lu, Z.-H. Xiang**
The Key Sericultural Laboratory of Agricultural Ministry, Southwest Agricultural University, 216,Tianshengqiao Street, BeiBei, Chongqing, China, 400716.
*email: xzh@swau.cq.cn

In 2003, the international silkworm genome project Chinese group has finished a 6x coverage sequencing of the domesticated silkworm *(Bombyx mori),* by using of whole genome shotgun (WGS) technique. Here we report a draft sequence for the genome of the domesticated silkworm, *Bombyx mori*. Our assembly contains 92.9% of all known silkworm genes. The gene number of silkworm genome is estimated to be 18,510, more than that of *Drosophila melanogaster*. Comparisons to the other two sequenced insect genomes**,** fruitfly and mosquito, reveal some remarkable parallels and differences. We reported the main strategy and results of this project as following: 1) The strategy of sequencing 2) The general results of sequencing 3) Assembly of the silkworm genome sequences 4) Annotation of the silkworm genome 5) Genomic comparison of silkworm and other insects 6) Biological analysis of the silkworm genome 7) Outline of the further study in China

Population genetics of kdr-type resistance to pyrethroids in the peach-potato aphid, *Myzus persicae***.**

J. Anstead, I. Denholm and M.S. Williamson.
Rothamsted Research, Harpenden, Herts, AL5 2JQ, UK, martin.williamson@bbsrc.ac.uk

The peach-potato aphid, *Myzus persicae,* is an important agricultural pest in many parts of the world. It is mainly controlled through insecticide applications and has developed strong resistance to most of the major chemical classes as a result of their widespread use. Resistance to pyrethroids is particularly problematic in *M. persicae* and is primarily the result of a target site resistance mechanism termed knockdown resistance (or kdr). We have found that this is caused by either one (L1014F) or two (L1014F + M918T) point mutations in the domain II region of the para-type voltage-gated sodium channel (the target for pyrethroids). Aphids that carry the double mutation are highly resistant to even the most potent pyrethroids, surviving doses of deltamethrin in excess of 100ppm. To facilitate rapid monitoring for pyrethroid resistance in *M. persicae*, we have developed an allelic discrimination PCR assay to determine the genotypes of the two mutations in individual adults using fluorescent Taqman® MGB probes. We are using this assay to study the origins and spread of the mutations in a diverse range of *M. persicae* populations.

Insecticide resistance and its management in the cotton bollworm *Helicoverpa armigera* in Pakistan

M Ahmad
Central Cotton Research Institute, Multan, Pakistan, mush_a@yahoo.com

The cotton bollworm, *Helicoverpa armigera* (Hubner) (Lepidoptera: Noctuidae) is a key pest of cotton and other crops in Pakistan. Indiscriminate use of pesticides prompted the development of insecticide resistance in this pest. Resistance to pyrethroids has been on the rise since 1991. Resistance factors are now >100 to all the pyrethroids. Endosulfan resistance remained moderate to high. However, some thiophosphates and carbamates mostly exhibited low levels of resistance. We never ran out of options for the control of *H. armigera*. The latest introduction of new chemistries with novel modes of action added to the effective armory. An IRM strategy including other IPM tactics has been recommended to the cotton growers for the better control of *H. armigera* and other cotton pests.

Mutations in acetylcholinesterase (AChE) of the cotton melon aphid (*Aphis gossypii* Glover) and the peach potato aphid (*Myzus persicae* Sulzer) confer resistance.

MC Andrews, A Callaghan, LM Field, GD Moores.
Rothamsted Research, Harpenden, Herts., UK, AL5 2JQ. Melanie.anews@bbsrc.ac.uk

Two mutations in the *ace1* gene of *Aphis gossypii* are associated with insensitivity of acetylcholinesterase (AChE) to carbamate and organophosphate insecticides. The first of these, S431F (331 in *Torpedo californica* numbering), is associated with insensitivity to the insecticide, pirimicarb. The mutation to a phenlyalanine is consistent with a loss of sensitivity to pirimicarb in a range of both *A. gossypii* and *M. persicae* clones. A rapid RFLP diagnostic allows the identification of individuals of both aphid species with a resistant genotype. This diagnostic further reveals the presence of S431 in several other pirimicarb-susceptible aphid species. The serine at this position in the wild-type enzyme has only been reported for aphids and is considered the reason why pirimicarb has a specific aphicidal action. A second mutation, A302S (201 in *T. californica*), confers insensitivity to a wide range of carbamates and organophosphates and has, to date, only been found in resistant strains of *A. gossypii.*

Stem application of monocrotophos in okra: dissipation of monocrotophos residues

ML Kiranmai, *T Ramesh Babu*
Acharya N.G. Ranga Agricultural University, Hyderabad 500 030, Andhra Pradesh, India, tatinenir@yahoo.com

The status of residues of monocrotophos at harvest and its dissipation pattern in okra fruits when employed as stem application at the rate of 1:6 (one part of monocrotophos in six parts of water) were studied in a field experiment. The residues of monocrotophos were below detectable level (BDL) during first picking when the stem application was imposed at or before 38 days after germination (DAG). The repeated application, even during fruiting, evidently established the cumulative residues of monocrotophos in okra fruits. The residues (0.57 ppm) recorded in okra fruits on first day of stem application accumulated up to 3rd day (2.21 ppm) and dissipated gradually to maximum residue level (MRL) of 0.2 ppm with Ttol. of 11.27 days. Therefore stem application of monocrotophos in okra should be restricted to 12 days prior to picking of fruits.

Effects of cypermethrin and chlorpyrifos residues in cattle dung on the development of the dung beetle *Copris tripartitus* (Coleoptera: Scarabaeidae)

HS Bang, JH Lee, GS Kyung, OS Kwon, YE Na, SJ Hwang
NIAST, RDA, Suwon 441-100, Korea, Banghs1@rda.go.kr

Fresh dung was collected from untreated cattle and cattle dosed with a spray-on formulation of cypermethrin and chlorpyrifos (2.1g /cow) on days 1, 3, 5 and 7 post-treatment. The dung was bioassayed using the dung beetle *Copris tripartitus* Waterhouse. Residues of cypermethrin and chlorpyrifos were sufficient to inhibit oviposition by *C. tripartitus* in day 1 dung but there was no significant effect on egg laying in dung collected at days 3-7 post-treatment in sexually matured female. But, in the second generation residues of cypermethrin and chlorpyrifos were sufficient to inhibit oviposition by *C. tripartitus* in treatment after 1 and 3 days. Although there was no significantly different effect on egg laying in dung collected at days 3-7 post-treatment in first breeding but, in second breeding, toxic effect reveal in 3 and 5 days dung treatments. Nulliparous dung beetles fed for 200days on dung collected 0, 1 and 3 days after treatment of cow with cypermethrin and chlorpyrifos show little ovarian development.

Effect of ecdysone agonists on tortricid male/female orientation

BA Barrett, J Hoelscher
1-87 Agriculture Bldg., University of Missouri, Columbia, MO 65211, USA, BarrettB@missouri.edu

The attractiveness and responsiveness of adult codling moth, *Cydia pomonella* (L.), redbanded leafroller, *Argyrotaenia velutinana* (Walker), and obliquebanded leafroller, *Choristoneura rosaceana* (Harris), exposed to surfaces treated with the ecdysteroid agonist methoxyfenozide were investigated in wind tunnel and orientation tube assays. When males were exposed to water-treated surfaces for 48 h the mean percent recaptures of such treated males in the wind tunnel assay were almost always (depending on species) significantly greater than the recaptures of males that had been exposed to methoxyfenozide-treated surfaces. Similarly, in the orientation tube assay, methoxyfenozide-treated males almost always had significantly lower mean levels of individuals exhibiting sexual excitability (intense wing fanning and upwind orientation) and mean distances traveled upwind in the orientation tubes. The two assays demonstrated that males exposed to methoxyfenozide-treated surfaces were not as responsive to calling females (treated and non-treated) as were the non-treated males. Conversely, females exposed to methoxyfenozide-treated surfaces were just as attractive to non-treated males as were water-treated females. It appears that a male's ability to respond to a calling female is more negatively affected by the ecdysone agonist than a female's ability to call and attract males.

Assessing the role of cytochrome P450s in insecticide resistance of *Lucilia cuprina*, *Helicoverpa armigera*, and *Drosophila melanogaster*

PJ Daborn, C Robin, Z Chen, J Fair, CJ Wee, V Grubor, L Willoughby, DG Heckel, P Batterham
Centre for Environmental Stress and Adaptation Research, Department of Genetics, The University of Melbourne, Victoria 3010, Australia
p.batterham@unimelb.edu.au

Cytochrome P450 are heme containing enzymes that perform a diverse array of REDOX reactions against exogenous and endogenous compounds. Characterised insect genomes have approximately 90-100 individual cytochrome P450 genes and the biological function for most of these is unknown. Previous studies have implicated the over-expression of some cytochrome P450 genes in insecticide resistance via metabolic degradation. Using degenerate PCR and cDNA library sequencing, we have cloned and characterised a number cytochrome P450 genes from the Australian sheep blowfly (*Lucilia cuprina*) and the cotton bollworm (*Helicoverpa armigera*), two insect pests of Australia. We have generated a micro-array of these cytochrome P450 genes, and are characterising the expression of these genes at different life cycle stages and in different tissues. We are also using - micro-array and realtime quantitative PCR to compare the expression levels of cytochrome P450 genes between resistant and susceptible strains. Our studies in *L. cuprina* and *H. armigera* are complemented by studies in *osophila melanogaster*. Using a micro-array containing all 90 *D. melanogaster* cytochrome P450 genes, we are studying gene induction by insecticides. We are over-expressing induced cytochrome P450 genes, and determining if over-expression can confer insecticide resistance.

Novel genetic basis of field-evolved insect resistance to Bt toxins

SW Baxter, JZ Zhao, LJ Gahan, AM Shelton, BE Tabashnik, DG Heckel
CESAR, Department of Genetics, University of Melbourne, Parkville, Victoria 3010, Australia.
s.baxter3@pgrad.unimelb.edu.au

Insecticidal toxins from *Bacillus thuringiensis* (Bt) are widely used in sprays and transgenic plants to control insects that attack crops and transmit diseases, but evolution of pest resistance threatens their continued efficacy. Diamondback moth (*Plutella xylostella*) is the only pest that has evolved Bt resistance in open field populations, although several others have been selected for resistance in the laboratory or glasshouses. The most common type of resistance (Mode 1) is characterized by recessive inheritance, >500-fold resistance to at least one Cry1A toxin, and negligible cross-resistance to Cry1C. The primary mechanism of Mode 1 resistance is reduced binding of Bt toxins to midgut membrane target sites. Mutations affecting a Cry1A-binding midgut cadherin protein are tightly linked to laboratory-selected Mode 1 resistance in two major pests, *Heliothis virescens* and *Pectinophora gossypiella*. The cadherin gene has thus been considered the prime target for DNA-based screening for resistance. Here we show that field-evolved Mode 1 resistance in diamondback moth has a different genetic basis, indicating that screening for resistance in the field should not be restricted to searching for cadherin mutations.

Managing pest resistance to Bt crops in India

JS Bentur, GT Gujar

Directorate of Rice Research, Hyderabad 500 030, AP India, jbentur@yahoo.comand Division of Entomology, Indian Agricultural Research Institute, New Delhi 110012, India, gtgujar@yahoo.com

Bt transgenic cotton first introduced in India in 2001 was cultivated on over 100,000 hactares in 2003. Besides, other Bt transgenic crops such as rice, egg plant, cole crops, pulses are in various stages of development. The target pest for Bt cotton is the American bollworm, *Helicoverpa armigera* and for Bt rice it is yellow stem borer (YSB), *Scirpophaga incertulas*. Based on the baseline toxicity data against the former in India and estimation of frequency of resistance alleles in the populations of YSB in the Philippines, it appears that these two species can rapidly buildup resistance against the Bt endotoxins. Bt resistance management for transgenic cotton is made mandatory requirement for the growers who have to maintain 20% refuge crop or minimum of 5 rows around the Bt cotton field, whichever is larger. However, in view of inadequate knowledge and expertise among the farmers, small land holdings and apprehension of expected reduction in yield due to non Bt lines, farmers tend to ignore the refuge cultivation. Studies on the baseline susceptibility of the American bollworm to Cry1Ac have helped in the monitoring of resistance in the Bt cotton. Similar studies are being done in other crops too. We feel, Bt resistance management should include detailed studies on various characteristics of Bt resistance in local pest populations of the target pests, and explore possibilities of field level management in tandem with the local agronomic practices and environmental conditions.

Bt maize effects on butterflies.

MR Berenbaum
Dept. Entomology, 320 Morrill Hall, University of Illinois, 505 S. Goodwin, Urbana IL 61801-3795, USA, maybe@uiuc.edu

Transgenic plants have been widely adopted by U.S. farmers despite concerns about potential nontarget impacts of this technology. The possibility that maize (*Zea mays*) genetically engineered to express *Bacillus thuringiensis* endotoxoin for control of European corn borers (*Ostrinia nubilalis*) may have impacts on non-target lepidopterans through pollen drift onto neighboring non-agricultural plants has received considerable attention. Since initial concerns about Bt corn were raised by a laboratory study, additional studies both in the field and the laboratory have revealed the remarkable complexities of accurately assessing risks of pest management practices in agroecosystems. These studies are examined in the context of ecological, economic, social, and cultural factors that affect food production and pest management in the United States.

The relative fitness of Bt resistant and susceptible *Helicoverpa armigera* – implications for the refuge strategy

LJ Bird, RJ Akhurst
CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia. lisabird@csiro.au

Transgenic crops producing the Cry1Ac toxin of *Bacillus thuringensis* (Bt) was introduced in Australia, China and India primarily for the control of *Helicoverpa* spp. As *Helicoverpa armigera* has a demonstrated capacity for developing resistance to many synthetic insecticides, development of resistance to Bt toxins remains the biggest threat to the sustainability of transgenic technology. The refuge strategy has been widely adopted to counter the onset of resistance. This strategy is most effective when resistance is conferred by rare, recessive alleles and when mating of heterozygotes in prevented. Under these conditions, the evolution of resistance can be substantially delayed. However, we have found evidence that two of these conditions are not always met. Results from glasshouse experiments have demonstrated that, although resistance in *H. armigera* is functionally recessive on young Cry1Ac cotton, attenuation in toxin expression results in survival of heterozygous genotypes on late season Cry1Ac cotton. Our resistant strain of *H. armigera* takes longer to develop on cotton that expresses high levels of Cry1Ac than their susceptible counterparts on non-Bt cotton. However, loss of potency in older cotton plants mitigates asynchrony in late season insect populations. The implications of these findings for resistance management of Bt crops will be discussed.

Novel approaches for controlling mosquitoes using natural inhibitors for trypsin modulating oostatic factor

D Borovsky
University of Florida, IFAS, FMEL, 200 9th St SE, Vero Beach Florida 32962, USA, dobo@mail.ifas.ufl.edu

Trypsin Modulating Oostatic Factor (TMOF) is a mosquito decapeptide that modulates trypsin biosynthesis in mosquitoes, flies and *Heliothis virescens*. Feeding the hormone and its analogues to mosquito and *H. virescens* larvae stopped trypsin biosynthesis in their midgut by binding a specific gut receptor and controlling the translation of the trypsin message. Cytoimmunochemical analyses show that the hormone is not only synthesized in the ovary as was initially hypothesized, but is also found in the central nervous system cells of adults and larvae. Since the hormone affects the growth and development of mosquito larvae the hormone and several analogues have been cloned and expressed in chlorella, yeast (*Saccharomyces cerevisiae* and *Pichia pastoris*) and Alfalfa cells to control insects using biorational insecticides. These results and the effect of the transformed cells on larval growth and development will be discussed.

Fluorometric PCR applications to insecticide resistance analysis in disease vectors.

WG Brogdon, AE Lenhart, G Groner, RA Wirtz
Entomology Branch F42, DPD, NCID, Centers for Disease Control and Prevention, 4770 Buford Highway NE, Atlanta, Georgia 30341, USA wgb1@cdc.gov

As insect genomes are published, molecular techniques have begun to be widely applied for the detection and assessment of insecticide resistance. Vectors develop insecticide resistance through mutations of insecticide target sites, such as the voltage-gated sodium channel, and increased activity of detoxification enzymes such as oxidases and esterases. The ability to use preserved or desiccated field-collected insects makes molecular analysis of insecticide resistance an especially attractive option. A useful approach to measuring all of these mechanisms is fluorometric PCR. This method allows detection of resistance mechanisms based on point mutations at the insecticide target site, resistance gene amplification, or increased expression of resistance genes. Knowledge of resistance gene sequence is a prerequisite in the development of these methods. Our efforts to apply quantitative PCR to detection, measurement and assessment of insecticide resistance in an assortment of disease vectors are summarized. The same molecular methods that serve to detect resistance are also central to the determination of population genetic relationships of the resistance alleles. We discuss our present state of knowledge of molecular markers and insect genomes as they relate to insecticide resistance.

Tri-trophic prey-mediated impacts of insect-resistant tobacco on a predatory carabid beetle

EPJ Burgess, BA Philip, LA Malone, JT Christeller
HortResearch, Private Bag 92169, Auckland, New Zealand, eburgess@hortresearch.co.nz

Larvae and adults of a New Zealand endemic predatory beetle, *Ctenognathus novaezelandiae*, were fed an exclusive diet of prey (*Spodoptera litura*) reared on control tobacco, or transgenic tobacco expressing either a protease inhibitor (PI) or a biotin-binding protein (BBP). BBP prey-fed beetle larvae accumulated greater mass than the other 2 treatments over a 7-week period in the middle of the 14-week experiment. Over the entire experiment, the mean biomass of BBP-fed larvae was greater than that of PI- but not control-fed larvae. There were no differences among treatments in larval survival or quantity of prey consumed. Adult female beetles grew larger and survived longer than males in all 3 treatments. Combined gender adult mean biomass over 40 weeks was the same for all 3 treatments. However, control-fed females had greater total biomass than PI or BBP-fed females, but control-fed males had less biomass than males given the other treatments. Over the entire experiment, BBP-fed adults consumed slightly less than the other 2 treatments. Fecundity was low in all 3 treatments and there were no differences among them. The greatest adult differences detected were between genders rather than among treatments, where analysis of data collected weekly showed only minor and transient effects.

Analysis of acetylcholinesterase insensitivity in California insect pests

F J Byrne, NC Toscano
Dept of Entomology, University of California, Riverside, CA92521, U.S.A., frank.byrne@ucr.edu

Acetylcholinesterases are important members of the serine hydrolase super-family of enzymes and are the targets of the organophosphate (OP) and carbamate insecticides. Although the future use of these insecticides in California is somewhat uncertain, due to the FQPA, they are still widely used in agriculture, both as stand-alone insecticides, and as synergists of the pyrethroid insecticides. As a consequence of their widespread and varied usage, OP and carbamate resistance has been identified in many important pests. Acetylcholinesterase insensitivity is an important mechanism of resistance to these insecticides, and cross-resistance within these chemical groups is not uncommon. We have conducted extensive studies on resistance in several important California insect pests. In this presentation, we will describe our studies on two pests – the beet armyworm (BAW), *Spodoptera exigua*, and the glassy-winged sharpshooter (GWSS), *Homalodisca coagulata*. The BAW has been long-established in California agriculture, whereas the GWSS is a recent introduction. These two pests differ in their pesticide exposure histories and this seems to be a contributing factor in their relative susceptibilities to OPs and carbamates. The effectiveness of OPs and carbamates for the management of these pests is discussed based on our toxicological and biochemical studies.

Activity profiles of neonicotinoid insecticides in plants and implications for IPM

SJ Castle, FJ Byrne, NC Toscano, JL Bi, N Prabhaker, JC Palumbo
USDA-ARS, 4135 E. Broadway Road, PHOENIX, AZ 85040, USA, scastle@wcrl.ars.usda.gov

The duration that an insecticide residue is active in a crop in terms of lethal and sub-lethal effects on insect populations is a critical concept in pest management that has been poorly developed. Application rates, the timing and spacing of applications, and the choice of materials could all be influenced by more reliable information on the activity period of insecticides in crops. Commercial ELISA kits were used to determine concentrations of imidacloprid and thiamethoxam in citrus, grapes, and melons at regular intervals following soil treatment. The uptake and residual profiles differed significantly for both compounds in all crops. Peak concentrations of imidacloprid in xylem fluid of large citrus trees were not attained until 6-8 weeks after application compared to 2 weeks for thiamethoxam. However, near-peak levels of imidacloprid were sustained for 6-10 weeks before declining gradually in contrast to thiamethoxam titres (applied at ¼ the rate of imidacloprid) that declined rapidly. The same pattern of higher application rates and longer residual of imidacloprid was also observed in melons. Comparison of young vs. old leaves on primary branches of melon vines revealed much higher concentrations in older leaves, a counterintuitive finding because better whitefly control is attained on younger leaves.

Contamination of refuges by Bt toxin genes from transgenic corn

CF Chilcutt, BE Tabashnik.
Department of Entomology, Texas A&M University System, 10345 Agnes St., Corpus Christi, TX, 78406, USA, c-chilcutt@tamu.edu

Transgenic crops producing insecticidal toxins from *Bacillus thuringiensis* (Bt) are widely used to control pests, but their benefits will be lost if pests evolve resistance. The mandated high-dose/refuge strategy for delaying pest resistance requires planting refuges of toxin-free crops near Bt crops to promote survival of susceptible pests. We report that pollen-mediated gene flow up to 31 m from Bt maize caused low to moderate Bt toxin levels in kernels of non-Bt maize refuge plants. Immunoassays of non-Bt maize sampled from the field showed that the mean concentration of Bt toxin Cry1Ab in kernels and the percentage of kernels with Cry1Ab decreased with distance from Bt maize. The highest mean Bt toxin concentration in kernels of non-Bt maize plants was 45% of the mean concentration in kernels from adjacent Bt plants. Most previous work on gene flow from transgenic crops has emphasized potential effects of transgene movement on wild relatives of crops, lanaces, and organic plantings, while implications for pest resistance have been largely ignored. Variable Bt toxin production in seeds of refuge plants undermines the high-dose/refuge strategy and could accelerate pest resistance to Bt crops. Thus, guidelines should be revised to reduce gene flow between Bt crops and refuges.

Insect comparative genomics: a carboxyl/cholinesterase perspective

C Claudianos, RJ Russell, R Feyereisen, H Ranson, R Maleszka, JG Oakeshott
Research School of Biological Sciences, Australian National University, ACT, 0200, Australia, claudianos@rsbs.anu.edu.au

Our comparative genome analyses of principle enzyme families involved in metabolic resistance to insecticides have generated new research opportunities. The data provide a credible basis for identifying the resistance-associated enzymes of insects and the means for identifying previously unknown molecules involved in fundamental biological process such as development. Carboxyl/cholinesterase enzymes have contributed to a major part of insect biochemical and genetic research. The most notable member of this supergene family, acetylcholinesterase (AChE), is the key processing enzyme for the neurotransmitter acetylcholine. Many other esterases have now been implicated in the metabolism of specific hormones and pheromones and accordingly in various aspects of insect development and behaviour. Intriguingly, the carboxyl/cholinesterase family provides a striking example how gene duplication/radiation/deletion shape the evolution of novel biology, notably how the function of a catalytically active domain has evolved to mediate receptor-ligand interactions that regulate morphogenetic process during development of the nervous system. We have recently classified carboxyl/cholinesterases into three principle functional groups (intracellular enzymes associated to dietary detoxification; secreted enzymes including those that process pheromones and hormones; receptors and enzymes involved in neuro/developmental functions). Our data (gene inventories) are also providing a template for new studies concerning the honeybee and silkworm genomes.

Characterization of CTCF proteins in mosquitoes

CE Gray, CJ Coates
Texas A&M University, MS 2475, College Station, TX 77843-2475, USA; c-coates@tamu.edu

CTCF (CTCCC-binding factor) is a multivalent, multifunctional transcription factor well characterized in vertebrates. Of particular interest is its association with every known vertebrate insulator and its emerging role in epigenetic regulation. Endogenous mosquito insulators would be valuable elements to flank transgene insertions, inhibiting both position effect and position effect variegation, thus allowing for more consistent gene expression. CTCF-like cDNAs were cloned, expressed and characterized from the medically important mosquitoes *Aedes aegypti* and *Anopheles gambiae.* The gene is transcribed constitutively in all developmental stages and appears to be up-regulated both in the ovaries from blood-fed females and in early embryos. Putative binding sites for the *An. gambiae* protein were determined *in-vitro* using PCR-assisted binding site selection and confirmed in gel-shift assays. ChIP (chromatin immunoprecipitation) assays are currently in progress. Additionally, an RNAi experiment to knockdown expression both in *An. gambiae* adult females and in *osophila melanogaster* females and early embryos, followed by RNA isolation and hybridization to microarray chips is being performed to identify specific CTCF targets. The results of these experiments will be presented.

Esterase mediated cross resistance between pyriproxyfen and buprofezin in B-biotype *Bemisia tabaci* in Australia

ELA Cottage, RV Gunning
NSW Agriculture, Tamworth Agricultural Institute, Tamworth, NSW, 2340, Australia. Emma.Cottage@agric.nsw.gov.au

B-biotype *Bemisia tabaci* was first detected in Australia in 1994. B-biotype *B. tabaci* is a severe pest worldwide and poses a serious threat to many ornamental, agricultural and horticultural industries in Australia. Control of B-biotype *B. tabaci* is hampered by resistance to many conventional insecticides. Consequently, insect growth regulators such as buprofezin and pyriproxyfen are important insecticides in managing this pest. Field resistance has been detected to both insecticides with cross resistance between the two as well. Studies have shown resistance to buprofezin in B-biotype *B. tabaci* to be esterase mediated and experiments were designed to investigate the potential of pyriproxyfen to bind to *B. tabaci* esterases. Esterase inhibition experiments showed inhibition by pyriproxyfen was greater in the buprofezin resistant strain than in its unselected counterpart. Concentrations as low as 0.321nM pyriproxyfen gave 70-80% inhibition of resistant *B. tabaci* esterases. Cross resistance between IGRs with different modes of action poses a grave threat to the viability of the management strategy of silverleaf whitefly in Australia.

Efficacy of novaluron for Colorado potato beetle control and potential for resistance development.

GC Cutler, JH Tolman, CD Scott-Dupree, CR Harris
Department of Environmental Biology, University of Guelph, Guelph, ON, N1G 2W1, Canada; cutler@uoguelph.ca

Novaluron (RimonÒ 10EC), a novel insect growth regulator, could play a key role in development of practical integrated pest management (IPM) programs for Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say). In laboratory tests, novaluron exhibited potent insecticidal activity against CPB larvae (e.g. 2nd instar (L2) LC_{50} = 0.42 ppm). Furthermore, the insecticidal activity of a single novaluron application was highly persistent under field conditions. In bioassay, 65-85% of L2 from an insecticide-susceptible laboratory strain died when fed potato foliage treated with novaluron at 25 and 50 g a.i./ha, respectively, 28 days after application. Thus, the selection pressure for novaluron-resistant CPB may be intense long after population densities have been reduced below an economic threshold level. Studies were also conducted to identify geographic variability and potentially problematic CPB populations before the widespread use of novaluron in the field. The susceptibility of L2 to novaluron was determined for 27 different populations collected from 6 Canadian provinces in summer of 2003. Despite no previous exposure to novaluron, the populations differed considerably in susceptibility with mortalities at a diagnostic dose ranging from 55-100%. Our results suggest that despite the potential of novaluron in CPB management, the possibility of rapid development of resistance exists.

Bemisia tabaci, **biotypes and insecticide resistance management.**

GJ Devine, M Hadjistylli, D Ma, K Gorman, I Denholm
Plant and Invertebrate Ecology Division, Rothamsted Research, England.

Many insect species exist as a complex of biotypes that can be differentiated by a variety of genotypic or phenotypic parameters. Some of these are of ound importance in pest management. For example some biotypes of the cotton whitefly (*Bemisia tabaci*) appear to be associated with different ecological, behavioural and insecticide-resistant characteristics. The processes that mediate the balance and evolution of such co-existing forms are neither well-described nor understood. It is clear however, that in some instances, the evolution of biotypes among pest species is influenced by the tools used for their control (e.g insecticides). In an effort to understand the factors that influence the dynamics of co-existing biotypes and how these impact upon the implementation of management strategies and the dynamics of insecticide resistance, we examine Mediterranean populations of *Bemisia tabaci*. We present work that characterises insecticide resistance in recently collected strains of 'B' and 'Q' biotypes, and examine the ability of these forms to introgress (by observing courtship behaviour, mating success, hybrid sex ratio and hybrid fecundity). We examine the consequences of such introgression for the inheritance of insecticide resistance.

Hydolysis of organophosphorus and pyrethroid insecticides by insect carboxylesterases modified by *in vitro* mutagenesis

AL Devonshire, RHeidari, BE Campbell, JG Oakeshott, RJ Russell
CSIRO Entomology, GPO Box 1700, Canberra, ACT, 2601, Australia

Resistance of *Lucilia cuprina* to Ops is due to mutations in the gene encoding carboxylesterase E3 that enhance its ability to hydrolyse insecticides. Mutagenesis *in vitro* and expression of these modifications (G137D and W251L) have confirmed their role. These and nearby amino acids were substituted by others expected to affect the efficiency of the enzymes in hydolysing OPs and pyrethroids. Various substitutions of W251 had a broadly similar effect to W251L on OP hydolysis, but some enhanced malathion carboxylesterase. With the exception of F309L, nearby mutations generally diminished OP hydolysis. W251L was the most effective substitution to improve permethrin hydolysis (up to 130-fold) whilst decreasing the trans:cis hydolysis ratio to favour the more insecticidal isomer Other mutations around the catalytic site generally enhanced pyrethroid hydolysis relative to the wild type, the most effective being F309L, which enhanced transpermethrin hydolysis more than W251L. Complementary assays with individual enantiomers of the dibromo analogue of cispermethrin showed the wild type and most mutants to have a marked preference for the least insecticidal 1S conformation of the cyclopropanecarboxylate, but this was reversed in mutants with the F309L substitution. The results show the potential to design such recombinant enzymes for bioremediation of insecticide residues.

Enhancing biodiversity in sugar beet through appropriate management of GMHT crops

AM Dewar

Broom's Barn Research Station, Higham, Bury St. Edmunds, Suffolk, IP28 6NP, UK, alan.dewar@bbsrc.ac.uk

The UK Farm Scale Evaluations of the environmental impact of genetically modified herbicide-tolerant (GMHT) crops reported that the biodiversity of wildlife in GMHT beet was adversely affected compared to that in the conventional crops. This was attributed to better control of weeds by glyphosate, to which the GM beet was tolerant, with knock-on consequences for the invertebrates that depended on those weeds for survival. In other separate studies on sugar beet, alternative glyphosate programmes, involving band sprays and/or delayed sprays (compared to the aft label recommendations) resulted in much weedier plots than under conventional regimes at different times in the season, with consequent benefits for some invertebrates. In many cases this was achieved with no loss of yield compared to conventional systems. Another regime that relied on one early spray of glyphosate resulted in greater numbers of late germinating weeds than in conventional sytems, and consequently greater seed production by those weeds for the benefit of seed-eating beetles and autumn-feeding birds. GMHT technology with regard to beet is so flexible that almost any scenario can be created and still allow farmers to grow a itable crop.

Ecdysteroid agonist insecticides – mechanism, selectivity and importance in IPM

TS Dhadialla
Dow AgroSciences LLC, 9330 Zionsville Road, Indianapolis, IN 46268, USA, tdhadialla@dow.com

Non-steroidal ecdysone agonists belonging to the bisacylhydrazine class of compounds are a new generation of insecticidal compounds that cause premature lethal molts in susceptible intoxicated insects. Of these, three bisacylhydrazine compounds, tebufenozide (MIMIC®, CONFIRM®, ROMDAN®), methoxyfenozide (INTREPID®, RUNNER®, PRODIGY®, FALCON®) and halofenozide (MACH 2®) have been commercialized. Both tebufenozide and methoxyfenozide are predominantly toxic to lepidopteran pests of cotton, corn and other agronomic plants. Halofenozide, a soil insecticide, is toxic to both lepidopteran and coleopteran pests. All three insecticidal compounds manifest their toxic action in susceptible insects via interaction with the ecdysone receptor, which is also the target of the insect molting hormone, 20-hydoxyecdysone. This selective toxicity of both tebufenozide and methoxyfenozide to lepidopteran pests is largely due to their high binding affinity to EcRs from those insects. The toxic action of halofenozide, which is a weak binder of EcR, is primarily due to its relatively higher metabolic stability in susceptible insects. The mode of action of the three insecticides at the whole insect, ultra-structural and biochemical levels will be discussed and data shown to demonstrate their safety to beneficial insects, mammals and the environment. The use of these insecticides in IPM and IRM programs will be emphasized.

Prodigy™ - a new IPM-compatible product for insect control in Australian crops

PR Downard, *RA Annetts*
Dow AgroSciences Australia Ltd Locked Bag 502, French's Forest NSW 1640 Australia, downard@dow.com.

Methoxyfenozide (formulated as Prodigy™ 240 SC and previously coded as RH 2485), is a moult-accelerating compound (or MAC), from the same chemical family as tebufenozide (Mimic™ 700 WP), a product which has been in the Australian market for many years. Methoxyfenozide is generally active at lower rates and has a wider spectrum of activity than tebufenozide, even though activity of both is strictly limited to the Order Lepidoptera. This selectivity makes methoxyfenozide an ideal candidate for use in integrated pest management (IPM) programmes as it has no direct effect on non-lepidopteran predators and parasitoids. As the only MAC compound used in Australia against helicoverpa, with no documented field resistance methoxyfenozide is a valuable new tool for inclusion in helicoverpa resistance management strategies. It's introduction reduces selection pressure on older products and further delays the onset of resistance. Development to date has focused on helicoverpa control in cotton and tomatoes, but methoxyfenozide does have several exciting possibilities. Globally, methoxyfenozide is already recognized as having excellent activity against *Spodoptera* spp. and may prove to be a cost-effective alternative for control of armyworms in a range of Australian crops (e.g. pastures, sugarcane, cereals and turf).

Gene resources for insecticide discovery

P East, M Dumancic, C Liao, S Trowell
CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia. Peter.East@csiro.au

The majority of insecticides and nematicides in current use act on only a small number of target receptors. Drawing on the resource provided by complete genome sequences, we have sought to identify and validate novel targets for nematicides and insecticides. The excitatory glutamate receptors involved in signalling at the insect neuromuscular junction are an attractive, but poorly understood candidate target. We have identified new members of this gene family from whitefly *Bemisia tabaci* and the bollworm *Helicoverpa armigera*. The availability of these gene sequences provided new insight into the diversity of excitatory glutamate receptor sub-types in insects. Pharmacological and molecular genetic approaches were used to identify novel serotonergic (5-HT$_3$) receptors regulating pharyngeal pumping in the free living nematode *Caenorhabditis elegans*. Lead compounds were assessed for their toxicity to *C. elegans*, *Myzus persicae*, *H. armigera* and *Heligosigmoides polygyrus*. A number of *C. elegans* cDNA sequences, one or more of which are believed to encode subunit(s) of the nematode's pharyngeal 5-HT$_3$ receptor were isolated. Preliminary gene knockdown data indicates that one of the cloned receptor subunits is vital for the proper development and normal pumping of the pharynx. Our data provide the first evidence for the existence of excitatory, 5-HT$_3$-like, receptors in nematodes and the first indication that receptors of this type are valid targets for pesticides.

Molecular mechanisms of phosphine toxicity and the genetics of resistance

PR Ebert, Q Cheng, N Valmas, SJ Zuryn, U Cha'on, DI Schlipalius, PJ Collins, Y Mau, W Chen, A Whan, YH Huang, HS Chiu

Department of Zoology and Entomology, University of Queensland, St Lucia, QLD 4072, Australia, p.ebert@uq.edu.au

Phosphine (PH_3) is the only globally significant fumigant available to protect stored grain from insect infestation. Phosphine is a somewhat hydophobic reducing compound that can complex with biologically significant metal ions, partially disrupt mitochondrial function and induce cytotoxic levels of oxidative stress. Despite a complex array of potential modes of action, strong resistance (600X) to this compound in the pest insect, *Rhyzopertha dominica*, is achieved with resistance alleles at only two loci, neither of which negatively affects fitness. Phosphine resistant mutants generated in the model organism, *C. elegans*, have an unusually long lifespan. One of these mutants is completely resistant to the toxic effect of hyperoxia in conjunction with an otherwise sublethal exposure to phosphine. Mutant and wild type nematodes exhibit no differences in terms of phosphine induced changes to either mitochondrial morphology or ATP levels. The mutant, however, appears to be protected from phosphine induced oxidative damage to lipids. Surprisingly, genome-wide microarray analysis in *C. elegans* does not implicate mitochondrial dysfunction or oxidative stress as the primary causes of phosphine toxicity. Rather, the stress response appears to mimic the expression profiles associated with the lifespan extension mutant, *daf-2*, as well as the unfolded protein response induced by denatured proteins.

Pyrethroid insecticide resistance and treated bednets efficacy in malaria control

AA Enayati, J Hemingway
School of Public Health, Mazandaran University of Medical Sciences, Sari, Iran. Ahmadali_enayati@yahoo.com or muaae@mazums.ac.ir

Metabolic and k resistance mechanisms were characterized in An. stephensi and this easily colonized species was used to evaluate the efficacy of ITNs. Bioassays performed on 4th instar larvae showed a resistance ratio of 182. The resistance was partially suppressed by PBO (54%) and DEF (51%) or both (68%). Biochemical assays revealed that esterases, monooxigenases and glutathione S-transferase levels were 1.72, 1.86 and 1.88-fold respectively in the DUB-S compared to the susceptible strain Beech. The overall permethrin metabolism rates by DUB-S mosquitoes measured by HPLC were 1.5-fold more than by Beech strain. The classic k mutation was detected in II6 of the para-type sodium channel gene from DUB-S strain. Bioassays performed on the resistant DUB-S mosquitoes using different pyrethroid-treated bednets showed that except for deltamethrin and a-cypermethrin treated bednets, the rest of the tested pyrethroid-treated bednets at standard WHO recommended doses did not produce adequate mortality rates. The deterrency test performed on susceptible and resistant An. stephensi showed that there are significant differences between the entry rates of susceptible and resistant mosquitoes into the exposure tube containing permethrin treated bednet. These data show that when mosquitoes have both k-type and metabolic resistance mechanisms, the efficacy of pyrethroid-treated bednets is questionable.

Update on the honey bee genome project

JD Evans and the Honey bee Genome Sequencing Consortium
USDA-ARS Bee Research Lab, Beltsville, MD USA 20705, evansj@ba.ars.usda.gov

Along with their longstanding importance for agriculture, honey bees (*Apis mellifera*) have been important models for behavior, physiology, ecology, and genetics. They play a considerable role in evolutionary comparisons across insects and in attempts to understand the forces that lead to, maintain, and challenge insect societies. A aft sequence for the honey bee genome was funded in 2002 by the U.S. National Institutes of Health, and Department of Agriculture, following a 'white paper' competition to identify compelling eukaryotic sequencing targets. The project began that year at the Baylor College of Medicine Human Genome Sequencing Center (www.hgsc.bcm.tmc.edu), with input from individual scientists and the Sanger/Wellcome Trust. The current assembly (version 1.1, January 2004) reflects 1.25 Gbp of mainly short-insert (shotgun) sequences, giving an estimated 6.0-fold coverage of the 210 Mbp genome. The assembly is comprised of 11,600 scaffolds (N_{50} = 223 kbp) containing 30,074 contigs (N_{50} = 19 kbp). Approximately 95% of known EST's, cDNA's and markers are in this assembly. Current plans are to incorporate reads from an AT-biased library and an existing BAC library and to generate cDNA's useful for gene calling. An updated assembly and an initial gene list are anticipated by the time of this meeting.

EST analysis of genes expressed in the different tissues of the spruce budworm, *Choristoneura fumiferana*

QL Feng, T Ladd, SC. Zheng, L Li, D Buhlers, PJ Krell, BM Arif, A Retnakaran
Great Lakes Forestry Centre, Canadian Forest Service, 1219 Queen Street East, Sault Ste. Marie, Ontario, Canada P6A 2E5. qfeng@nrcan.gc.ca

More than 35,000 sequence reads have been generated from five cDNA libraries of the epidermis, midgut, fat body, whole larvae and cell line of the spruce budworm, *Choristoneura fumiferana*. These expressed sequence tags (ESTs) have been assembled into approximately 8000 unigenes using Phrap program. Annotation of these sequences has been conducted against the protein database Swiss-Prot/TrEMBL and the GenBank of NCBI. The unique sequences have been classified for their molecular function, cellular location, and biological process using the Gene Ontology classification system. A spruce budworm EST database has been established and is available to the scientific community. These annotated EST sequences will serve as a resource base for gene mining, comparative analysis and genome mapping. The ESTs have also being used for developing cDNA microarrays, which will be used to study the global gene expression in the spruce budworm in response to different stresses. This project is supported by funds of Genome Canada and Canadian Biotechnology Strategy.

Implementation and impact of transgenic Bt cottons in Australia

GP Fitt
CSIRO Entomology and Australian Cotton Cooperative Research Centre, Long Pocket Laboratories, 120 Meiers Rd, Indooroopilly, Queensland, 4068, Australia. Gary.Fitt@csiro.au

Bt cottons (INGARD®) expressing the CryIAc endotoxin, were commercialised in Australia in 1996/97 through an industry agreed deployment strategy which limits use to 30% of total cotton. A comprehensive management strategy minimises the risk of Bt resistance in *Helicoverpa armigera*, the target pest. In 6 years of commercial use Bt cottons have reduced pesticide applications for *Helicoverpa* by an average of 50%, providing major environmental benefits. Fibre quality has not been affected, while in some cases yields have increased. Despite early difficulties with variable performance, growers have rapidly adopted the technology and will gain long-term benefits through enhanced environmental sustainability, as Bt cotton is used in environmentally sensitive areas. Perhaps more importantly Bt cottons show great potential for IPM systems where a combination of soft approaches yields considerable benefits. That single gene Bt cotton has not been a "magic bullet" is fortunate in demonstrating that Bt cottons need to be introduced within an IPM system and supported by rigorous resistance management strategies. Two-gene Bt cottons expressing Cry 1Ac and Cry 2Ab (Bollgard II) have now been commercialised and will replace INGARD® in 2004/5. BGII provides enhanced efficacy and further reductions in pesticide requirement with associated environmental benefits. BGII also bring reduced resistance risk, but will remain part of a conservative resistance management strategy similar to that for INGARD varieties.

Pleiotropic effects of insecticide resistance genes in an aphid pest on vulnerability to attack by parasitoid wasps

SP Foster, I Denholm, W Powell
Plant and Invertebrate Ecology Division, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, UK. stephen.foster@bbsrc.ac.uk

Studying the phenomenon of insecticide resistance provides a rare and valuable insight into the fundamental processes underlying evolution as resistance often appears over short timescales in human terms. In effect, this process represents a classic case of 'forced evolution' and as a result can produce resistance mechanisms that have negative pleiotropic effects on fitness in the absence of insecticides. The paper describes experiments done at different spatial scales measuring the vulnerability of insecticide-susceptible and –resistant peach-potato aphids (*Myzus persicae*) to attack by the parasitoid, *Diaeretiella rapae*. It also discusses the potential impact of the findings on Integrated Pest Management strategies utilising beneficial insects.

Insect AChE

D Fournier
IPBS 205 route de Narbonne 31077 Toulouse, France, fournier@ipbs.fr

Two genes encode acetylcholinestesterase (AChE) in insects, but only one seems to be expressed in the synapse of the central nervous system. Protein is a dimer anchored to the presynaptic memebrane via a glycolipid. Structure has been solved for the *Drosophila* enzyme, the active site is buried 20 Å inside the protein, at the bottom of a narrow gorge. This structure results to complex kinetics resulting from the traffic of substrate and products in the active site gorge. Another consequence of this structure is the sensitivity to insecticide: insect AChE is more sensitive to insecticide than its vertebrate counterpart. This property has been used to design biosensors to detect insecticide residues and the enzyme has been engineered to improve its capacity of detection. Extensive use of insecticides resulted in insecticide resistance. Several mutations have been evidenced. They often combined in the same site resulting in an enzyme more resistant and with a broader spectrum of resistance. Mutations affected enzyme efficiency : they decrease or increase the limitating step of substrate hydolysis, deacetylation and decreases enzyme stability. This alteration of enzyme has been compensated in most of strains by an overproduction of the enzyme.

First season of methoprene application mirroring Fire Ant Control Centre treatment program has not had any prompt deleterious effects on the native soil invertebrate assemblage.

TN Fuessel, KP Plowman, CH Wild,
School of Environmental and Applied Science, Griffith University Gold Coast Campus, PMB 50 Gold Coast Mail Centre , Queensland 9726.
t.fuessel@griffith.edu.au

In response to the accidental introduction of the invasive ant *Solenopsis invicta* (Buren) to Brisbane, Australia, an eradication program was mounted. This program employs a range of chemicals including the insect growth regulators methoprene and pyriproxifen, which though specific to invertebrates and intended solely for *S. invicta*, may have deleterious effects on other invertebrates. The impact of Methoprene on soil invertebrates and nutrient cycling is being evaluated using a control-impact study conducted in eucalyptus woodlands where *S. invicta* is absent. Methoprene is applied to treatment sites following Fire Ant Control Centre procedure, with 3 applications of 2 kg/ha each treatment season (November to April). Soil samples are collected: before treatment; and one month after each subsequent treatment over two treatment seasons (Nov 2002-May 2004). Soil invertebrates are extracted and sorted to morphospecies to form a community dataset for each site. Due to their numerical dominance, and also importance for processes such as decomposition and nutrient cycling, only the mite component of the invertebrate community will be reported here. Results at the completion of the first treatment season indicate that the application of Methoprene is not associated with a decrease in any of the diversity parameters. Community data are also analysed using ordination techniques to investigate whether the actual species composition is influenced by methoprene application.

Large-insert BAC libraries for fundamental studies in Lepidoptera

MR Goldsmith, C Wu, HB Zhang

Biological Sciences Department, University of Rhode Island, Kingston, RI 02881-0816, mki101@uri.edu and Department of Soil and Crop Sciences and Institute for Plant Genomics and Biotechnology, Texas A&M University, College Station, Texas 77843-2123, USA

The tobacco hornworm, *Manduca sexta*, the tobacco budworm. *Heliothis virescens*, and the Müllerian mimic, *Heliconius erato*, are well-established lepidopteran models for studying fundamental problems in olfaction, neurobiology, and development (*M. sexta*), evolution of insecticide resistance and plant host specialization (*H. virescens*), and wing pattern mimicry (*H. erato*). We have constructed two separate BAC libraries for each species using *Bam* HI and *Eco* RI partial digestion. Average insert sizes of *Bam* HI and *Eco* RI libraries are 152 kb and 165 kb for *M. sexta*, 171 kb and 150 kb for *H. virescens*, and 175 kb and 153 kb for *H. erato*, with <5% non-recombinant clones. Genome coverage totals an estimated 12.9x for *M. sexta*, 16.3x for *H. virescens* and 15.4x for *H. erato*. We are screening the libraries with well-conserved single-copy genes to better estimate genome coverage and obtain BAC clones to use as anchor loci for comparative studies. All libraries are publicly available at http://hbz.tamu.edu. We are indebted to L. Riddiford, F. Gould, and O. McMillan for insects, and M. Cornwall and N. Pierce for vouchering specimens. Supported in part by NSF grant no. IBN-0208388 to MRG, HBZ, and CW.

Functional genomics of the midgut of the cotton bollworm, *Helicoverpa armigera*

KHJ Gordon, PD East
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia, karl.gordon@csiro.au

The Lepidopteran insect, *Helicoverpa armigera,* or cotton bollworm, is a major pest of agriculture worldwide. Many control strategies involve orally-transmitted control agents that target the larval midgut. A functional genomics study of this organ has the potential to increase understanding of its molecular and cellular biology and to identify new targets for pest control. We have undertaken an EST project to identify genes important for midgut function, growth and development and gene/enzyme pathways involved in insect-plant and insect-pathogen interactions. Sequence analysis of midgut cDNA libraries now covers ~5,000 ESTs each from young (2nd and early 3rd instar) and from 5th instar larvae. Clustering yielded a unigene set of ~3,900 contigs. Searches against the UniProt (EBI) database and model organism proteomes yielded confident Gene Ontology annotation for ~55% of the contigs. These include genes associated with key midgut functions: digestive hydolases; nutrient and ion transport and pH maintenance; a range of detoxification enzymes and genes forming the peritrophic membrane or involved in midgut cell proliferation, differentiation and adhesion. Many have not previously been identified in lepidopteran systems. Additionally, comparison with silkworm ESTs identified likely orphan lepidopteran genes. Microarrays based on the non-redundant gene set are being established for expression iling studies.

Pesticide resistance in Brazil and IRAC-BR activities: current situation and perspectives

PCRG Marçon, AC Santos, F Orsi, RNC Guedes, C Omoto
IRAC-BR, Caixa Postal 168, Mogi Mirim, SP 13.800-970, Brazil, guedes@ufv.br

Recognition of pesticide resistance problems in Brazil dates of the late 1960s, but it was not followed by further studies until the 1990s, when the interest was renewed due to reports of insect-pest control failures. The establishment of the Brazilian Insecticide Resistance Action Committee (IRAC-BR) in 1997 was a reflex of this concern and provided new impetus to pesticide resistance studies in the country. The major activities of the IRAC-BR have been centered on institutional, research and educational programs. The institutional program is based on the promotion of the Committee and its activities, while the research program establishes priorities and provides support for projects of interest. At present, the research effort is centered in two long-standing projects, *Tuta absoluta* in tomatoes and *Spodoptera frugiperda* in maize/cotton, and several other shorter-term projects. The educational program provides basic training in Insecticide Resistance to a diverse public. Annually, IRAC-BR offers short-courses, workshops, lectures and round-table discussions in different regions of the country. IRAC-BR also sponsors a National Research Award, in two categories, undergraduate and graduate research projects. This award was created to stimulate creativity, positive criticism and human resource formation in Insecticide Resistance Management in Brazil. These initiatives from IRAC-BR have been well received in Brazil and the fruits from this effort are beginning to ripen.

Esterases mediate resistance to biological insecticides in *Helicoverpa armigera*

RV Gunning, ME Balfe, GD Moores
Tamworth Agricultural Institute, RMB 944, Calala Lane, Tamworth, NSW. 2340 Australia, robin.gunning@agric.nsw.gov.au

The cotton bolloworm *Helicoverpa armigera* is a serious pest of cotton and other summer crops in Australia, where it has a long history of insecticide resistance to most insecticides. Particularly critical for Australian agriculture was the evolution of pyrethroid resistance. Pyrethroid resistance which was found to be largely due to overproduction of specific esterase isoenzymes (R_m 0.24 - 0.33), which sequester and hydolyse pyrethroids. Modern pest resistance management strategies have incorporated new biological insecticides with novel modes of action. Such biological insecticides are spinosad and *Bacillus thurlingiensis* toxins and as well insecticidal proteins of B thurlingiensis which have been incorporated into genetically engineered plants. Nonetheless, there is an enduring threat of resistance. *H. armigera* has already developed resistance to spinosad and some CRY toxins and in this paper we report esterase mediated resistance mechanisms.

A microsomal esterase confers insecticide resistance in *Spodoptera littoralis*

O Gurkan, P Jewess, G Moores
Rothamsted Research, Harpenden, Herts UK AL5 2JQ and Ankara University, Faculty of Agriculture, Plant Protection Dept. Ankara, Turkiye.
Oktay.gurkan@bbsrc.ac.uk

Spodoptera littoralis (Lepidoptera: Noctuidae) (Boisduval), the Egyptian cotton leafworm, is a major pest of cotton and vegetable crops in Mediterranean Europe and Africa. A field strain collected from cotton at Adana in Turkey was found to have a resistance factor of 8-fold against chlorpyrifos by leaf dip bioassay. Preliminary studies of AChE sensitivity against chlorpyrifos-oxon indicated no evidence of insensitive AChE. An enhanced microsomal esterase was revealed that correlated with the observed resistance when compared to a susceptible standard strain. We report here on the purification and kinetic parameters of this microsomal esterase.

Transgenic corn and rootworm: ecology, evolution and management.

CA Guse, DW Crowder, DW Onstad
607 E. Peabody Champaign, IL USA 61820, cguse@uiuc.edu, (217) 265-5008

The western corn rootworm in North America depends almost exclusively on corn for larval survival and adult nutrition. Two-year crop rotations were very effective at controlling rootworms since oviposition historically only occurred in corn. In recent years however, crop rotation has failed in the corn-belt east of the Mississippi river. Adults in this region lay eggs in fields other than corn and because of rotation these eggs hatch in corn the following year. The change in the behavior of adult rootworms resulted in the increased use of insecticides and a renewed interest in developing ecologically sound control strategies. We report on a series of modeling efforts that examined how land use lead to the evolution of behavioral changes in adults and how landscape diversity and weather patterns contribute to the dispersal and ultimate distribution of this rotation resistance variant in North America. We then examine a variety of control options combining cultural practices with transgenic crops and other crop technologies to simultaneously manage rotation resistance and the risk of developing resistance to transgenic corn. The results were sensitive to landscape diversity, toxin dose, expression of resistance, initial allele frequency and density-dependent larval survival.

EST-cDNA clones were mapped based on RFLP in the silkworm, *Bombyx mori* L.

W Hara
NIAS, Ohwashi1-2, Tsukuba Ibaraki, 305-8634, Japan, whara@affrc.go.jp

We have developed the genetic analysis by using molecular markers based on restriction fragment length polymorphism (RFLP) in the silkworm, *Bombyx mori*.. In the silkworm there is no crossover on female chromosomes, so a (RF02 x RF50) female was crossed to a RF02 male and from this BC_1 segregant more than 250 ug individual DNAs were prepared and used to know their genotypes. Every clone gave homozygous or heterozygous genotype for each individual and the patterns for each clone of 15 BC_1 segregants could be identified from each other. After the 28 patterns for every chromosome were made, every new clone was easily to know their linkage group from the genotyping of 15 individuals. After linkage analysis, all clones were mapped by using the 100 segregants of the cross between a (RF02 x RF50) male and a RF02 female. From all of the genotypes, non-recombinant individuals are those with either all A, homozygous, or B, heterozygous, but recombinant individuals have both A and B. The linear order of clones is known after data is sorted and distance between clones determined by counting the recombinants. Now about 300 cDNA clones have been mapped on molecular genetic map.

Molecular tools for reconstructing the past and predicting the future of insecticide resistance

C Hartley, R Russell, A Devonshire, D Yeates, J La Salle, R Newcomb, J Oakeshott
CSIRO Entomology, GPO Box 1700, Canberra ACT 2600 Australia

We have been using the tools of modern biotechnology to reconstruct the past and predict the future course of the evolution of metabolic resistance to organophosphorus (OP) insecticides in the higher dipterans *Lucilia cuprina* (Calliphoridae) and *Musca domestica* (Muscidae). Resistance in both species is due to mutations that convert a carboxylesterase enzyme into a catalytically inefficient but physiologically protective phosphotriesterase. There are a pair of allelic mutations in each species which give resistance to structurally distinct sets of OPs. The two mutations involve the same substitutions in the same residues of orthologous proteins in the two species. In order to reconstruct the history of the resistance we have been using PCR to clone and sequence the gene involved from preserved museum specimens over an 80 year temporal transect. This transect goes back over 20 years before the first use of OP insecticides. We find that at least one of the resistance alleles existed in natural populations before the introduction of the pesticides. In order to predict the future course of resistance we have been using the tools of directed *in vitro* evolution and rational enzyme design in attempts to improve the catalytic efficiency of the extant natural mutants. We have now been able to recover *in vitro* mutants which are catalytically superior in the degradation of OPs.

The management of cotton aphid (*Aphis gossypii* Glover) in Australian cotton

GA Herron, LJ Wilson
NSW Agriculture, PMB 8, Camden 2570, Australia, grant.herron@agric.nsw.gov.au

Until recently, cotton aphid, *Aphis gossypii* Glover, has been a persistent but readily controlled secondary pest of Australian cotton. However, during the 1998-1999 cotton-season, control failures linked to resistance were reported for organophosphate and carbamate insecticides, with some populations controllable only with diafenthiuron. Since then resistance hotspots have developed annually over eastern Australia that have only been controllable with new chemistries. The reasons for this are complex and include seasonal differences in rainfall patterns affecting over wintering host availability for aphids and a reduction in insecticide use, particularly endosulfan, with the coincident introduction of transgenic cotton. In response, aphid management has been multi-faceted and based on a complex integrated pest management (IPM) approach. This includes an Integrated Resistance Management Strategy (IRMS) that has recently been altered to better manage the selective aphicide pirimicarb. This useful IPM chemical is usually quickly lost to high-level target site resistance but we aim to manage it through improved tactical product use.

Chemical control of western flower thrips in Australia

GA Herron, SM Broughton, AD Clift
NSW Agriculture, EMAI, PMB 8 Camden NSW 2570, Australia, grant.herron@agric.nsw.gov.au

Insecticides are the main method used by commercial growers to control Western flower thrips (WFT) *Frankliniella occidentalis*, **in Australia. However, as has occurred overseas, WFT are resistant to a number of insecticides and insecticide groups. Furthermore, the current field application rates of many insecticides used in Australia may be too low to be effective. This would increase selection for resistance, because insecticides are being applied at sub-lethal doses. To test this, we carried out a series of field trials. Crops tested included ornamentals, tomatoes, lettuce, strawberries, cucumber and capsicum. Six key chemicals (abamectin, acephate, dichlorvos, endosulfan methidathion and pyrazophos) were evaluated. All field trials were integrated with insecticide resistance monitoring to remove the confounding effects of chemical resistance. Field trials confirmed that many application rates used for WFT were too low to be effective. Resistance monitoring showed that abamectin, methiocarb, and pyrazophos are the only chemicals where resistance was not detected. Low-level resistance was detected against acephate, dimethoate, endosulfan, fipronil, methamidophos, methidathion and spinosad. Increasing levels of resistance were detected against chlorpyrifos, dichlorvos and maldison.**

The GMO guidelines project - developing the science in risk assessment of transgenic plants

A Hilbeck, D Andow
Swiss Federal Institute of Technology, Geobotanical Institute, Zürichbergstrasse 38, CH-8044 Zürich, Switzerland. Email: angelika.hilbeck@env.ethz.ch

The GMO Guidelines Project (www.gmo-guidelines.info) has developed a conceptual framework for a methodology of case-specific ecological risk assessments of genetically modified plants. It consists of a generic framework that is constructed on five scientific sections and incorporates many different scientific disciplines: 1) Problem Formulation and Options Assessment (PFOA), 2. Transgene Expression and Locus Structure (TELS), 3. Biodiversity and Non-target Impacts, 4. Gene Flow and its Consequences, 5. Resistance Evolution and Management. The generic framework of the GMO-Guidelines is comprised of a risk assessment model, which is driven by systematically structured, detailed scientific questions. The model can be applied to any case and the information and data for answering each question tailors the assessment to the specific context yielding a case- and country-specific risk assessment. We applied the framework to three case examples: Bt-maize/Kenya, Bt-cotton/Brazil and Bt-cotton/Vietnam. In our presentation, we will briefly present the major outcomes of these case studies. Several unique features of the Project: a) We work collaboratively with scientists from developing countries and jointly conduct the case study risk assessments. Thereby, we build scientific capacity and build confidence in their own scientific capabilities; b) We frame risk assessment in a multi-stakeholder deliberative process of PFOA.

Modification of sucrose synthesis in GM aspens: effects on leaf-beetle preference.

J Hjältén, A Lindau
Department of Animal Ecology, Swedish University of Agricultural Sciences, SE-901 83 Umeå, Sweden. E-mail: joakim.hjalten@szooek.slu.se

GM forest trees potentially pose ecological problems beyond those faced by transgenic agricultural crops because: forest trees are essentially undomesticated which makes escape of transgenics to the wild more probable and trees also have long life spans, dominate the forest ecosystems and define the structure of many communities. Therefore, it is of outmost importance that we gain basic knowledge of the potential ecological effects of transgenic tree species. The aim was to determine if genetic modifications of aspens, not primarily intended to influence natural enemies, will lead to changes in the plants nutritional quality and secondary chemistry, thus effecting interactions between natural enemies (insects) and GM trees. We used GM (*Populus tremula x tremuloides*) aspens modified with respect to increased sucrose-synthesis (ZEA SPS), resulting in increased mesophyll sucrose concentration, dry mass and growth. Two different lines (different degrees of up regulation) were used and unmodified wild-type aspen served as controls. We used two common leaf feeding chrysomelid beetles, *Lochmeae caprea* and *Phratora vitellinae* in cafeteria test. *Phratora vitellinae* utilized transgenic aspens marginally less than the wildtype whereas no difference was found for *Lochmeae caprea* preference. The relationship between these results and plant primary and secondary chemistry and its implication for plant-herbivore interactions is discussed.

Biorational insecticides – important components in pest management of cotton, vegetable and ornamentals, an overview

AR Horowitz, I Ishaaya

Department of Entomology, Agricultural Research Organization, The Volcani Center, Gilat Research Station, MP Negev 85280, [2]Bet Dagan 50250, Israel, hrami@volcani.agri.gov.il

There have been efforts to develop biorational insecticides with selective properties to act on biochemical sites present only in the target arthropods and not in non-target organisms. This approach has led to the development of insecticides such as the neonicotinoids (which affect nicotine acetylcholine receptors), the benzoylphenyl ureas (BPUs) and buprofezin (which inhibit chitin synthesis), and the juvenile hormone (JH) mimics and ecdysone agonists. Compounds originating from natural products, which act on GABA gated chloride channel, glutamate receptors and the chloride channels (such as the avermectins and the spinosyns) and at the mitochondrial level (chlorfenapyr) with much more association to the insects than mammals, have been developed and used successfully to combat diverse insect pests and spider mites. Additional new groups of insecticides include the phenylpyrazoles (fipronil), the pyridines (pymetrozine) and the oxadiazines (indoxacarb), which act on GABA receptors, on the nerves controlling the salivary pump and on the sodium channel, respectively. All the above, are considered biorational, or "low risk" insecticides, which have relatively low detrimental effect on the environment and its inhabitants, rendering them important potential components in IPM programs. The selectivity of these biorational insecticides to beneficials and resistance evolution in key pests will be discussed.

Selection of insecticide resistant strains of African malaria vector mosquitoes

RH Hunt, *M Coetzee*
School of Animal Plant & Environmental Sciences, University of the Witwatersrand, 1 Jan Smuts Avenue, Johannesburg 2001, South Africa.
maureen.coetzee@nhls.ac.za

Insecticide resistance in the major African malaria vector mosquitoes seriously impacts on control operations in many countries. In 1999/2000, South Africa experienced its worst malaria epidemic in over 50 years, due to the return of pyrethroid resistant *Anopheles funestus*. The situation is confounded by cross-resistance to carbamates in *An. funestus* and low level resistance to DDT and pyrethroids in the other southern African vector *Anopheles arabiensis*. Resistant strains of both species have been established and laboratory investigations into the mechanisms of the resistance carried out. Only a metabolic mechanism appears to be responsible for the pyrethroid resistance in *An. funestus*. In *An. arabiensis*, however, two mechanisms have been found in populations from different parts of Africa, one a knockdown (*kdr*) type resistance and the other a metabolic mechanism. The possibility of cross-resistance to other classes of insecticides is discussed.

Actions of clothianidin and related neonicotinoids on recombinant and native nicotinic acetylcholine receptors

M Ihara, K Matsuda, DB Sattelle, K Komai
Graduate School of Agriculture, Kinki Universitiy, 3327-204 Nakamachi, Nara 631-8505, Japan, gc196005@nara.kindai.ac.jp

Imidacloprid and related neonicotinoids are insecticides acting selectively on insect nicotinic acetylcholine receptors (insect nAChRs). Among neonicotinoids, imidacloprid has pyridine and imidazolidine moieties, whereas clothianidin lacks both moieties. Since it was conceivable that such structural differences could result in different actions of these two insecticides on nAChRs, we have investigated, using two-electrode voltage-clamp electrophysiology, the agonist actions of clothianidin and imidacloprid on *Drosophila* SAD-chicken b2 hybrid nAChR expressed in *Xenopus laevis* oocytes. Also, we have used whole-cell patch-clamp electrophysiology, to study clothianidin actions on native nAChRs in the TAG neurons from male adult American cockroaches as well as in the mushroom body neurons from *Drosophila melanogaster* larvae. Clothianidin was found to activate not only the recombinant SADb2 hybrid nAChR but also native insect nAChRs with a greater efficacy than that of imidacloprid. Structure-agonist action relationship analysis suggested that opening of the imidazolidine ring is likely to account for the greater agonist efficacy of clothianidin compared to that of imidacloprid.

Novaluron (Rimon), a novel IGR – cross-resistance, selectivity and importance in pest management

I Ishaaya, S Kontsedalov, A Barazani, AR Horowitz
Department of Entomology, Agricultural research Organization, The Volcani Center, Bet Dagan 50250. vpisha@volcani.agri.gov.il

Novaluron, 1-[chloro-4(1,1,2-trifluoro-methoxyethoxy)phenyl]-3-(2,6-difluorobenzoyl)urea, a novel benzoylphenyl urea acts by both ingestion and contact. It is a powerful suppressor of lepidopteran larvae such as *Spodoptera littoralis* and *Helicoverpa armigera* (by ingestion) and whiteflies such as *Bemisia tabaci* (by contact). The compound has translaminar activity thereby affecting leafminers such as *Liriomyza huidobrensis.* Its residual activity under field conditions ranges between 10 and 30 days depending on environmental conditions. Artificial rain at a rate of 40 mm/h applied 5 and 24 h after novaluron treatment in a cotton field had no appreciable effect on the potency of novaluron on *S. littoralis* larvae. Novaluron has no appreciable cross-resistance with the juvenile hormone mimic pyriproxyfen or with the neonicotinoids. Hence these compounds can be used as components in insecticide resistance management for controlling whiteflies and other insect pests in cotton and field crops. Novaluron has no appreciable effect on parasitoids and phytoseiid mites, and probably has a mild effect on other natural enemies. Hence, it can be considered an important component in IPM programs.

The susceptibility of *Aedes aegypti* from northern Queensland to synthetic pyrethroids

CC Jansen, SC Barker, WG Brogdon, SA Ritchie, SP Frances, RD Cooper
Australian Army Malaria Institute, Weary Dunlop drive, Gallipoli Barracks, ENOGGERA, QLD, 4051, Australia, Cassie.Jansen@defence.gov.au

Aedes aegypti is the only mosquito vector of the dengue virus in northern Queensland. Despite complete reliance upon synthetic pyrethroids to control adult *Ae. aegypti* during dengue outbreaks, little is known regarding the susceptibility of *Ae. aegypti* from northern Queensland to these insecticides. Insecticide exposure bottle assays and biochemical microplate assays were conducted to examine the susceptibility of *Ae. aegypti* to synthetic pyrethroids. The susceptibility of five strains of *Ae. aegypti* from northern Queensland to five commonly used synthetic pyrethroids was compared with that of an insecticide-susceptible laboratory strain. All strains tested were fully susceptible to the synthetic pyrethroids used by mosquito control authorities in northern Queensland (lambda-cyhalothrin and deltamethrin). However, some wild strains showed significantly reduced susceptibility to permethrin, bioresmethrin and alpha-cypermethrin. Biochemical microplate assays were used to measure the activity levels of two types of enzymes (β-esterases and monoxygenases) that often confer resistance to synthetic pyrethroids. Elevated esterase activity was detected in three wild strains relative to the reference strain, but elevated oxidase activity was not detected in any of the mosquito strains. The presence of resistant traits in wild populations of *Ae. aegypti* demonstrated here supports the need to establish a resistance monitoring programme in northern Queensland to ensure the continued success of dengue outbreak control.

Identification and sequence analysis of the chromosomal region containing *nsd-2*, a densovirus-resistance gene in *Bombyx mori*

K Kadono-Okuda, J Nohata, K Yamamoto, S Sasanuma, M Sasanuma, R Eguchi, W Hara, K Mita
Insect Genome Laboratory, National Institute of Agrobiological Sciences, 1-2, Owashi, Tsukuba, 305-8634, Japan, Kadono@affrc.go.jp

Bombyx mori densovirus (BmDNV) multiplies in the columnar cell nuclei of the mid gut epithelia in the silkworm, *Bombyx mori*. It is classified into 2 types, DNV-1 and DNV-2. Some silkworm strains were identified as resistant against DNV-1 and/or DNV-2. So far four non-susceptibility genes have been reported, namely; *nsd-1*, *Nid-1*, *nsd-2* and *nsd-Z*. However, none of them have yet been isolated as responsible genes. Studies on these genes are useful in understanding the mechanism of non-susceptibility in relation to the viral invasion and multiplication. We identified four closely linked cDNA markers with *Nid-1* and *nsd-2*. By taking advantage of *Bombyx* genome information, the BAC contigs covering these cDNA markers were expanded by screening of the BAC library with BAC end sequences, fingerprinting and shotgun sequencing of BAC clones. At the same time, backcrossed F_1 segregants were selected by virus nonsusceptibility and the linked boundary of the chromosome was defined by sequence analysis.

The use of surface plasmon resonance in characterisation of metabolic resistance

F Kemp, *GD Moores*

Reading University, Whiteknights, Reading, UK RG6 6AH c.f.kemp@reading.ac.uk

Insecticide resistance can be the result of target-site insensitivity, metabolic resistance, or both. In general, target-site insensitivity can be readily determined by direct assays on the receptor or target involved. Metabolic resistance can often be harder to characterise, often being implicated indirectly by synergism studies or the use of model substrates. These may or may not accurately reflect the 'true' interaction between pesticide and the degradative enzyme. The use of BIAcore surface plasmon resonance technology allowed the direct interaction of insecticides with a purified esterase to be measured. Additionally such interactions are measured in real time, allowing a unique insight into the binding between resistance-associated esterase and xenobiotics.

Bt-maize and *Trichogramma* wasp – two compatible strategies in control of European corn borer (*Ostrinia nubilalis*)

F Kocourek, *K Ríha*
Research Institute of Crop Production, novská 507 – Prague 6 – Ruzyně, 161 06, Czech Republic,
kocourek@vurv.cz

The efficacy of *Bt* maize and Trichogramma wasp (Tw) against *O. nubilalis* was tested in two field trials in 2002 and 2003. The hybrids of maize MON 810 (Bt-maize), Monumental (isolinie) and Raissa (local variety) were used. Tw was applied as preparation Trichocarp. Plant injury before harvest on untreated plot ranged from 0.75 to 2.5 per plant in 2002, and 0.22 – 1.4 in 2003. Biological efficacy of *Bt* maize was 100%, the biological efficacy of Tw ranged from 35 to 69%. The increase of yield on *Bt* maize plot reached 21 - 27% in 2002, and 7 – 15% in 2003 and on plots treated by Tw ranged from 0.6 to 17 in both years. The content of four mycotoxins in grain of maize ascertained by ELISA will be presented. Mathematical model of population dynamics of *O. nubilalis* in strips of maize treated by Tw in comparison with untreated strips will be presented. Tw can be applied in insect resistant management (IRM) of European corn borer. Strips of non-transgenic maize hybrid protected by Tw can be used as a refugee to decrease spread of Bt-resistance. The work was funded by the Ministry of Agriculture of the CR project no. QD 1360.

Fluorescence PCR techniques for detecting mutations in the sodium channel gene and for analysis of family 6 oxidase genes conferring pyrethroid resistance in *Aedes aegypti*

AE Lenhart, WG Brogdon
CDC DPD/ENT, 4770 Buford Hwy. MS F-42, Atlanta, GA 30341 USA

Multiple mutation sites in transmembrane segment 6 of domain II of the sodium channel gene confer pyrethroid resistance in *Aedes aegypti*. Existing strategies for identification of genotypes using PCR are often difficult to use with routine success, especially in the case of heterozygotes. We sought to develop more robust PCR methods based on fluorometric PCR and primer mismatch PCR that remove much ambiguity in scoring results. Here we describe several approaches to making the scoring of resistance genotypes a more straightforward and reproducible procedure. Data are shown for *Aedes aegypti* populations from several continents expressing varying degrees of pyrethroid resistance, as well as for the two mutations known from *Anopheles gambiae*. Elevated expression of P450 oxidases can also confer pyrethroid resistance in *Aedes aegypti* populations. A conserved repeat motif in the downstream P450 reductase binding site of *Aedes aegypti* family 6 P450 genes was used as a probe for quantitative analysis of oxidase copy number and expression. Oligonucleotides were selected for conserved regions of sequence (across the *Culicidae*) and for specific oxidase sequence variants. Through fluorescence PCR analysis, this allowed a comparison of oxidase copy number and expression as well as comparison to homologous sequences in other *Aedes*, *Culex*, and *Anopheles* species.

Biokinetics in insecticide discovery

R Lind
Syngenta, Jealott's Hill International Research Centre, Bracknell, Berkshire, RG42 6EY, UK, rob.lind@syngenta.com

Biokinetics is the study of uptake, distribution, metabolism and excretion of xenobiotics and is an important factor to address in the development of new chemical insecticides. Methods have been developed within Syngenta to address these factors on whole insect systems, and the plants upon which insects feed, to gain an insight into biokinetic processes. An understanding of these factors allows iterative cycles of chemical synthesis to improve biokinetic properties which ultimately lead to increased biological potency. Furthermore, biokinetics has played a major role in understanding the translation of in vitro biochemical signals to in vivo biological potency. Conversely this can occur the other way round when a propesticidal compound is tested and again biokinetics can be used to ascertain the conversion of the parent to the active primary metabolite. This was recently exemplified in cyanotropane insecticidal chemistry which demonstrated potent biological activity on sucking pests (hemiptera) but had very weak micromolar activity on the insect nicotinic acetylcholine receptor (nAChR). Biokinetics proved the rapid conversion of the parent to a stable metabolite in insects which had high nanomolar affinity to the insect nAChR thus linking the in vivo to in vitro potency of this chemical series.

Genetic variation and phenotypic plasticity in *Leptinotarsa decemlineata* under different selection pressures

L Lindström, MSc S Boman, A Grapputo, A Lyytinen, J Mappes
Department Of Biological And Environmental Science, Po Box 35, Fi-40014 University Of Jyväskylä, Finland, lilema@cc.jyu.fi

Invasive pest species provide us an opportunity to study genetic variation linked to selection pressures in natural populations. As pests are invading new areas they face new temperature regimes as well as human induced selection by pesticides. Different countries use also different varieties of cultivated crop species, which may retard insect performance. All these selection pressures are expected to shape the life history traits of a species. Finland is still free of the Colorado potato beetle *Leptinotarsa decemlineata* but on the boarder of its range. To assess beetles potential to invade Finland we compared the life-history traits of four European populations (Italy, Poland, Estonia, Northern Russia). Adult size varied very little between populations when reared on two different temperature regimes. However, developmental times differed among populations suggesting that there may be enough genetic variability for the beetle to adapt further to cooler climates. The frequency of alleles conferring resistance to permethrin was highest in Polish, and declined for Estonian and Russian populations, which suggests that the Polish population has experienced highest pesticide selection. However, resistance to aziphos-methyls was in overall high and similar in all populations. Finally, host plant variety affected little the adult size and the developmental time.

Insecticide choice in alfalfa hay may protect water quality

RF Long
UC Cooperative Extension, 70 Cottonwood St. Woodland, CA 95695 USA, rflong@ucdavis.edu

Some insecticides used for controlling Egyptian alfalfa weevil, *Hypera brunneipennis,* have been detected in California's surface waters and are of concern due to their impact on water quality and toxicity to some aquatic life. To assess the impact of insecticide choice on water quality, we collected tail-water samples from on-farm alfalfa sites in the northern Sacramento Valley, CA over a 3-year period. Samples were collected during irrigation after organophosphate and pyrethroid sprays were applied. We found significant differences between insecticide classes in the mortality of *Ceriodaphnia dubia* (water flea) a test organism used to detect pesticides in water. Nearly all sites where organophosphate insecticides were used resulted in 100% water flea mortality in a 24-hout test of tail-water samples. The pyrethroid-treated sections of the same fields exhibited insignificant water flea mortality nor were any pyrethroids found to a detection limit of 50 ppt. The pyrethroids used in this study provided significantly better control of Egyptian alfalfa weevil than the organophosphates with no significant differences in beneficial insect counts. Although water runoff does not always occur in alfalfa fields, insecticide choice may be an important tool for protecting water quality in this crop.

Resistance traits of genetically modified silver birch (*Betula pendula*) against insects

P Lyytikäinen-Saarenmaa, L Vihervuori, H Pasonen, A Pappinen
Department of Applied Biology, PO Box 27, FIN-00014 University of Helsinki, Finland, Paivi.Lyytikainen-Saarenmaa@helsinki.fi

Genetic modification has recently been applied to forest trees, aiming to improve productivity, quality and resistance to insect pests and diseases. We introduced a sugar beet chitinase gene into silver birch, using the *Agrobacterium* mediated gene transfer. Chitinases have been characterised as defense related proteins, particularly in plant/fungus interactions. Fifteen transgenic birch lines showing varying levels of sugar beet chitinase 4 expression and a wild type birch were applied in a field test. Birch seedlings were planted in an agricultural field according to a randomized block desing in 2000. We conducted an inventory of spatial and temporal distribution of insect species and damages caused by herbivorous insects on birch seedlings. Systematic sampling of transgenic and wild type trees was carried out early, middle and late in the growing season 2003 using four randomized field trial blocks. Furthermore, we studied the effect of the quality of partially defoliated birch foliage on performance of *Orgyia antigua* (Lymantridae) larvae in the laboratory. Transgenic and wild type trees were artificially defoliated in nine field trial blocks. This study has been a part of a risk assessment project aiming to provide new information on the biological interactions between genetically modified trees and other organisms.

Effects of neem (*Azadirachta indica* A. Juss) on rice bug, *Leptocorisa chinensis* (Dallas)

DL Ma, Y Suzuki, H Takeuchi, T Watanabe, M Ishizaki
Dept. of Entomology & Nematology, National Agricultural Research Center, 3-1-1 Kannondai, Tsukuba 305-8666 Japan, madeling@affrc.go.jp

Ovicidal, ovipositional, nymphicidal effects of neem (*Azadirachta indica* A. Juss) on rice bug, *Leptocorisa chinensis* (Dallas), were tested under laboratory and caging conditions. Neem oil alone and azadirachtin (Aza) at 60-180 ppm did not show ovicidal effect on D7. However, a high mortality was observed on D10 in treatment with the mixture of neem oil and abamectin at a low rate and moderate mortalities in treatments of Aza at high rates > 180 ppm. Neem extracts did not significantly affect the survival of adults and the damage to rice when used as ovipositional deterrents. Treatment of 1-3 instars showed that the mixture of neem oil and abamectin achieved the best results in increasing the mortality and delaying the nymphal development, followed by treatments of Aza in a rate-dependent manner. Toxicity of Aza to various instars was also nymphal-age and observation-time dependent. No second instars in rice survived to three weeks when two sprays of Aza at 60 ppm were applied. Two sprays of Aza at 60 ppm and 1.4% neem oil significantly increased rice yield by 23-44%. Egg number was moderately reduced on Aza treated plants. Neem may be integrated into an existing IPM package for *L. chinensis*.

Overview on environmental impact of Bt-corn (Event Bt 176) on non target organisms

B Manachini, *GC Lozzia*
Agricultural Entomology Institute, Celoria, 2–20133MI ITALY, barbara.manachini@unimi.it

Field studies were conducted in Italy to assess the potential impact of transgenic *Bacillus thuringiensis* corn on non target organisms. Bt corn was modified to express the Cry1Ab toxin against the lepidopteran pest *Ostrinia nubilalis.* We monitored above-ground herbivores, predators, and parasitoids as well as soil-related organisms such as Carabidae and Nematoda. Community structures and degree of biodiversity were compared between transgenic and isogenic crops. No significant impact of Bt-corn on plant-dwelling organisms was observed. However, remarkable differences were found in the case of *Lydella thompsoni*, a parasitoid of *O. nubilalis.* Contrasting results were detected for soil organisms. The Carabidae assemblages were similar, and any differences appeared to have no correlation with Bt maize. The biodiversity of the Nematoda was quite low for both types of crops and no significant differences were found for the majority of the cases. However, Nematoda assemblages were significantly different in Bt than isogenic crops planted in clay-rich soils. These results indicate that we should not neglect taxa of agro-ecosystems before releasing transgenic crops or any other xenobiotics.

Increased efficacy of conventional insecticides against greenhouse pests by the use of piperonyl butoxide (PBO).

MJ Verdu, GD Moores, A Cervera, G Bingham, J Catalan, MD Garcera, S Young, N Lopez, R Martinez-Pardo.
Cateático de Fisiología, Dto. Biol. Func. Antrop. Fis. F. CC. Biológicas, Universidad de Valencia. (Campus de Burjassot), Moliner 50. Burjassot. 46100. Valencia. España mtnezp@uv.es

The Tobacco Whitefly, *Bemisia tabaci* (Gennadius) and Western Flower Thrip, *Frankliniella occidentalis* (Pergande) are serious insect pests of agricultural and horticultural crops throughout the world. They can cause damage through both direct feeding and also through transmission of virus. The primary strategy for control for both species remains chemical sprays. However, both have the potential for fast development of resistance due to short generation time, high fecundity, and a haplodiploid breeding system. As a result, high resistance has evolved to conventional insecticides. Results of *in vitro* assays indicated efficacious use of piperonyl butoxide could substantially reduce or nullify the metabolic resistance mechanisms conferring resistance in these species. Subsequent field trials where a pyrethroid (lambda cyhalothrin) and an Insect Growth Regulator (pyriproxyfen) were applied following a pre-treatment of piperonyl butoxide, reflected the *in vitro* findings.

Biofumigation: plant cellular disruption and water achieves high toxin levels in soil

JN Matthiessen, B Warton, MA Shackleton
CSIRO Entomology, Private Bag 5 PO, Wembley WA 6913, Australia, John.Matthiessen@csiro.au

Some brassicas are potentially large sources of isothiocyanate (ITC) toxins, in the same chemical family as the methyl isothiocyanate produced by the widely used broad-spectrum pseudo-fumigant pesticide metham sodium. Endeavours to harness this potential in the form of biologically active green manures for IPM is dubbed 'biofumigation'. Recent laboratory studies have shown that ITC concentration in soil increased 100-fold with a combination of disruption of plant tissue at the cellular level (achieved by freezing and thawing) and high levels of moisture. Analytical determination of ITCs in soil following manipulation of *Brassica* green manure crops showed that similar improvements in the concentration of these compounds could be achieved in the field. It was crucial to thoroughly pulverise plant tissue with a club-type mulcher running at high speed. A blade mulcher tended to chop the plant tissue into fragments without liquefying it. Leaving the pulverised mulch on the surface and immediately watering it heavily achieved the greatest ITC concentration in soil. It is evident that the intrinsic water content of brassicas is insufficient to allow maximum hydrolysis of the precursor glucosinolates to ITCs. Addition of water boosts this process and carries the ITCs into the soil.

The crucial role of calcium in enhanced biodegradation of soil-applied pesticides

JN Matthiessen, B Warton, MM Roper
CSIRO Entomology, Private Bag 5 PO, Wembley WA 6913, Australia, John.Matthiessen@csiro.au

Enhanced biodegradation occurs where particular, but otherwise entomologically innocuous, soil bacteria are selected by repeated use to catabolise soil-applied pesticides. It is a subtle process akin to resistance in reducing soil-borne pest control efficacy. It is more widespread than is generally recognised, possibly because of its indirect mode of action, counter-intuitive mechanism and probable confusion with resistance. Extremely severe enhanced biodegradation of the widely used broad-spectrum soil-applied pesticide metham sodium occurs in Australia in intensive horticulture, particularly on sandy soils. Highly resilient spore-forming bacteria are the cause. Pesticide persistence in affected soil was just seven hours, but 15 days in similar soil never exposed to metham sodium and in affected soil sterilised by autoclaving. A positive correlation has often been reported between the risk of onset or degree of enhanced biodegradation and soil pH. However, high agricultural soil pH is often associated with greater calcium concentration through liming (adding calcium carbonate) soils with pH below agronomically desirable levels. We have found that high soil pH alone is insufficient to exacerbate enhanced biodegradation. Rather, a powerful synergy is established when high levels of calcium occur in the same soil. Reassessment of soil pH targets and adjustment methods less reliant on calcium-rich alkalis offer scope to reduce the risk of enhanced biodegradation.

Ethanedinitrile: a promising replacement soil fumigant for methyl bromide

JN Matthiessen, Y Ren, SW Mattner
CSIRO Entomology, Private Bag 5 PO, Wembley WA 6913, Australia, John.Matthiessen@csiro.au

Methyl bromide, a long-used powerful broad-spectrum soil fumigant, is scheduled for withawal from soil use in 2005 under the Montreal protocol. Many highly intensive horticultural industries with extreme market-iven or mandated sanitation demands face significant challenges in maintaining equivalent plant protection efficacy with alternatives. Most current alternatives have a narrower activity spectrum, greater risk of phytotoxicity entailing economic penalty in longer plant-back times, are susceptible to enhanced biodegradation (a concept alien to the methyl bromide experience) or are generally less forgiving for robust use in the highly diverse and variable field environment. CSIRO Entomology has identified and taken patent protection on ethanedinitrile (C_2N_2) (EDN) as a potential soil fumigant. Its chemical properties place it at no risk as an ozone-depletor or greenhouse gas and it is safer to use than methyl bromide. Laboratory and preliminary field tests have shown that it offers equal, if not greater, spectrum of activity and potency than methyl bromide, and an extraordinarily rapid action and rate of dissipation that promises extremely short plant-back times and little prospect that enhanced biodegradation will impede efficacy with longer-term use.

Insect resistance traits in the near future

T Meade, GD Thompson, NP Storer.
Dow AgroSciences, 9330 Zionsville Rd., Indianapolis, IN 46268, meade@dow.com

Since their introduction nearly 10 years ago, insect resistance (IR) traits have become a significant feature of the crop protection landscape. In spite of the rapid adoption of this technology, there are relatively few IR traits currently in the marketplace, and they are only available in two major crops (maize and cotton). A limited number of new IR traits are in the product development pipelines of the major crop protection companies with projected product launches within the next 5 years. What is known about these new IR traits will be discussed. The discovery and development process for IR traits will also be discussed in the context of identifying barriers to the introduction of new IR traits.

Efficacy of a spinosad suspension concentrate formulation for controlling chewing and sucking lice on cattle under field conditions

C Jones, LL Smith, DE Snyder, DE Hutchens, Z Cui, D Mowrey, LD Firkins, AJ Paul, JA Meyer
2001 West Main Street, Greenfield, Indiana, 46140, USA, meyerje@lilly.com

Field studies were conducted with cattle in Wisconsin and Illinois between January and April, 2000, to determine the efficacy of 0.04% spray and 2 mg/kg pour-on treatments of a spinosad suspension concentrate formulation against chewing and sucking lice. Positive control substances included in the study were Co-Ral® EC (5.8% coumaphos) and CyLence™ Pour-on (1% cyfluthrin). Animals in the negative control group remained untreated. All lice species were visually sampled on each animal at weekly intervals after treatment, for eight weeks. Individual louse counts were summed over each examination site for each species. A repeated measures analysis using a mixed model (SAS PROC MIXED), was conducted for data pooled across both study sites. Both spinosad treatments and CyLence™ Pour-on provided excellent efficacy (98-100%) against *Bovicola bovis* over the entire study period; Co-Ral® EC efficacy dropped below 90% from Weeks 6-8. The efficacy of the spinosad spray treatment against *Linognathus vituli* was >93% for the entire study and >88% for the spinosad pour-on treatment. Co-Ral® EC was >90% efficacious against *L. vituli* during Weeks 1-7, while CyLence™ Pour-on only exceeded 90% for Weeks 3-7. *Solenopotes capillatus* were found only at the Wisconsin site; all treatments were highly efficacious throughout the study period.

Progress of *Bombyx* genome project in Japan

K Mita, M Kasahara, S Sasaki, Y Nagayasu, T Yamada, H Kanamori, N Namiki, M Kitagawa, H. Yamashita, Y. Yasukochi, K. Kadono-Okuda, K. Yamamoto, M. Ajimura, G. Rvikumar, M Shimomura, Y Nagamura, T Shin-I, H Abe, T Shimada, S Morishita, T Sasaki
Genome Research Department, National Institute of Agrobiological Sciences, Tsukuba 305-8634, Japan, kmita@nias.affrc.go.jp,

In Lepidoptera, the genome information had been quite limited so far. Now the situation changed quickly, since National Institute of Agrobiological Sciences (NIAS) is performing the *Bombyx* genome project including *Bombyx* whole genome shotgun sequencing, cDNA collection and construction of physical map systematically in collaboration with many groups, and the explosive accumulation of *Bombyx* genome information will be expected. We will present the recent progress on our *Bombyx* genome works.
EST db: Recently, *Bombyx* EST db, “SilkBase”, was transferred to “KAIKObase” http://sgp.dna.affrc.go.jp,, where EST db is combined with genome and map information as the integrated database.
Linkage map: About 2,000 genetic markers were mapped in 28 linkage groups under the efforts of several groups. The high density map was made public as “BombMap” in KAIKObase.
BAC library: Three BAC libraries prepared by different restriction enzymes are available.
EST microarray: EST microarray containing 6,000 non-redundant ESTs was available for functional studies.
Genomic sequence: NIAS carried out *Bombyx* WGS, whose data will be public in KAIKObase of NIAS HP shortly.

Reduced sensitivity of acetylcholinesterase in green rice leafhopper, *Nephotettix Cincticeps* Uhler, resistant to organophosphorus and *N*-methyl carbamate insecticides

Y Kato, T Tanaka, T Miyata
Laboratory of Applied Entomology, Graduate School of Bioagricultural University, Chikusa-ku, Nagoya, 464-8601 Japan, tmiyata@agr.nagoya-u.ac.jp

Green rice leafhopper (GRLH) showed resistance to various organophosphorus and *N*-methyl carbamate insecticides. Major resistance mechanism is a reduced sensitivity of acetylcholinesterase (AChE) to these insecticides. A hydophilic form of AChE was purified from *N*-methyl carbamate susceptible (SA) and highly *N*-methyl carbamate-resistant (N3D) strains of GRLH. Both of purified AChE from SA and N3D strains displayed the highest activities towards acetylthiocholine (ATCh) at pH 8.5. In the SA strain, the optimum concentration for ATCh, propionylthiocholine (PTCh), and butyrylthiocholine (BTCh) were about $1x10^{-3}$, $2.5x10^{-3}$, and $1x10^{-3}$ M, respectively. However, in the N3D strain, substrate inhibition was not identified for ATCh, PTCh, and BTCh to $1x10^{-2}$ M. The V_{max} value in the N3D strain was 1.75- and 3.15-fold higher for ATCh and BTCh than that in the N3D strain. However, it was 1.13-fold lower for PTCh. The increased activity of AChE in the N3D strain is due to the qualitatively modified enzyme with a higher catalectic efficiency. AChE from the N3D strain was 65-fold less sensitive than SA strain to inhibition by propoxur. In contrast, AChE from the N3D strain 65-fold more sensitive to inhibition by monocrotophos than AChE from the SA strain. This indicated negatively correlated cross-insensitivity of AChE to propoxur and monocrotophos.

Large scale field trials in the USA with Bt cotton

WJ Moar, M Eubanks, B Freeman, S Turnipseed, J Ruberson, G Head.
Dept. of Entomology and Plant Pathology, Auburn University, Auburn, AL 36849,USA moarwil@auburn.edu

Field studies were conducted in 2000-2002 to compare arthropod populations between Bollgard$^{\text{Ò}}$ and conventional cotton season-long in Alabama, Georgia, and South Carolina. For each region, three or four paired fields were evaluated weekly, with each pair consisting of a Bollgard$^{\text{Ò}}$ field and a conventional cotton field (treated for lepidoptera when necessary). Insect species sampled included *Heliothis virescens*, *Helicoverpa zea*, *Spodoptera frugiperda*, *Spodoptera exigua*, *Trichoplusia ni*, *Pseudoplusia includens*, phytophagous stink bugs and plant bugs, cotton aphids, *Solenopsis invicta*, *Geocoris* spp., *Orius* spp., spiders, parasitic wasps, green and brown lacewings, and *Nabis* spp. Most results show that there were no significant differences for any arthropod population between a particular Bollgard$^{\text{Ò}}$ field and the corresponding conventional cotton field. However, the most amatic significant differences occurred in South Carolina when comparing conventional cotton sprayed with at least several applications of insecticides to control primarily *H. zea*, and Bollgard$^{\text{Ò}}$that was not treated for *H. zea*. In these instances, there were significantly more non-target arthropods in the Bollgard fields than in the conventional fields. These results demonstrate that the use of Bollgard$^{\text{Ò}}$usually has no impact on non-target arthropod populations, and when compared with cotton treated with insecticides for lepidoptera, results in significantly more non-target arthropods.

Molecular diagnosis of *para*-locus mutations in head lice (*Pediculus humanus capitis)* from around the world: their role in resistance to synthetic pyrethroids?

A Murrell, M Ashrafi, WG Brogdon, M Picollo, SC Barker
Department of Microbiology and Parasitology, and Institute for Molecular Biosciences, The University of Queensland, Brisbane 4072, Australia.
a.murrell@uq.edu.au.

Throughout the world head lice (*Pediculus humanus capitis*) infest people, and the pediculicides used to treat them do not always work. One group of chemicals applied to treat head lice are the synthetic pyrethroids, and resistance to these chemicals has been detected in lice in many parts of the world using the World Health Organisation (WHO) mortality assay. The genetic basis for resistance in lice to synthetic pyrethroids is hypothesised to be due to mutation in the *para*-orthologous sodium channel α-subunit (*para*-locus); where most of the sodium channel gene mutations that are known to be associated with knockdown resistance in insects are located. A number of point mutations have been detected in the *para*-locus of synthetic pyrethroid-resistant lice. We sequenced a region of the *para*-locus where two of these mutations have been previously found, in lice from Australia, Argentina, France, Guatemala, Thailand, Panama and the U.S. We observed the occurrence of these and other mutations and the correlation between genetic data and WHO mortality assays for many individual lice. We also developed a possible genetic test for resistance, a polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) assay to quickly and accurately diagnose individual lice as heterozygous or homozygous for genetic change to the *para*-locus.

Using genomic tools to isolate and characterise olfactory genes from the tortricid pest, *Epiphyas postvittana*

R Newcomb, M Jordan, C Turner , D Stanley, A Authier, A Kralicek, L Gatehouse, R Crowhurst, D Greenwood
HortResearch, Private Bag 92169 Auckland, New Zealand rnewcomb@hortresearch.co.nz

With completion of the *Drosophila* genome, efforts have turned to insects of major economic interest for whole genome sequencing. However in the short-term whole genome sequencing will still remain beyond the reach of many projects working on individual insect species. Tools such as EST sequencing and proteomics can contribute to finding genes/proteins involved in targeted processes and create useful information for comparative genomic analysis. We are using these approaches to identify genes involved in the detection of odorants, particularly sex pheromones, from the horticultural tortricid pest, *Epiphyas postvittana*. Potential odorant binding proteins, odorant receptors and odorant hydolases have been isolated from ESTs derived from male antennae. Comparison of male and female antennal proteins on 1-D and 2-D gels reveals proteins both up and down-regulated in males relative to females, and mass spectrometry reveals some of these proteins correspond to genes from the EST collection. These techniques have given us quick access to potential olfaction genes. Functional studies of these genes to examine expression in antennae, protein structure and function, and involvement in olfaction using expression in insect cell lines and RNAi in whole insects will be described.

Expressed sequence tags from the brown planthopper, *Nilaparvata lugens* and its tissue-specific genes

H Noda, S Kawai, Y Koizumi, J Wang, Q Zhang, K Mita
National Institute of Agrobiological Sciences, Owashi, Tsukuba, Ibaraki 305-8634, Japan, hnada@affrc.go.jp

A total of about 35,000 expressed sequence tags (ESTs) were produced from various tissues and stages of *Nilaparvata lugens*, one of the serious pests of rice plant. cDNA libraries were made from two stages of eggs, fourth instar nymphs, two stages of adult ovary, testis, male midgut, female midgut, female salivary glands, female head, female thorax, female abdomen, male head and thorax, and male abdomen. There were more than 8,000 non-redundant ESTs, potentially representing unique genes. Eleven ESTs were found only from the female abdomen and ovary, and five out of the eleven were expressed only in the mature ovary. At least ten ESTs were testis-specific. Nucleotide sequences of truncated region of these cDNAs were determined by 5' and 3' RACE. BLAST search disclosed that the sequences of many gonad-specific genes were dissimilar to those in the databases. The ESTs were also used for determining whole mitochondria genome sequence, because the mitochondrial gene sequences were contaminated in the EST data. *Nilaparvata lugens* mitochondria genome size was 17,251 bp.

Prospects and potential pitfalls associated with the use of transgenic corn for fall armyworm management

GS Nuessly, BT Scully, MG Hentz, R Beiriger
Everglades Research and Education Center, UF/IFAS, 3200 E. Palm Beach Rd., Belle Glade, FL, USA, 33430-4702, GSN@IFAS.UFL.EDU

Transgenic corns that produce Bt toxins have been available for control of European corn borer in the Midwestern USA for several years. While the Bt-event in sweet corn is well expressed and also provides essentially 100% control of fall armyworms, the event in field corns provides only 60 to 85% control of this migratory, polyphagous pest. Despite the reduced potential for fall armyworm control, these transgenic products provide substantial yield gains over traditional field corns for grain and silage. With the recent development of sub-tropically adapted, Bt-enhanced field corns, acreage of Bt-corn grown for silage has spread south into the insect's overwintering region of Florida. IRM stewardship agreements standardized and enforced by the EPA to limit resistance development encourage growers to plant a proportion of their acreage to non-Bt corn reservoirs dependent upon their location within the U.S. cotton growing belts. Corn growers are increasingly pressed to produce high yields with low inputs to compete in the marketplace and are pushing to reduce or eliminate the reservoirs. These and other issues, including non-compliance and season-long availability of Bt-enhanced corn and cotton, will be examined for their potential for selection of Bt-resistance and its area wide implications for fall armyworm control.

Cost economics of Bt cotton cultivation in irrigated ecosystem

BV Patil, M Bheemanna, BK Suresh, SG Hanchinal, V Anand Kumar
Regional Agricultural Research Station and College of Agriculture, Raichur-584 101, Karnataka, India, E-mail: bvp2001@rediffmail.com

Bollworms, *Helicoverpa armigera* (Hubner), *Earias vittella* (F.) and *Pectinophora gossypiella* (Saunders) have made cotton cultivation uneconomical. Transgenic cotton hybrids with in built δ endotoxin reduces pest problem and cost of cultivation. Studies were undertaken at Regional Agricultural Research Station (RARS) and in farmers' field. MECH-162 Bt and non Bt during 2002-03 and MECH-184 Bt and non Bt during 2003-04 and local hybrid (NHH-44) were cultivated. Sprays were imposed as and when the pest population/damage crossed ETL. Totally 3, 4 and 4 sprays during 2002-03 and 3, 12 and 12 sprays during 2003-04 were imposed on Bt, Non Bt and NHH-44 hybrids respectively in RARS, whereas, in farmers' field 4, 9, and 9 sprays during 2002-03 and 6, 12 and 12 sprays during 2003-04 were imposed on Bt, Non Bt and NHH-44 hybrids respectively. Incidence of bollworms only in Bt cotton MECH-162 and 184 was much below ETL. More good opened bolls and less bad opened bolls per plant were recorded with significantly higher seed cotton yield in Bt cotton as compared to non Bt and local hybrid. Bt cotton hybrids recorded 35 to 45 percent increase in net it over local hybrid making it commercially viable and itable.

Wound-inducible expression in transgenic plants after insect attack

MR Perera, MGK Jones
Plant Biotechnology Research Group, School Of Biological Sciences And Biotechnology, Wa State Agricultural Biotechnology Centre, Murdoch University, Perth, WA 6150, Australia. mperera@murdoch.edu.au

Promoters of genes that are induced by microbial pathogens, wounding and treatment with wound-signalling compound could be valuable in regulating the expression of resistance genes when plants are attacked by insects or pathogens. A plant expression vector pMP4 was developed using a GUS/GFP fusion construct driven by a *Shpx6b* peroxidase gene promoter (J. Manners, UQ) from a tropical forage legume *Stylosanthes humilis*. This construct was introduced into insect susceptible tobacco using *Agrobacterium tumefaciens*. Expression of *gus* and *gfp* reporter genes in T_1 transgenic tobacco leaves after infestation/treatment with chewing insects, sucking insects, the plant defense regulator MeJa, and mechanical wounding were investigated. *Gus* reporter gene levels were also assayed to quantify expression and the results were consistent with the observed histological patterns of expression. The results show that the *Shpx6b* promoter switches on the expression of linked genes after damage by insect herbivores, and could be useful in regulating the expression of heterologous genes for insect and /or pathogen resistance in transgenic plants.

Appraisal of cross resistance potential to neonicotinoid insecticides by *Bemisia tabaci*

N Prabhaker, SJ Castle, NC Toscano, TJ Henneberry
Dept. of Entomology, University of California, Riverside, CA 92501, USA, nscastle@earthlink.net

Resistance that occurs to a particular insecticide is often assumed to extend to all members of the class. However, structural differences among compounds may affect vulnerability to degradation by metabolic enzymes, or differences in target site receptors may influence susceptibility to specific insecticides, thereby mitigating cross-resistance effects. Neonicotinoids are an important class of insecticides used worldwide against *B. tabaci* and many other insect pests. Populations from southern Spain resistant to imidacloprid have also shown cross-resistance to thiamethoxam and acetamiprid. To further assess the expression of cross-resistance to neonicotinoid insecticides, *B. tabaci* populations from California and Arizona were monitored periodically to determine their susceptibilities to acetamiprid, dinotefuran, imidacloprid, and thiamethoxam. In addition, two imidacloprid-resistant strains were tested for cross-resistance potential. Field strains expressing different levels of resistance to imidacloprid did not always show cross-resistance to other compounds. For example, a population from Arizona collected in November 2003 had an LC_{50} of 115ppm to imidacloprid in a leaf-uptake bioassay, but only 8 and 9 to dinotefuran and thiamethoxam, respectively. The resistance factor was even greater in a strain from Guatemala that yielded an LC_{50} of 653ppm to imidacloprid, but only 29 to dinotefuran. Implications for cross-resistance between neonicotinoids among the various strains are examined.

Developing protocols for field evaluations of non-target organisms in Bt crops

JR Prasifka, *RL Hellmich*
Genetics Lab c/o Insectary, Iowa State University, Ames, IA 50011, USA, prasifka@iastate.edu

Transgenic crops containing insecticidal genes from Bacillus thuringiensis (Bt) bacteria offer unprecedented power to combat agricultural pests, but concerns about their possible unintended effects remain. Laboratory research suggests accidental exposure or indirect effects of Bt toxins may negatively impact non-target species, though this result is rarely seen in field studies. However, such field research sometimes employs methods inappropriate for evaluating Bt crops, which may have relatively small effects on a select number of species. Nonetheless, simple modifications to experimental protocols and analysis could greatly increase the value of field tests of non-target effects. A synthesis of existing data may guide choices of appropriate indicator taxa, needed replication, and optimal sample timing. Current statistical methods may also allow for more powerful analysis of time-series community data. Field experiments assessing the effects of plot size on community and species-level tests of non-target effects may allow for research plots which are both practical and realistic. Overall, such changes will improve researchers' power to detect differences, positive or negative, between Bt crop production and alternate management practices. However, methods developed for current Bt corn varieties should be adaptable to studies of new cultivars, non-Bt management practices, and other cropping systems.

Studies on detection and characterization of organophosphate-resistance in *Anopheles culicifacies* sibling species in Madhya Pradesh, Central India

K Raghavendra, AK Mishra, SK Chand, G Goswami, N Singh, SK Subbarao
Malaria Research Centre (Icmr), 22 Sham Nath Marg, DELHI-110054, India, kamarajur2000@yahoo.com

Field studies carried out in villages in two blocks in Chhindwara district indicated presence of malathion resistance in *Anopheles culicifacies,* the principal vector of malaria in this area, in the absence of use of malathion spraying for malaria control. *An. culicifacies* s.l. was found 36-86% resistant to malathion but was susceptible to other organophosphate, carbamate and synthetic pyrethroid insecticides. Selection of malathion-resistance in *An. culicifacies* appears to be due to insecticides used in plant protection. Biochemical assays indicated non involvement of general esterases and insensitive acetylcholinesterase in conferring malathion-resistance. Synergist-malathion bioassays indicated the involvement of specific malathion carboxylesterase (MCE). ASPCR assays have revealed prevalence of species B (73%) and species C (27%) and exhibited diferential susceptibility to malathion. The observed percent susceptibility to malathion in species B was 68% while in species C it was 13% These results will be presented in detail and the implication of development of resistance owing to selection by agricultural pesticides will be discussed.

Sugarcane borer (Lepidoptera: Crambidae) resistance management studies in Louisiana

TE Reagan, FPF Reay-Jones, J Ottea, C McAllister, W Akbar.
Department of Entomology, Louisiana Agricultural Experiment Station, Louisiana State University Agricultural Center, Baton Rouge, LA 70803, USA.
treagan@agctr.lsu.edu

During the last decade, sugarcane borer (SCB), *Diatraea saccharalis* (F.) management in Louisiana has been impacted by cultural practice changes emphasizing early planting initiated in August, and the increasing dominance of a high yielding borer-susceptible variety (LCP 85-384) now approaching 88% of the planted acreage. Insecticide foliar sprays for SCB control rose from 0.2 applications per season in 1994-95 to 1.8 applications per field in 2002-03. Due to the growing popularity of the ecdysone agonist, tebufenozide (Confirm®), insecticide resistance monitoring efforts were begun throughout the sugarcane industry in 2002. Increases in LC_{50} values from traditionally low insecticide use areas have ranged up to 2.6 fold in areas averaging more than one application per season. In one area of heavy tebufenozide use, LC_{50} values remained high despite discontinuance of selection pressure. Resistance management studies will be discussed in relation to broader SCB management issues.

Twenty years of insecticide resistance management in the Australian cotton industry.

LC Rossiter, R Gunning
Australian Cotton Research Institute, NSW Agriculture, Locked Bag 1000, Narrabri, NSW 2390. Email: louise.rossiter@agric.nsw.gov.au

The Australian Cotton industry has been guided by an Insecticide Resistance Management Strategy (IRMS) for twenty years. Since its introduction in the 1983/84 cotton season to combat widespread pyrethroid resistance by the primary pest of cotton *Helicoverpa armigera*, it has been modified and expanded to encompass an increased number of chemical groups, embrace integrated pest management and account for a wider range of insect pests. Compliance to this voluntary strategy is near to 100 % by the cotton industry, and in recent years the grains industry has become involved in the strategy providing a more co-ordinated attempt across multiple farming practices to manage resistance and maintain the chemicals available for pest control. This paper shall provide an overview of the IRMS, its evolution over the last twenty years, the principles involved and why uptake by the industry has been so successful. The current status of insecticide resistance by the primary pests of cotton shall be discussed, as well as the future of the IRMS, including the possible impact of transgenic cotton on the pest complex and insecticide resistance management.

Global status of insecticide resistance mechanisms in *Helicoverpa armigera*

DA Russell, KR Kranthi, T Martin, Y Wu, M Ahmad, G Devine, I Denholm
NRI, Chatham Maritime, Kent, UK. E-mail derek.russell@latrobe.edu.au

The cotton bollworm *Helicoverpa armigera* (Hübner) has displayed an enormous potential to resist almost all the insecticide molecules used against it thus far. Amongst the range of mechanisms that confer resistance, enhanced metabolic detoxification has been found to be the most important. Recent evidence showed that increased oxidative breakdown of pyrethroids was found to be associated with pyrethroid resistant strains from West Africa, India, China, and Pakistan. Thus far, at least four cytochrome p450 genes CYP6B2, CYP6B6, CYP6B7 and CYP4G8 have been implicated in pyrethroid resistance. Pyrethroid resistance due to enhanced esterases, reduced penetration and nerve insensitivity was reported from India, China, Pakistan, Thailand and Australia. Several genes associated with nerve-insensitive resistance were explored for specific structural changes, but the mutations generally associated with sodium channels and GABA chloride channels in other insecticide resistant species were not found in *H. armigera* and those that were reported previously in the intracellular segment linking repeat domains III and IV of the para-homologous sodium channel gene, that were associated with nerve insensitive *H. armigera* larvae, were not confirmed. Insensitive acetylcholinesterase and or unique esterase isozymes were found to be associated with resistance to organophosphates and carbamates. Resistance diagnostic kits based on the unique resistance associated isozymes, have been made in India.

Resistance issues in Bt cotton in India and China

KR Kranthi, DA Russell, Y Wu
Natural Resources Institute, Chatham Maritime, ME4 4TB, UK, d.a.russell@gre.ac.uk

Genes for resistance to Cry toxins being selected in the field *in Helicoverpa armigera* by Bt cottons may not be necessarily those which are also being found in laboratory selections. Resistant individuals are present in the field at frequencies of between one in 0.42x10^{-3} and one in 1.3x10^{-3} in India and China. There appears to be both a recessive target site mechanism and a dominant enzymatic degradation mechanism. Currently the former seems likely to be more important in Chinese field populations and the latter in Indian populations with important implications for resistance management strategies. A simulation model was produced taking account of the biology of the pest, the local cropping pattern, initial resistance gene frequency, dominance, mode of inheritance, relative survival rates of RR, RS and SS individuals on Bt and non-Bt hosts throughout the year and other variables. Factors of importance in determining the time to a filed resistance gene frequency of 0.5 in the two countries are different. Where resistance is semi-dominant, in-crop refugia were of little value in delaying resistance development. However even fitness costs as low as 5% doubled the time to significant resistance in most scenarios. Integrating other artificial mortality factors at times of peak pest presence was the simplest effective strategy for delaying resistance in systems where >40% of the cotton is Bt transgenic. The likely impact on resistance development of the range of dual gene combinations currently being commercialised in the two countries has been modeled and is discussed.

Survival and development of *Spodoptera frugiperda* and two of its natural enemies on Bt transgenic maize

CJ Sanders, TH Schuler, JK Pell, GM Poppy, A Raybould
Rothamsted Research, Harpenden, Herts, UK; University of Southampton, Southampton, Hants, UK;
christopher.sanders@bbsrc.ac.uk

This paper reports effects of conventionally-bred partially resistant and transgenic maize hybrids on *Spodoptera frugiperda* (herbivore), *Campoletis sonorensis* (parasitoid) and *Beauveria bassiana* (entomopathogenic fungus).   *Spodoptera frugiperda* larvae fed maize expressing the Bt toxin Cry1Ab had an increased development time and reduced pupal weights compared to larvae fed conventionally-bred resistant and susceptible maize hybrids. *Campoletis sonorensis* cocoon and adult weights were significantly reduced by 15-30% when reared in hosts fed Bt maize. The extent of this effect varied with the weight of host at oviposition, its subsequent development and host weight at parasitoid emergence. Resistant maize, whether transgenic or conventionally-bred, may increase the susceptibility of *S. frugiperda* to *B. bassiana*, as larvae develop more slowly than on susceptible maize, with greater time intervals between moults. This increases the time for *B. bassiana* spores to germinate and invade the host through the cuticle before they are shed during moulting. Alternatively, resistant plants may induce an immune response in *S. frugiperda*, reducing susceptibility to fungal attack. Results of ongoing experiments on this interaction will be presented.

The *Diabrotica* genetics consortium: a paradigm for global cooperation in research

TW Sappington
USDA-ARS, CICGRU, Genetics Lab, ISU, Ames, IA 50011, USA, tsapping@iastate.edu

The evolution and spread of insecticide- and rotation resistance, the introduction and spread of the western corn rootworm (*Diabrotica virgifera virgifera*) in Europe, and the recent large-scale commercial deployment of rootworm-active *Bt* corn in North America have generated a growing sense of urgency among scientists involved in rootworm genetics research. These are all complex problems, with a number of researchers in several countries working on various aspects. In the last year, a group of more than 35 scientists from 25 different institutions in the U.S., Canada, France, and Germany have come together to form the *Diabrotica* Genetics Consortium. The main role of the Consortium is to facilitate communication among those working on related problems, both to avoid unnecessary overlap of effort and to reveal opportunities for synergism through cooperation/collaboration. It is founded on the principle that open communication of research goals, activities, findings, and future plans is in the best interest of all concerned and in the best interest of advancing science. The scientists comprising the Consortium are committed to sharing information and ideas in an atmosphere of mutual trust, respect, and sensitivity to the essional needs of one another in accord with the highest ideals of scientific endeavor.

Induction and transmission of Bt-tolerance in the flour moth *Ephestia kuehniella*

O Schmidt, MM Rahman, HLS Roberts
Insect Molecular Biology, University of Adelaide, Glen Osmond, SA 5064, Australia.
otto.schmidt@adelaide.edu.au,

The use of *Bacillus thuringiensis* endotoxins to control insect vectors of human diseases and agricultural pests is under threat from the possible evolution of resistance in major pest species. In addition to high levels of resistance, produced by receptor insensitivity, several cases of tolerance to low to medium levels of toxin have been reported in laboratory colonies of lepidopteran species. Since the molecular basis of some of these cases of tolerance to the toxin are not known, we explored alternative mechanisms. Here we present evidence that tolerance to a Bt-formulation in a laboratory colony of the flour moth *Ephestia kuehniella* can be induced by pre-exposure to a low concentration of the Bt-formulation and that the tolerance correlates with an elevated immune response. The data also indicate that both immune induction and Bt-tolerance can be transmitted to offspring by a maternal effect and their magnitudes are determined by more than one gene.

Effects of reduced prey choice caused by GM plants on a predatory insect

TH Schuler[1], A Clark, GM Poppy, I Denholm
[1]Division of Plant and Invertebrate Ecology, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, UK; tanja.schuler@bbsrc.ac.uk

Bt plants are highly toxic to certain pest species. Predatory insects may be affected by the reduced abundance of target pests if sufficient alternative prey is not available. This paper will present experiments investigating such indirect effects under laboratory conditions. Lacewing (*Chrysoperla carnea*) larvae were released into large cages containing Bt and wildtype plants previously infested with a constant number of diamondback moth (*Plutella xylostella*) eggs but different numbers of aphids (*Myzus persicae*). No *P. xylostella* larvae survived on Bt plants but aphid populations reached high densities on both plant types. Lacewings recovered from Bt plants at the end of the experiment did not differ in weight from ones recovered from wildtype plants. At the highest initial aphid densities there was also no difference in the proportion of lacewings surviving on the two plant types. Significantly fewer lacewings were recovered from Bt plants than from wildtype plants as initial aphid numbers were reduced. Interestingly, however, numbers of *C. carnea* recovered from wildtype plants were only significantly correlated with numbers of surviving *P. xylostella* at the highest aphid densities. Possible roles of escape behaviour of *P. xylostella* as well as cannibalism between *C. carnea* larvae in these interactions will be discussed.

The effect of spinosad on different developmental stages of Colorado potato beetle *Leptinotarsa decemlineata* (Say) (Col.: Chrysomelidae)

M Mohammadi Sharif , *MJ Hejazi*
Department of Plant Protection, Faculty of Agriculture, Tabriz University, Tabriz, 51666-4888, Iran. msharif@tabrizu.ac.ir

The Colorado potato beetle (CPB) *Leptinotarsa decemlineata* is a major insect pest of potatoes. In this study we investigated the effect of spinosad on egg, larval and adult stages of CPB. A strain of CPB was collected from Ardabil, where this pest was reported for the first time from Iran in 1984; and was reared in greenhouse conditions. Bioassays were conducted using eggs, neonates, 1st, 2nd, 3rd and 4th instar larvae as well as adults. In preliminary experiments, no ovicidal effect was observed. The concentrations used for treating the larval stages and adults ranged from 1-80 ppm. To estimate the LC values, each treatment was replicated 4 times. Bioassays were conducted at 26 ± 1 °C and 16:8 (L:D) h photoperiod in transparent plastic containers. The mortalities were recorded 24 hrs after treatment. Based on probit analysis of the data, LC_{50}s were 2.1, 3.2, 4.6, 6.5, 20.2 and 12.0 ppm and the estimates for LC_{90} values were 8.0, 12.9, 17.0, 30.1, 67.8 and 30.2 ppm for neonates, 1st, 2nd, 3rd and 4th instar larvae and the adults, respectively. If spinosad also performs well in the field, this insecticide will be a suitable candidate for CPB management programs in the region.

Laboratory selection for resistance to Bt toxins in the European corn borer: potential and limitations

BD Siegfried, HAA Siqueira, AP Alves, EJG Pereira, NP Storer
202 Plant Industry Building, Department of Entomology, University of Nebraska Lincoln, NE 68506-0816. bsiegfried1@unl.edu

Transgenic maize hybrids expressing toxins from *Bacillus thuringiensis* have been available for managing European corn borer (*Ostrinia nubilalis* Hübner) populations since 1996. However, there is concern that this technology will result in widespread resistance to Bt toxins. The "high dose-refuge strategy" is the currently accepted method for managing resistance in *O. nubilalis* and has become a requirement of registration for all transgenic events. However, this strategy is based on a number of assumptions that are difficult to validate until resistance is identified and characterized. Resistant strains resulting form laboratory selections provide a potential tool to assess these assumptions in the absence of field derived resistant populations. However, such laboratory experiments are limited by their inability to reflect the selection intensity imposed on a field population exposed to transgenic plants. Our laboratory has been selecting *O. nubilalis* by exposure to Bt toxins incorporated into an artificial diet since 1998. A number of different colonies that vary with regard to the nature of the resistance, degree of dominance, number of genes and ability to survive on transgenic plants have been developed. The relevance of these strains in terms of their ability to improve and refine resistance management recommendations will be discussed.

Insecticide mode of action classification: a key to insecticide resistance management

CA Staetz
Insecticide Resistance Action Committee (IRAC International) (FMC Corporation), P.O. Box 8, Princeton, New Jersey, 08543, USA,
charles_staetz@fmc.com

The Insecticide Resistance Action Committee (IRAC) has developed a classification scheme for insecticides (and acaricides) that is based on mode of action (MoA). Experience has shown that effective insecticide resistance management (IRM) strategies seek to minimise the selection for resistance for any one type of insecticide or acaracide. In practice, alternations, sequences or rotations of compounds from different MoA groups provide a sustainable and effective approach to IRM. This ensures that selection for resistance through the use of compounds in the same MoA group is minimised. It is recognized that insecticide resistance can also result from enhanced metabolism by enzymes within the pest, reduced penetration of the pesticide into the pest or behavioural changes of the pest. These resistance mechanisms are not linked to any site of action classification, but are specific for individual compounds or chemical groupings. Despite this, alternation of compounds from different chemical classes remains an entirely viable resistance management technique because such a practice will always minimise selection pressures. This presentation describes the mode of action classification scheme and its use in IRM.

Insecticide resistance surveillance of disease vectors in Peru

JD Stancil, *C Flores Mendoza*
NMRCD, UNIT 3800, APO, AA 34031, USA, stancil@nmrcd.med.navy.mil

Vector-borne diseases, such as malaria and dengue, are significant public health problems in many countries of South America, including Peru. While environmental modifications and infrastructure improvements to reduce vector populations are the ideal, the reality in many areas of the world is that insecticides play a crucial role in vector suppression. Resistance to these insecticides can potentially interfere with vector control operations. In Peru, there is little information concerning insecticide resistance in *Anopheles darlingi* or *Aedes aegypti*, the principal vectors of malaria and dengue, respectively. Utilizing the CDC bottle bioassay, personnel from the U.S. Naval Medical Research Center Detachment, Lima and the Peruvian Instituto Nacional de Salud, have conducted over 3,300 assays of over 70,000 *An. darlingi* and *Ae. aegypti* mosquitoes to establish diagnostic concentrations for 8 insecticides representing 3 chemical classes. In addition to the assays, a workshop was held to train 22 technicians from 11 regional reference laboratories in Peru on the CDC bottle bioassay methodology. The goal of these assays and training is to ultimately establish a national insecticide resistance monitoring program and assist the Peruvian health authorities in implementing effective vector control programs.

Mechanisms underlying mite outbreaks following imidacloprid applications: effects on mite fecundity and natural enemy communities in landscapes.

A Szczepaniec, M Raupp
4112 Plant Sciences Bldg., Univ. of MD, College Park, MD 20742, USA , ada0708@umd.edu

Imidacloprid, a chloronicotinoid insecticide has become one of the most widely used products for insect control. It provides excellent control for many pests; however, following the elimination of the primary pest, secondary infestations of mites have been observed. The mechanisms underlying this phenomenon are thought to include alterations in mite fecundity levels stimulated by sublethal levels of the insecticide (hormoligosis), and disruption of natural enemy communities. To investigate the effect of imidacloprid on beneficial insects, we examined the influence of the insecticide on longevity and survival of a general predator, *Orius insidiosus*, and abundance and diversity of natural enemies on imidacloprid treated plants. Hormoligosis in boxwood mite (*Eurytetranychus buxi*) was also investigated. *Orius insidiosus* was shown to be negatively affected by imidacloprid in plants. However, the study of insect diversity and abundance indicated that beneficial insect communities differed only slightly between imidacloprid treated and untreated sites. Moreover, we were able to create increased densities of mites and attendant damage in the absence of predators. The results of the study suggest that the mechanisms leading to increased mite populations involve several aspects of mite and natural enemy ecology and, possibly, changes in mite or plant physiology.

Delayed resistance to Bt crops: is Arizona's story unique or universal?

S Morin, JA Fabrick, MS Sisterson, L Antilla, M Whitlow, Y Carrière, TJ Dennehy, BE Tabashnik.
Department of Entomology, University of Arizona, Tucson AZ, 85721, USA. brucet@ag.arizona.edu

Transgenic cotton producing *Bacillus thuringiensis* (Bt) toxin Cry1Ac that kills pink bollworm, *Pectinophora gossypiella*, has accounted for more than half of Arizona's cotton since 1997. Despite the wide use of Bt cotton and surprisingly high frequency of pink bollworm resistance to Cry1Ac detected in 1997, Bt cotton has remained extremely effective against pink bollworm. Laboratory bioassays show that the frequency of resistance to Cry1Ac did not increase from 1997 to 2003. Field-based estimates also show sustained efficacy during this period. In laboratory-selected strains with up to 3,100-fold resistance to Cry1Ac and survival on Bt cotton plants, resistance is linked with three recessive mutations in the gene encoding a cadherin protein that binds Cry1Ac. DNA-based monitoring of field-sampled individuals using the polymerase chain reaction (PCR) indicates that the frequency of the three identified resistance alleles remains low. Other examples of delayed resistance to Bt crops have been reported from Australia, China, and elsewhere in the USA. Factors delaying pest resistance to Bt crops include refuges of non-Bt crops, low initial resistance allele frequency, recessively inherited resistance, fitness costs, and incomplete resistance. The success of Bt crops exceeds expectations of many, but does not preclude future resistance problems.

Construction of transgenic *Bombyx white egg-1* mutant introduced kynurenine 3-monooxygenase gene

I Kobayashi, G Quan, K Uchino, K Kojima, T Kanda, T Shimada, T Tamura
NIAS, Owashi1-2, Tsukuba, Ibaraki 305-8634, Japan, ttamura@affrc.go.jp

Bombyx white egg 1 mutant (*w-1*) is characterized by the white colour egg and eye. It was known that the mutant kynurenine 3-monooxygenase gene possesses a partial in the exons. To understand an effect of complementation of wild type *KMO* gene, we introduced *KMO* cDNA with the promoter of native *KMO* or cytoplasmic actin gene (*A3*). We obtained three transgenic lines with A3 promoter and one line with the native promoter. The adult eyes of these lines turned to be brown and the eggs laid by the transformed females were also brown. The analysis by RTPCR showed that the lines with *A3KMO* gene accumulated the transcript in the mid gut, fat body and Malpighian tubes. A line with *KMO* promoter expressed it only in the fat boy and Malpighian tubes. The strength of eye and egg colour in the transgenic line was proportional to the *KMO* expression level. Interestingly, the transgenic larvae with *A3KMO* gene changed the larval skin colour more brownish. These results suggest that the morphological change in *w-1* mutant is caused by a deletion of *KMO* gene. The mutant and *KMO* gene can be used as a host and marker for a construction of transgenic silkworm.

Presence of avidin and aprotinin in the bodies and frass of *Spodoptera litura* (Lepidoptera: Noctuidae) larvae feeding on transgenic tobacco plants.

LA Malone, JH Todd, JT Christeller, RM Marshall, EPJ Burgess, BA Philip
HortResearch, Mt Albert Research Centre, Private Bag 92169, Auckland, New Zealand, jtodd@hortresearch.co.nz

To determine whether herbivorous insects and their frass could be environmental sources of novel proteins from transgenic plants, *Spodoptera litura* larvae were fed on transgenic tobacco leaves expressing either the biotin-binding protein, avidin, or the protease inhibitor, aprotinin. Control larvae received non-transgenic tobacco. Samples of 20 larvae each were taken on Days 5, 6 and 7 and two samples of frass on Days 6 and 7. Insects in all treatments grew significantly between Days 5 and 7, but the avidin-fed larvae were significantly smaller and produced less frass than the others on Day 7. All insects produced more frass on Day 7 than on Day 6, but the mass of frass produced per mg insect did not vary from day to day. Both novel proteins were present in larvae at lower concentrations than in the transgenic leaves they had fed upon. Unbound avidin was found in the samples of avidin-fed larvae and their frass. Aprotinin was detected in all larval and frass samples from insects fed aprotinin-tobacco. Unbound aprotinin accounted for only a portion of that found in larvae and in frass.

Bollgard® II cotton, tested for the first time in West Africa, shows excellent lepidopteran control and potential for improved cotton production

O Hema, O Traoure, D Sanfo
Programme Coton / INERA 01 B.P. 208 Bobo- Dioulasso 01 Burkina Faso

Field studies were conducted in Burkina Faso during the 2003 cropping season to evaluate the efficacy, against lepidopteran insects, of cotton expressing two endotoxins of *Bacillus thuringiensis* subsp. *kurstaki* (Berliner), commonly known as Bollgard® II cotton. Bollgard® II, treated against sucking and piercing pests only, was compared, in two research stations, to local varieties treated against lepidopteran insects and sucking pests. Our data showed that Bollgard® II cotton provided control of major lepidopteran species that attack cotton in Burkina Faso. The average number of bollworm larvae per plant over time was significantly different between transgenic cotton (treated against sucking pests only) and a local variety (treated against lepidopteran insects and sucking pests). The average number of *Helicoverpa armigera* larvae per Bollgard® II plant was reduced by 92% when compared to the local varieties. Bollgard II and the local spraying regimen were similarly highly effective in reducing foliar feeding lepidopterans. The difference in damage by lepidopteran insects, resulted in fewer abscissions of floral and fruiting bodies and higher numbers of bolls per plot in the Bollgard® II cotton. In Frako-Bâ and Kouaré evaluation sites, Bollgard® II cotton rendered a yield 13% and 19% higher, respectively, than the commercial local variety.

Bt crops in Argentina: efficacy and resistance management

GW Videla.
Dorrego 487 (2700) Pergamino, Argentina. guillermo.w.videla@la2.monsanto.com

Bt crops began to be de-regulated in 1998 (Bt Cotton: MON 531; Bt Corn: E 176, and MON 810). In 2001, Bt 11 was also authorized. Both Bt crops have steadily increased their acreages. Last season, 45 % of the corn area was planted with Bt corn, and 20% of the cotton was Bt. Bt corn produces Cry1Ab protein, and Bt cotton produces Cry1Ac protein. Corn and cotton producing areas do not significantly overlap, and the only lepidopteran pest in common for both crops in the country is *Spodoptera frugiperda*. Target pests for Bt-cotton are: *Alabama argillacea*, *Heliothis virescens/Helicoverpa gelotopoeon* complex, and *Pectinophora gossypiella*. For Bt-corn, the target species is *Diatraea saccharalis*. The Insect Resistant Management (IRM) group proposes strategies for the management of Bt crops, based on local and external experiences. Research is conducted by third party entomologists from Universities, and National Research Institutes. Mainly, the the strategy is based on a required refuge (non-Bt crop), which is 20% for Bt-cotton, with the possibility of insecticidal-non-Bt applications as needed, according to economic thresholds. For Bt-corn, the requirement is 10% refuge without any insecticides for the target pest. IRM strategy also considers studies such as baselines, emergency plans, monitoring, and continuous studies related to the size of the refuge, that will be discussed during the presentation.

Altered gene expression levels linked to fenvalerate resistance in cotton bollworm, *Helicoverpa armigera*

CW Wee, DG Heckel
CESAR-Centre for Environmental Stress and Adaptation Research, Department of Genetics, University of Melbourne, Victoria 3010, Australia
(c.wee@pgrad.unimelb.edu.au)

The ANO2 strain of *Helicoverpa armigera* is 50-fold resistant to the pyrethroid insecticide fenvalerate; largely due to a single gene, *RFen1*, on Linkage Group 13. The cDNA-AFLP technique was used to search for changes in gene expression levels controlled by or linked to *RFen1*. Larvae from a segregating backcross family were genotyped at a linked marker locus, enabling prediction of their fenvalerate resistance status without exposure to insecticide. mRNA was isolated from individual larvae and used to make cDNA, which was processed for AFLPs (double restriction digestion, ligation to adapters, amplification by two rounds of PCR, and resolution of labelled fragments on a sequencing gel). 256 different primer combinations were tried and a total of 426 bands showing differences between resistant and susceptible groups were identified. Three were cytochrome p450s, with similarity to *Depressaria pastinacella* CYP6AE1 and *Helicoverpa armigera* CYP4S1 and CYP4AP1. The latter was upregulated whereas the other two were down-regulated in the resistant group. In addition, two carboxylesterases were down-regulated and one was up-regulated in the resistant group. Currently, real time RT-PCR is being used to verify the results and full length sequences of these potential detoxification genes are being sought using rapid amplification of cDNA ends (RACE).

Bt: Organic production – new life for the oldest commercial biopesticide.

ME Whalon
Department of Entomology and Center for Integrated Plant Systems, Michigan State University, East Lansing, Michigan, USA. E-mail: whalon@msu.edu
Fax: 517-353-5598

The Organization for Economic Cooperation and Development predicts that biopesticide may grow to 20% of the world's pesticide market by 2020. Biopesticides represent approximately 1% of the world pesticide market, and Bt products represent > 75% of biopesticides sold. Other organizations like the World Health Organization, Food and Agriculture Organization and European Commission are also predicting dramatic growth for biopesticides over the next 10-20 years. Sprayable Bt formulations have penetrated cotton, fruit and vegetable, aquatic and other insecticide markets in the US, EU and the world. Organic producer dependence on Bt for worm and, in a more limited fashion, beetle control globally. In fact, many organic workers claim that Bt is more important to the organic community than to other producers because conventional producers have a greater array of management tools to choose from. With organic produce sales increasing steadily worldwide, Bt use and resistance management should be an important consideration in any system that anticipates frequent application, but especially in organic production systems where use can be extreme. Fortunately, the organic formulation of Spinosad™--a fermentation macrocyclic lactone product, is changing management practices in many cropping systems and this may change Bt's organic market dominance. In addition, new insect growth regulators and other novel modes of action may be entering the organic market in the next few years providing new opportunities to implement truly integrated management programs in organic production.

The international arthropod resistance database and newsletter: a report

M Whalon, R Hollingworth, D Mota-Sanchez
Michigan State University, East Lansing , MI 48823, USA. Whalon@msu.edu

A number of resources related to resistance management have been cultivated at Michigan State University in the USA. This presentation will highlight these developments and how resistance workers all over the world can access and participate. The first of these is the Resistant Pest Management Newsletter (RPM News), which has a worldwide circulation of roughly 2,500 resistance workers in academia, industry, and government. It provides information on ongoing changes and advances in the field of resistance management, and is produced in cooperation with the Insecticide Resistance Action Committee (IRAC), the US Department of Agriculture (CSREES) and the US Western Regional Coordinating Committee (WRCC-60). Our goal in implementing a resistance database is to help address arthropod resistance by evolving an integrated, cooperative system to effectively deliver resistance information efficiently. Our information currently resides in an electronic database at Michigan State University's Center for Integrated Plant Systems and is available via the Internet at http://www.cips.msu.edu/resistance/rmdb/. The database design features a central table of 'resistance' records with five key pieces of information: the arthropod, the pesticide, the location (country), the year, and a reference to the document reporting the case. There are secondary tables that elaborate on these five key informational groups as well as auxiliary tables to help refine the information further or link to external data sources.

Juvenile hormone bioanalogs – selectivity, importance and perspectives in insect pest management

Z Wimmer, J Kuldová, I. Hrdy, B Bennettová
Institute of Organic Chemistry and Biochemistry AS CR, Flemingovo náměstí 2, CZ-16610 Prague 6, Czech Republic. wimmer@uochb.cas.cz

Insect juvenile hormone bioanalogs (JHAs, juvenoids) have been the target of the long-term research in our team for many years. A special interest has been paid to several series of 2-(4-hydoxybenzyl)cycloalkanols for their high biological activity values obtained in screening tests to a broad variety of insect species. Even if a number of these JHAs have been proven to be stable but non-persistent under the environmental conditions, designing of ways for limited increase of their stability in environment and for modification of their physico-chemical properties had been performed. This effort resulted in designing and developing the pioneer hormonogen substances (juvenogens). The juvenogen molecule consists of a JHA, bearing convenient functionality, which can be easily transformed into another functionality by chemical means or by enzymic ways. This step results in a synthesis of a biologically inactive or low active substance, which is characterized by physico-chemical properties different from those found with the parent JHA. The new substance, a juvenogen (a hormonogen chemical species), can be prepared as a targeted species, a substance bearing physico-chemical properties designed in advance. This strategy enables to synthesize "juvenogens upon demand", which are designed for application on selected insect species under selected laboratory or environmental conditions.

UK-wide studies of biodiversity impact of GMHT crops

IP Woiwod
Plant and Invertebrate Ecology Division, Rothamsted Research, Harpenden, Hertfordshire AL5 2JQ, UK, Ian.Woiwod@bbsrc.ac.uk

By the end of 1998 four genetically modified herbicide-tolerant (GMHT) crops were nearing the end of the regulatory hurdles for commercial growing in the UK. Although human health and direct environmental effects had been assessed and they had been declared safe the question was raised about indirect environmental effects caused by more efficient weed control. The result was the Farm Scale Evaluations, one of the largest agro-environmental impact studies ever undertaken, covering plant and invertebrates at 60-70 field sites for each of 4 crops over a three year period. The background and results from these trials will be discussed in relation to wider issues about insect biodiversity in agricultural landscapes.

Current status and future prospect of Bt cotton commercialization in China

K Wu, *Y Guo*
Institute Of Plant Protection, Chinese Academy Of Agricultural Sciences, Beijing 100094, China, wkm@caascose.net.cn

Transgenic cotton that expressed a gene derived from the bacterium *Bacillus thuringiensis* (Bt) was introduced for combating *H. armigera* in 1997, and rapidly increased to 58% of the total cotton area of 4.8 million ha. in 2003. In the Yellow River cotton-farming region of Northern China, where *H. armigera* has historically caused major yield losses, Bt cotton has been exclusively planted. The pest management tactics associated with Bt cotton planting causes astic reduction in use of insecticides due to the high efficacy of the transgenic cultivars in suppression of *H. armigera* infestations, increases the abundance of beneficial insects and improves the natural control of some pests. The monitoring results indicate that movement toward Bt cotton resistance in *H. armigera* is not apparent in face of intensive planting of Bt cotton over several years, which could be associated with the migratory behavior of the insect and the natural refuges derived from the mixed planting system of cotton, corn, soybean and peanut on single- family holdings with a small scale under one half hectare.

The involvement of microsomal oxidases in pyrethroid resistance in *Helicoverpa armigera* from Asia

Y Yang, Y Wu, S Chen, GJ Devine, I Denholm, P Jewess, GD Moores
Department of Entomology, College of Plant Protection, Nanjing Agricultural University, Nanjing 210095, P.R.China, wyd@njau.edu.cn

Five contemporary strains of the bollworm *Helicoverpa armigera* Hübner from China, Pakistan and India, all with high resistance to pyrethroids, were compared with a standard susceptible strain that originated from the Cote D'Ivoire in the 1970s ('SCD'). The strong synergism of pyrethroids by PBO implied that an oxidative metabolism could be involved in pyrethroid resistance in all resistant strains. The activities of cytochrome P450 monooxygenases from midguts of final instar larvae to *p*-nitroanisole (PNOD), ethoxycoumarin (ECOD), methoxyresorufin (MROD) significantly increased in all the resistant strains when compared with the susceptible strain. This further implies that cytochrome P450 monooxygenases are involved in pyrethroid resistance in Asian *H. armigera*. Comparative *in vitro* studies of the metabolism of ^{14}C-deltamethrin by midgut microsomes of the resistant PAK and susceptible SCD strains showed that the resistant strain had a much greater capacity than the susceptible strain for the metabolic degradation of deltamethrin. This enhanced metabolic degradation occurred in the presence of NADPH which suggested an oxidative detoxification. In the resistant strains, minor increases in glutathione S-transferase activity (to the substrates CDNB and DCNB), and esterase activity (to the substrate α-naphthyl acetate) further suggested that, of the putative metabolic mechanisms, oxidases are the most important. This study provides the first evidence that cytochrome P450 monooxygenases are a major metabolic mechanism responsible for pyrethroid resistance in *H. armigera* from Asia.

Bt rice studies of ecological risk and nontarget effects in China

GY Ye, HW Yao, ZC Liu, M Chen, CY Jiang, H Cui
State Key Laboratory of Rice Biology, Institute of Applied Entomology, Zhejiang University, Hangzhou 310029, China, chu@zju.edu.cn

Bt rice has been permitted for field trials since 1998. After then, impacts of our different Bt rice lines containing *cry*1Ab or *cry*1Ab/*cry*1Ac gene with high resistance against rice stem borers and leaffoles, on the arthropod community and population dynamics of some dominant nontarget phytophages and spiders under field conditions was evaluated using different sampling methods. The results showed that our Bt rice lines generally did not have any significant negative effects on the arthropod community in rice paddy habitat, except that sometime resulting in the marked decrease in the abundance of some parasitoids of target pests such as braconids and ichneumonids. These tested lines also did not act any adverse impacts on the predation, growth and development, reproduction of two common spiders, *Pirata subpiraticus* and *Ummeliata insecticeps,* using either leaffolders or planthoppers feeding on Bt rice plants as their prey. In contrast, some Bt rice lines might not be suitable for the brown planthopper, *Nilaparvata lugens* to feed and lay eggs. In addition, no significant adverse effects were found on the survival, growth and development as well as the fecundity of the domestic silkworm, *Bombyx mori* fed with the mulberry leaves contaminated by Bt rice pollen grains.

In vivo effect of PBO on resistance-associated esterases from Australian *Helicoverpa armigera* Hübner (Lepidoptera: Noctuidae)

SJ Young, RV Gunning, GD Moores
Rothamsted Research, Harpenden, AL5 2JQ, UK graham.moores@bbsrc.ac.uk

Piperonyl butoxide (PBO) is a commercially important and successful insecticide synergist against a variety of insects in house-hold situations and against public health pests. In agriculture use has been restricted to use against the cotton bollworm, *Helicoverpa armigera* (Hübner) (Lepidoptera:Noctuidae). It has been deployed in the field to help partially restore the efficacy of pyrethroids that are currently compromised by metabolic based resistance. It has been established that PBO inhibits some insect esterases associated with insecticide resistance (Gunning *et al.*, 1998; Moores *et al.*, 1998; Young *et al.*, 2002; Young *et al* 2003). Kinetic esterase assays using *H. armigera* reveal that esterase activity was inhibited by the insecticide synergist, PBO, over a 24hr period. Esterase inhibition by PBO did not occur immediately after doseage but occurs with maximum enzyme inhibition being obtained several hours later. Laboratory analysis with *H. armigera* and pyrethroids confirmed that maximum synergism occurred at the pre-treatment times corresponding to maximum *in vivo* esterase inhibition in biochemical studies. These results were confirmed in the field when using a 5 hr pre-treatment of PBO prior to pyrethroid exposure. These results indicate that with improved temporal application of PBO, it may be possible to restore some pyrethroid efficacy in *H. armigera*. It would also be expected that partial restoration of efficacy with other conventional insecticides currently compromised by esterase based resistance mechanisms would occur.

PTD significantly synergize Bt and overcome the low resistance of diamondback moth to Cry1Ac

YJ Zhang , FS Yang , QJ Wu, BY Xu , J Zhang, DW Qiu , GR Zhu
Institute of Vegetables and Flowers, Chinese Academy of Agricultural Science, Zhongguancun South Street, Beijing 100081 China, zhangyj@mail.caas.net.cn (or youjunzhang@hotmail.com)

Protein Transduction Domains (PTD) are kinds of peptides which can automatically penetrate bio-membrane and be acted as a carrier to transfer foreign molecule into cell(Science. 1999,285(3):1569-1572.). A fusion gene,pET21b-TAT-Cry1Ac, consisting of Cry1Ac and TAT(a kind of PTD) ,as well as its control pET21b-Cry1Ac was constructed and expressed in E.coli. The toxicity of this two expressed and purified fusion proteins to Diamondback moth were determined. To the susceptible strain the LC50 of Cry1Ac and TAT-Cry1Ac are 20.55 mg/L and 4.25 mg/L; and 124.23mg/L and 12.81 mg/L to the low resistant strain. TAT-linked Cry1Ac show a synergistic ratio of 4.84 folds to the susceptible strain, 9.70 folds to the resistant strain, and restore the susceptibility of low resistant Diamondback moth to Cry1Ac. PTD show strong potential in synergizing Bt insecticidal protein and overcoming Bt resistance.

Fluctuating asymmetry of target and non-target insects in response to the stress of GM cotton

BP Zhai, N Li, XD Liu, L Meng
Department of Entomology, Nanjing Agricultural University, Nanjing 210095, P.R. China

Fitness and fluctuating asymmetry (FA) in response to the stress of GM cotton were examined among the different symmetric characters of target and non-target pests (cotton bollworm, *Helicoverpa armigera*, CB, and cotton aphid, *Aphis gossypii*) and a beneficial species (Asian lady beetle, *Harmonic axyridis*, ALB). The results indicate that non-target effects do arise from some GM cultivars. The FA values of CB in lab decreased gradually generation by generation. The light-trap catches of CB collected in northern China with different planting history of Bt-cotton (1~5 years) also exhibited a similar trend on FA. Bt-cotton and conventional cotton are equally suitable hosts for cotton aphid. The fitness and FA of ALB and cotton aphid were similarly when fed on the aphids from both Bt-cotton and conventional cotton. But the Bt+CpTI cotton present significant impacts on the fitness of cotton aphid that their intrinsic rate of increase and fecundity decrease significantly in the first and second generation. The aphids feeding on Bt+CpTI cotton showed higher FA and their feeding behavior detected by EPG is different significantly with Bt-cotton and conventional cotton. The possibility of FA as a sensitive indicator for the ecological risk and environmental stress of GM crops are discussed.

"P450 from multiple insect genomes: from phylogeny to function"

R. Feyereisen, E. Deleury and C. Abgrall
"INRA UMR1112 Centre de Recherches de Sophia Antipolis, 400 route des Chappes, BP167 06903 Sophia Antipolis cedex, France rfeyer@antibes.inra.fr"

"Cytochromes P450 are enzymes involved in the metabolism of signal molecules such as ecdysteroids, juvenile hormones and pheromones, and in the response to chemical stresses of the environment (insecticides, plant secondary compounds). P450 are encoded by genes from a very large family, the CYP genes. *Drosophila melanogaster* has 85 CYP genes with 5 pseudogenes (http://P450.antibes.inra.fr). In the mosquito, *Anopheles gambiae*, only 10 P450 gene orthologs were found vs the predicted ±40. Results on the P450 genes from the genomes of *Drosophila pseudoobscura*, *Apis mellifera* and *Bombyx mori* will be presented. The current assembly of the honeybee genome reveals significantly fewer P450 genes in this insect when compared to the three Diptera and the silkworm. Mitochondrial P450 genes of insects are particular when compared to mitochondrial P450s of vertebrates, because some of them (CYP12) behave like environmental response genes (multiple genes, no 1:1 orthology between species, inducibility) whereas others are involved in steroid hormone metabolism (the Halloween genes). Microsomal P450 genes involved in conserved, endogenous functions can also be identified by orthology, following their characterization in one species. The case of the P450 involved in juvenile hormone biosynthesis is an example that will be discussed.
"

Insecticide resistance and its management in the cotton bollworm *Helicoverpa armigera* in Pakistan

M Ahmad
Central Cotton Research Institute, Multan, Pakistan, mush_a@yahoo.com

The cotton bollworm, *Helicoverpa armigera* (Hubner) (Lepidoptera: Noctuidae) is a key pest of cotton and other crops in Pakistan. Indiscriminate use of pesticides prompted the development of insecticide resistance in this pest. Resistance to pyrethroids has been on the rise since 1991. Resistance factors are now >100 to all the pyrethroids. Endosulfan resistance remained moderate to high. However, some thiophosphates and carbamates mostly exhibited low levels of resistance. We never ran out of options for the control of *H. armigera*. The latest introduction of new chemistries with novel modes of action added to the effective armory. An IRM strategy including other IPM tactics has been recommended to the cotton growers for the better control of *H. armigera* and other cotton pests.

Mutations in acetylcholinesterase (AChE) of the cotton melon aphid (*Aphis gossypii* Glover) and the peach potato aphid (*Myzus persicae* Sulzer) confer resistance.

MC Andrews, A Callaghan, LM Field, GD Moores.
Rothamsted Research, Harpenden, Herts., UK, AL5 2JQ. Melanie.anews@bbsrc.ac.uk

Two mutations in the *ace1* gene of *Aphis gossypii* are associated with insensitivity of acetylcholinesterase (AChE) to carbamate and organophosphate insecticides. The first of these, S431F (331 in *Torpedo californica* numbering), is associated with insensitivity to the insecticide, pirimicarb. The mutation to a phenlyalanine is consistent with a loss of sensitivity to pirimicarb in a range of both *A. gossypii* and *M. persicae* clones. A rapid RFLP diagnostic allows the identification of individuals of both aphid species with a resistant genotype. This diagnostic further reveals the presence of S431 in several other pirimicarb-susceptible aphid species. The serine at this position in the wild-type enzyme has only been reported for aphids and is considered the reason why pirimicarb has a specific aphicidal action. A second mutation, A302S (201 in *T. californica*), confers insensitivity to a wide range of carbamates and organophosphates and has, to date, only been found in resistant strains of *A. gossypii.*

Stem application of monocrotophos in okra: dissipation of monocrotophos residues

ML Kiranmai, *T Ramesh Babu*
Acharya N.G. Ranga Agricultural University, Hyderabad 500 030, Andhra Pradesh, India, tatinenir@yahoo.com

The status of residues of monocrotophos at harvest and its dissipation pattern in okra fruits when employed as stem application at the rate of 1:6 (one part of monocrotophos in six parts of water) were studied in a field experiment. The residues of monocrotophos were below detectable level (BDL) during first picking when the stem application was imposed at or before 38 days after germination (DAG). The repeated application, even during fruiting, evidently established the cumulative residues of monocrotophos in okra fruits. The residues (0.57 ppm) recorded in okra fruits on first day of stem application accumulated up to 3rd day (2.21 ppm) and dissipated gradually to maximum residue level (MRL) of 0.2 ppm with Ttol. of 11.27 days. Therefore stem application of monocrotophos in okra should be restricted to 12 days prior to picking of fruits.

Effects of cypermethrin and chlorpyrifos residues in cattle dung on the development of the dung beetle *Copris tripartitus* (Coleoptera: Scarabaeidae)

HS Bang, JH Lee, GS Kyung, OS Kwon, YE Na, SJ Hwang
NIAST, RDA, Suwon 441-100, Korea, Banghs1@rda.go.kr

Fresh dung was collected from untreated cattle and cattle dosed with a spray-on formulation of cypermethrin and chlorpyrifos (2.1g /cow) on days 1, 3, 5 and 7 post-treatment. The dung was bioassayed using the dung beetle *Copris tripartitus* Waterhouse. Residues of cypermethrin and chlorpyrifos were sufficient to inhibit oviposition by *C. tripartitus* in day 1 dung but there was no significant effect on egg laying in dung collected at days 3-7 post-treatment in sexually matured female. But, in the second generation residues of cypermethrin and chlorpyrifos were sufficient to inhibit oviposition by *C. tripartitus* in treatment after 1 and 3 days. Although there was no significantly different effect on egg laying in dung collected at days 3-7 post-treatment in first breeding but, in second breeding, toxic effect reveal in 3 and 5 days dung treatments. Nulliparous dung beetles fed for 200days on dung collected 0, 1 and 3 days after treatment of cow with cypermethrin and chlorpyrifos show little ovarian development.

Effect of ecdysone agonists on tortricid male/female orientation

BA Barrett, J Hoelscher
1-87 Agriculture Bldg., University of Missouri, Columbia, MO 65211, USA, BarrettB@missouri.edu

The attractiveness and responsiveness of adult codling moth, *Cydia pomonella* (L.), redbanded leafroller, *Argyrotaenia velutinana* (Walker), and obliquebanded leafroller, *Choristoneura rosaceana* (Harris), exposed to surfaces treated with the ecdysteroid agonist methoxyfenozide were investigated in wind tunnel and orientation tube assays. When males were exposed to water-treated surfaces for 48 h the mean percent recaptures of such treated males in the wind tunnel assay were almost always (depending on species) significantly greater than the recaptures of males that had been exposed to methoxyfenozide-treated surfaces. Similarly, in the orientation tube assay, methoxyfenozide-treated males almost always had significantly lower mean levels of individuals exhibiting sexual excitability (intense wing fanning and upwind orientation) and mean distances traveled upwind in the orientation tubes. The two assays demonstrated that males exposed to methoxyfenozide-treated surfaces were not as responsive to calling females (treated and non-treated) as were the non-treated males. Conversely, females exposed to methoxyfenozide-treated surfaces were just as attractive to non-treated males as were water-treated females. It appears that a male's ability to respond to a calling female is more negatively affected by the ecdysone agonist than a female's ability to call and attract males.

Assessing the role of cytochrome P450s in insecticide resistance of *Lucilia cuprina*, *Helicoverpa armigera*, and *Drosophila melanogaster*

PJ Daborn, C Robin, Z Chen, J Fair, CJ Wee, V Grubor, L Willoughby, DG Heckel, P Batterham
Centre for Environmental Stress and Adaptation Research, Department of Genetics, The University of Melbourne, Victoria 3010, Australia
p.batterham@unimelb.edu.au

Cytochrome P450 are heme containing enzymes that perform a diverse array of REDOX reactions against exogenous and endogenous compounds. Characterised insect genomes have approximately 90-100 individual cytochrome P450 genes and the biological function for most of these is unknown. Previous studies have implicated the over-expression of some cytochrome P450 genes in insecticide resistance via metabolic degradation. Using degenerate PCR and cDNA library sequencing, we have cloned and characterised a number cytochrome P450 genes from the Australian sheep blowfly (*Lucilia cuprina*) and the cotton bollworm (*Helicoverpa armigera*), two insect pests of Australia. We have generated a micro-array of these cytochrome P450 genes, and are characterising the expression of these genes at different life cycle stages and in different tissues. We are also using - micro-array and realtime quantitative PCR to compare the expression levels of cytochrome P450 genes between resistant and susceptible strains. Our studies in *L. cuprina* and *H. armigera* are complemented by studies in *osophila melanogaster*. Using a micro-array containing all 90 *D. melanogaster* cytochrome P450 genes, we are studying gene induction by insecticides. We are over-expressing induced cytochrome P450 genes, and determining if over-expression can confer insecticide resistance.

Novel genetic basis of field-evolved insect resistance to Bt toxins

SW Baxter, JZ Zhao, LJ Gahan, AM Shelton, BE Tabashnik, DG Heckel
CESAR, Department of Genetics, University of Melbourne, Parkville, Victoria 3010, Australia.
s.baxter3@pgrad.unimelb.edu.au

Insecticidal toxins from *Bacillus thuringiensis* (Bt) are widely used in sprays and transgenic plants to control insects that attack crops and transmit diseases, but evolution of pest resistance threatens their continued efficacy. Diamondback moth (*Plutella xylostella*) is the only pest that has evolved Bt resistance in open field populations, although several others have been selected for resistance in the laboratory or glasshouses. The most common type of resistance (Mode 1) is characterized by recessive inheritance, >500-fold resistance to at least one Cry1A toxin, and negligible cross-resistance to Cry1C. The primary mechanism of Mode 1 resistance is reduced binding of Bt toxins to midgut membrane target sites. Mutations affecting a Cry1A-binding midgut cadherin protein are tightly linked to laboratory-selected Mode 1 resistance in two major pests, *Heliothis virescens* and *Pectinophora gossypiella*. The cadherin gene has thus been considered the prime target for DNA-based screening for resistance. Here we show that field-evolved Mode 1 resistance in diamondback moth has a different genetic basis, indicating that screening for resistance in the field should not be restricted to searching for cadherin mutations.

Managing pest resistance to Bt crops in India

JS Bentur, GT Gujar

Directorate of Rice Research, Hyderabad 500 030, AP India, jbentur@yahoo.com and Division of Entomology, Indian Agricultural Research Institute, New Delhi 110012, India, gtgujar@yahoo.com

Bt transgenic cotton first introduced in India in 2001 was cultivated on over 100,000 hactares in 2003. Besides, other Bt transgenic crops such as rice, egg plant, cole crops, pulses are in various stages of development. The target pest for Bt cotton is the American bollworm, *Helicoverpa armigera* and for Bt rice it is yellow stem borer (YSB), *Scirpophaga incertulas*. Based on the baseline toxicity data against the former in India and estimation of frequency of resistance alleles in the populations of YSB in the Philippines, it appears that these two species can rapidly buildup resistance against the Bt endotoxins. Bt resistance management for transgenic cotton is made mandatory requirement for the growers who have to maintain 20% refuge crop or minimum of 5 rows around the Bt cotton field, whichever is larger. However, in view of inadequate knowledge and expertise among the farmers, small land holdings and apprehension of expected reduction in yield due to non Bt lines, farmers tend to ignore the refuge cultivation. Studies on the baseline susceptibility of the American bollworm to Cry1Ac have helped in the monitoring of resistance in the Bt cotton. Similar studies are being done in other crops too. We feel, Bt resistance management should include detailed studies on various characteristics of Bt resistance in local pest populations of the target pests, and explore possibilities of field level management in tandem with the local agronomic practices and environmental conditions.

Bt maize effects on butterflies.

MR Berenbaum
Dept. Entomology, 320 Morrill Hall, University of Illinois, 505 S. Goodwin, Urbana IL 61801-3795, USA, maybe@uiuc.edu

Transgenic plants have been widely adopted by U.S. farmers despite concerns about potential nontarget impacts of this technology. The possibility that maize (*Zea mays*) genetically engineered to express *Bacillus thuringiensis* endotoxoin for control of European corn borers (*Ostrinia nubilalis*) may have impacts on non-target lepidopterans through pollen drift onto neighboring non-agricultural plants has received considerable attention. Since initial concerns about Bt corn were raised by a laboratory study, additional studies both in the field and the laboratory have revealed the remarkable complexities of accurately assessing risks of pest management practices in agroecosystems. These studies are examined in the context of ecological, economic, social, and cultural factors that affect food production and pest management in the United States.

The relative fitness of Bt resistant and susceptible *Helicoverpa armigera* **– implications for the refuge strategy**

LJ Bird, RJ Akhurst
CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia. lisabird@csiro.au

Transgenic crops producing the Cry1Ac toxin of *Bacillus thuringensis* (Bt) was introduced in Australia, China and India primarily for the control of *Helicoverpa* spp. As *Helicoverpa armigera* has a demonstrated capacity for developing resistance to many synthetic insecticides, development of resistance to Bt toxins remains the biggest threat to the sustainability of transgenic technology. The refuge strategy has been widely adopted to counter the onset of resistance. This strategy is most effective when resistance is conferred by rare, recessive alleles and when mating of heterozygotes in prevented. Under these conditions, the evolution of resistance can be substantially delayed. However, we have found evidence that two of these conditions are not always met. Results from glasshouse experiments have demonstrated that, although resistance in *H. armigera* is functionally recessive on young Cry1Ac cotton, attenuation in toxin expression results in survival of heterozygous genotypes on late season Cry1Ac cotton. Our resistant strain of *H. armigera* takes longer to develop on cotton that expresses high levels of Cry1Ac than their susceptible counterparts on non-Bt cotton. However, loss of potency in older cotton plants mitigates asynchrony in late season insect populations. The implications of these findings for resistance management of Bt crops will be discussed.

Novel approaches for controlling mosquitoes using natural inhibitors for trypsin modulating oostatic factor

D Borovsky
University of Florida, IFAS, FMEL, 200 9th St SE, Vero Beach Florida 32962, USA, dobo@mail.ifas.ufl.edu

Trypsin Modulating Oostatic Factor (TMOF) is a mosquito decapeptide that modulates trypsin biosynthesis in mosquitoes, flies and *Heliothis virescens*. Feeding the hormone and its analogues to mosquito and *H. virescens* larvae stopped trypsin biosynthesis in their midgut by binding a specific gut receptor and controlling the translation of the trypsin message. Cytoimmunochemical analyses show that the hormone is not only synthesized in the ovary as was initially hypothesized, but is also found in the central nervous system cells of adults and larvae. Since the hormone affects the growth and development of mosquito larvae the hormone and several analogues have been cloned and expressed in chlorella, yeast (*Saccharomyces cerevisiae* and *Pichia pastoris*) and Alfalfa cells to control insects using biorational insecticides. These results and the effect of the transformed cells on larval growth and development will be discussed.

Fluorometric PCR applications to insecticide resistance analysis in disease vectors.

WG Brogdon, AE Lenhart, G Groner, RA Wirtz
Entomology Branch F42, DPD, NCID, Centers for Disease Control and Prevention, 4770 Buford Highway NE, Atlanta, Georgia 30341, USA wgb1@cdc.gov

As insect genomes are published, molecular techniques have begun to be widely applied for the detection and assessment of insecticide resistance. Vectors develop insecticide resistance through mutations of insecticide target sites, such as the voltage-gated sodium channel, and increased activity of detoxification enzymes such as oxidases and esterases. The ability to use preserved or desiccated field-collected insects makes molecular analysis of insecticide resistance an especially attractive option. A useful approach to measuring all of these mechanisms is fluorometric PCR. This method allows detection of resistance mechanisms based on point mutations at the insecticide target site, resistance gene amplification, or increased expression of resistance genes. Knowledge of resistance gene sequence is a prerequisite in the development of these methods. Our efforts to apply quantitative PCR to detection, measurement and assessment of insecticide resistance in an assortment of disease vectors are summarized. The same molecular methods that serve to detect resistance are also central to the determination of population genetic relationships of the resistance alleles. We discuss our present state of knowledge of molecular markers and insect genomes as they relate to insecticide resistance.

Tri-trophic prey-mediated impacts of insect-resistant tobacco on a predatory carabid beetle

EPJ Burgess, BA Philip, LA Malone, JT Christeller
HortResearch, Private Bag 92169, Auckland, New Zealand, eburgess@hortresearch.co.nz

Larvae and adults of a New Zealand endemic predatory beetle, *Ctenognathus novaezelandiae*, were fed an exclusive diet of prey (*Spodoptera litura*) reared on control tobacco, or transgenic tobacco expressing either a protease inhibitor (PI) or a biotin-binding protein (BBP). BBP prey-fed beetle larvae accumulated greater mass than the other 2 treatments over a 7-week period in the middle of the 14-week experiment. Over the entire experiment, the mean biomass of BBP-fed larvae was greater than that of PI- but not control-fed larvae. There were no differences among treatments in larval survival or quantity of prey consumed. Adult female beetles grew larger and survived longer than males in all 3 treatments. Combined gender adult mean biomass over 40 weeks was the same for all 3 treatments. However, control-fed females had greater total biomass than PI or BBP-fed females, but control-fed males had less biomass than males given the other treatments. Over the entire experiment, BBP-fed adults consumed slightly less than the other 2 treatments. Fecundity was low in all 3 treatments and there were no differences among them. The greatest adult differences detected were between genders rather than among treatments, where analysis of data collected weekly showed only minor and transient effects.

Analysis of acetylcholinesterase insensitivity in California insect pests

F J Byrne, NC Toscano
Dept of Entomology, University of California, Riverside, CA92521, U.S.A., frank.byrne@ucr.edu

Acetylcholinesterases are important members of the serine hydrolase super-family of enzymes and are the targets of the organophosphate (OP) and carbamate insecticides. Although the future use of these insecticides in California is somewhat uncertain, due to the FQPA, they are still widely used in agriculture, both as stand-alone insecticides, and as synergists of the pyrethroid insecticides. As a consequence of their widespread and varied usage, OP and carbamate resistance has been identified in many important pests. Acetylcholinesterase insensitivity is an important mechanism of resistance to these insecticides, and cross-resistance within these chemical groups is not uncommon. We have conducted extensive studies on resistance in several important California insect pests. In this presentation, we will describe our studies on two pests – the beet armyworm (BAW), *Spodoptera exigua*, and the glassy-winged sharpshooter (GWSS), *Homalodisca coagulata*. The BAW has been long-established in California agriculture, whereas the GWSS is a recent introduction. These two pests differ in their pesticide exposure histories and this seems to be a contributing factor in their relative susceptibilities to OPs and carbamates. The effectiveness of OPs and carbamates for the management of these pests is discussed based on our toxicological and biochemical studies.

Activity profiles of neonicotinoid insecticides in plants and implications for IPM

SJ Castle, FJ Byrne, NC Toscano, JL Bi, N Prabhaker, JC Palumbo
USDA-ARS, 4135 E. Broadway Road, PHOENIX, AZ 85040, USA, scastle@wcrl.ars.usda.gov

The duration that an insecticide residue is active in a crop in terms of lethal and sub-lethal effects on insect populations is a critical concept in pest management that has been poorly developed. Application rates, the timing and spacing of applications, and the choice of materials could all be influenced by more reliable information on the activity period of insecticides in crops. Commercial ELISA kits were used to determine concentrations of imidacloprid and thiamethoxam in citrus, grapes, and melons at regular intervals following soil treatment. The uptake and residual profiles differed significantly for both compounds in all crops. Peak concentrations of imidacloprid in xylem fluid of large citrus trees were not attained until 6-8 weeks after application compared to 2 weeks for thiamethoxam. However, near-peak levels of imidacloprid were sustained for 6-10 weeks before declining gradually in contrast to thiamethoxam titres (applied at ¼ the rate of imidacloprid) that declined rapidly. The same pattern of higher application rates and longer residual of imidacloprid was also observed in melons. Comparison of young vs. old leaves on primary branches of melon vines revealed much higher concentrations in older leaves, a counterintuitive finding because better whitefly control is attained on younger leaves.

Contamination of refuges by Bt toxin genes from transgenic corn

CF Chilcutt, BE Tabashnik.
Department of Entomology, Texas A&M University System, 10345 Agnes St., Corpus Christi, TX, 78406, USA, c-chilcutt@tamu.edu

Transgenic crops producing insecticidal toxins from *Bacillus thuringiensis* (Bt) are widely used to control pests, but their benefits will be lost if pests evolve resistance. The mandated high-dose/refuge strategy for delaying pest resistance requires planting refuges of toxin-free crops near Bt crops to promote survival of susceptible pests. We report that pollen-mediated gene flow up to 31 m from Bt maize caused low to moderate Bt toxin levels in kernels of non-Bt maize refuge plants. Immunoassays of non-Bt maize sampled from the field showed that the mean concentration of Bt toxin Cry1Ab in kernels and the percentage of kernels with Cry1Ab decreased with distance from Bt maize. The highest mean Bt toxin concentration in kernels of non-Bt maize plants was 45% of the mean concentration in kernels from adjacent Bt plants. Most previous work on gene flow from transgenic crops has emphasized potential effects of transgene movement on wild relatives of crops, lanaces, and organic plantings, while implications for pest resistance have been largely ignored. Variable Bt toxin production in seeds of refuge plants undermines the high-dose/refuge strategy and could accelerate pest resistance to Bt crops. Thus, guidelines should be revised to reduce gene flow between Bt crops and refuges.

Insect comparative genomics: a carboxyl/cholinesterase perspective

C Claudianos, RJ Russell, R Feyereisen, H Ranson, R Maleszka, JG Oakeshott
Research School of Biological Sciences, Australian National University, ACT, 0200, Australia, claudianos@rsbs.anu.edu.au

Our comparative genome analyses of principle enzyme families involved in metabolic resistance to insecticides have generated new research opportunities. The data provide a credible basis for identifying the resistance-associated enzymes of insects and the means for identifying previously unknown molecules involved in fundamental biological process such as development. Carboxyl/cholinesterase enzymes have contributed to a major part of insect biochemical and genetic research. The most notable member of this supergene family, acetylcholinesterase (AChE), is the key processing enzyme for the neurotransmitter acetylcholine. Many other esterases have now been implicated in the metabolism of specific hormones and pheromones and accordingly in various aspects of insect development and behaviour. Intriguingly, the carboxyl/cholinesterase family provides a striking example how gene duplication/radiation/deletion shape the evolution of novel biology, notably how the function of a catalytically active domain has evolved to mediate receptor-ligand interactions that regulate morphogenetic process during development of the nervous system. We have recently classified carboxyl/cholinesterases into three principle functional groups (intracellular enzymes associated to dietary detoxification; secreted enzymes including those that process pheromones and hormones; receptors and enzymes involved in neuro/developmental functions). Our data (gene inventories) are also providing a template for new studies concerning the honeybee and silkworm genomes.

Characterization of CTCF proteins in mosquitoes

CE Gray, CJ Coates
Texas A&M University, MS 2475, College Station, TX 77843-2475, USA; c-coates@tamu.edu

CTCF (CTCCC-binding factor) is a multivalent, multifunctional transcription factor well characterized in vertebrates. Of particular interest is its association with every known vertebrate insulator and its emerging role in epigenetic regulation. Endogenous mosquito insulators would be valuable elements to flank transgene insertions, inhibiting both position effect and position effect variegation, thus allowing for more consistent gene expression. CTCF-like cDNAs were cloned, expressed and characterized from the medically important mosquitoes *Aedes aegypti* and *Anopheles gambiae.* The gene is transcribed constitutively in all developmental stages and appears to be up-regulated both in the ovaries from blood-fed females and in early embryos. Putative binding sites for the *An. gambiae* protein were determined *in-vitro* using PCR-assisted binding site selection and confirmed in gel-shift assays. ChIP (chromatin immunoprecipitation) assays are currently in progress. Additionally, an RNAi experiment to knockdown expression both in *An. gambiae* adult females and in *osophila melanogaster* females and early embryos, followed by RNA isolation and hybridization to microarray chips is being performed to identify specific CTCF targets. The results of these experiments will be presented.

Esterase mediated cross resistance between pyriproxyfen and buprofezin in B-biotype *Bemisia tabaci* in Australia

ELA Cottage, RV Gunning
NSW Agriculture, Tamworth Agricultural Institute, Tamworth, NSW, 2340, Australia. Emma.Cottage@agric.nsw.gov.au

B-biotype *Bemisia tabaci* was first detected in Australia in 1994. B-biotype *B. tabaci* is a severe pest worldwide and poses a serious threat to many ornamental, agricultural and horticultural industries in Australia. Control of B-biotype *B. tabaci* is hampered by resistance to many conventional insecticides. Consequently, insect growth regulators such as buprofezin and pyriproxyfen are important insecticides in managing this pest. Field resistance has been detected to both insecticides with cross resistance between the two as well. Studies have shown resistance to buprofezin in B-biotype *B. tabaci* to be esterase mediated and experiments were designed to investigate the potential of pyriproxyfen to bind to *B. tabaci* esterases. Esterase inhibition experiments showed inhibition by pyriproxyfen was greater in the buprofezin resistant strain than in its unselected counterpart. Concentrations as low as 0.321nM pyriproxyfen gave 70-80% inhibition of resistant *B. tabaci* esterases. Cross resistance between IGRs with different modes of action poses a grave threat to the viability of the management strategy of silverleaf whitefly in Australia.

Efficacy of novaluron for Colorado potato beetle control and potential for resistance development.

GC Cutler, JH Tolman, CD Scott-Dupree, CR Harris
Department of Environmental Biology, University of Guelph, Guelph, ON, N1G 2W1, Canada; cutler@uoguelph.ca

Novaluron (RimonÒ 10EC), a novel insect growth regulator, could play a key role in development of practical integrated pest management (IPM) programs for Colorado potato beetle (CPB), *Leptinotarsa decemlineata* (Say). In laboratory tests, novaluron exhibited potent insecticidal activity against CPB larvae (e.g. 2nd instar (L2) LC_{50} = 0.42 ppm). Furthermore, the insecticidal activity of a single novaluron application was highly persistent under field conditions. In bioassay, 65-85% of L2 from an insecticide-susceptible laboratory strain died when fed potato foliage treated with novaluron at 25 and 50 g a.i./ha, respectively, 28 days after application. Thus, the selection pressure for novaluron-resistant CPB may be intense long after population densities have been reduced below an economic threshold level. Studies were also conducted to identify geographic variability and potentially problematic CPB populations before the widespread use of novaluron in the field. The susceptibility of L2 to novaluron was determined for 27 different populations collected from 6 Canadian provinces in summer of 2003. Despite no previous exposure to novaluron, the populations differed considerably in susceptibility with mortalities at a diagnostic dose ranging from 55-100%. Our results suggest that despite the potential of novaluron in CPB management, the possibility of rapid development of resistance exists.

Bemisia tabaci, **biotypes and insecticide resistance management.**

GJ Devine, M Hadjistylli, D Ma, K Gorman, I Denholm
Plant and Invertebrate Ecology Division, Rothamsted Research, England.

Many insect species exist as a complex of biotypes that can be differentiated by a variety of genotypic or phenotypic parameters. Some of these are of ound importance in pest management. For example some biotypes of the cotton whitefly (*Bemisia tabaci*) appear to be associated with different ecological, behavioural and insecticide-resistant characteristics. The processes that mediate the balance and evolution of such co-existing forms are neither well-described nor understood. It is clear however, that in some instances, the evolution of biotypes among pest species is influenced by the tools used for their control (e.g insecticides). In an effort to understand the factors that influence the dynamics of co-existing biotypes and how these impact upon the implementation of management strategies and the dynamics of insecticide resistance, we examine Mediterranean populations of *Bemisia tabaci*. We present work that characterises insecticide resistance in recently collected strains of 'B' and 'Q' biotypes, and examine the ability of these forms to introgress (by observing courtship behaviour, mating success, hybrid sex ratio and hybrid fecundity). We examine the consequences of such introgression for the inheritance of insecticide resistance.

Hydolysis of organophosphorus and pyrethroid insecticides by insect carboxylesterases modified by *in vitro* mutagenesis

AL Devonshire, RHeidari, BE Campbell, JG Oakeshott, RJ Russell
CSIRO Entomology, GPO Box 1700, Canberra, ACT, 2601, Australia

Resistance of *Lucilia cuprina* to Ops is due to mutations in the gene encoding carboxylesterase E3 that enhance its ability to hydrolyse insecticides. Mutagenesis *in vitro* and expression of these modifications (G137D and W251L) have confirmed their role. These and nearby amino acids were substituted by others expected to affect the efficiency of the enzymes in hydolysing OPs and pyrethroids. Various substitutions of W251 had a broadly similar effect to W251L on OP hydolysis, but some enhanced malathion carboxylesterase. With the exception of F309L, nearby mutations generally diminished OP hydolysis. W251L was the most effective substitution to improve permethrin hydolysis (up to 130-fold) whilst decreasing the trans:cis hydolysis ratio to favour the more insecticidal isomer Other mutations around the catalytic site generally enhanced pyrethroid hydolysis relative to the wild type, the most effective being F309L, which enhanced transpermethrin hydolysis more than W251L. Complementary assays with individual enantiomers of the dibromo analogue of cispermethrin showed the wild type and most mutants to have a marked preference for the least insecticidal 1S conformation of the cyclopropanecarboxylate, but this was reversed in mutants with the F309L substitution. The results show the potential to design such recombinant enzymes for bioremediation of insecticide residues.

Enhancing biodiversity in sugar beet through appropriate management of GMHT crops

AM Dewar
Broom's Barn Research Station, Higham, Bury St. Edmunds, Suffolk, IP28 6NP, UK, alan.dewar@bbsrc.ac.uk

The UK Farm Scale Evaluations of the environmental impact of genetically modified herbicide-tolerant (GMHT) crops reported that the biodiversity of wildlife in GMHT beet was adversely affected compared to that in the conventional crops. This was attributed to better control of weeds by glyphosate, to which the GM beet was tolerant, with knock-on consequences for the invertebrates that depended on those weeds for survival. In other separate studies on sugar beet, alternative glyphosate programmes, involving band sprays and/or delayed sprays (compared to the aft label recommendations) resulted in much weedier plots than under conventional regimes at different times in the season, with consequent benefits for some invertebrates. In many cases this was achieved with no loss of yield compared to conventional systems. Another regime that relied on one early spray of glyphosate resulted in greater numbers of late germinating weeds than in conventional sytems, and consequently greater seed production by those weeds for the benefit of seed-eating beetles and autumn-feeding birds. GMHT technology with regard to beet is so flexible that almost any scenario can be created and still allow farmers to grow a itable crop.

Ecdysteroid agonist insecticides – mechanism, selectivity and importance in IPM

TS Dhadialla
Dow AgroSciences LLC, 9330 Zionsville Road, Indianapolis, IN 46268, USA, tdhadialla@dow.com

Non-steroidal ecdysone agonists belonging to the bisacylhydrazine class of compounds are a new generation of insecticidal compounds that cause premature lethal molts in susceptible intoxicated insects. Of these, three bisacylhydrazine compounds, tebufenozide (MIMIC®, CONFIRM®, ROMDAN®), methoxyfenozide (INTREPID®, RUNNER®, PRODIGY®, FALCON®) and halofenozide (MACH 2®) have been commercialized. Both tebufenozide and methoxyfenozide are predominantly toxic to lepidopteran pests of cotton, corn and other agronomic plants. Halofenozide, a soil insecticide, is toxic to both lepidopteran and coleopteran pests. All three insecticidal compounds manifest their toxic action in susceptible insects via interaction with the ecdysone receptor, which is also the target of the insect molting hormone, 20-hydoxyecdysone. This selective toxicity of both tebufenozide and methoxyfenozide to lepidopteran pests is largely due to their high binding affinity to EcRs from those insects. The toxic action of halofenozide, which is a weak binder of EcR, is primarily due to its relatively higher metabolic stability in susceptible insects. The mode of action of the three insecticides at the whole insect, ultra-structural and biochemical levels will be discussed and data shown to demonstrate their safety to beneficial insects, mammals and the environment. The use of these insecticides in IPM and IRM programs will be emphasized.

Prodigy™ - a new IPM-compatible product for insect control in Australian crops

PR Downard, RA Annetts
Dow AgroSciences Australia Ltd Locked Bag 502, French's Forest NSW 1640 Australia, downard@dow.com.

Methoxyfenozide (formulated as Prodigy™ 240 SC and previously coded as RH 2485), is a moult-accelerating compound (or MAC), from the same chemical family as tebufenozide (Mimic™ 700 WP), a product which has been in the Australian market for many years. Methoxyfenozide is generally active at lower rates and has a wider spectrum of activity than tebufenozide, even though activity of both is strictly limited to the Order Lepidoptera. This selectivity makes methoxyfenozide an ideal candidate for use in integrated pest management (IPM) programmes as it has no direct effect on non-lepidopteran predators and parasitoids. As the only MAC compound used in Australia against helicoverpa, with no documented field resistance methoxyfenozide is a valuable new tool for inclusion in helicoverpa resistance management strategies. It's introduction reduces selection pressure on older products and further delays the onset of resistance. Development to date has focused on helicoverpa control in cotton and tomatoes, but methoxyfenozide does have several exciting possibilities. Globally, methoxyfenozide is already recognized as having excellent activity against *Spodoptera* spp. and may prove to be a cost-effective alternative for control of armyworms in a range of Australian crops (e.g. pastures, sugarcane, cereals and turf).

Gene resources for insecticide discovery

P East, M Dumancic, C Liao, S Trowell
CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia. Peter.East@csiro.au

The majority of insecticides and nematicides in current use act on only a small number of target receptors. Drawing on the resource provided by complete genome sequences, we have sought to identify and validate novel targets for nematicides and insecticides. The excitatory glutamate receptors involved in signalling at the insect neuromuscular junction are an attractive, but poorly understood candidate target. We have identified new members of this gene family from whitefly *Bemisia tabaci* and the bollworm *Helicoverpa armigera*. The availability of these gene sequences provided new insight into the diversity of excitatory glutamate receptor sub-types in insects. Pharmacological and molecular genetic approaches were used to identify novel serotonergic (5-HT$_3$) receptors regulating pharyngeal pumping in the free living nematode *Caenorhabditis elegans*. Lead compounds were assessed for their toxicity to *C. elegans*, *Myzus persicae*, *H. armigera* and *Heligosigmoides polygyrus*. A number of *C. elegans* cDNA sequences, one or more of which are believed to encode subunit(s) of the nematode's pharyngeal 5-HT$_3$ receptor were isolated. Preliminary gene knockdown data indicates that one of the cloned receptor subunits is vital for the proper development and normal pumping of the pharynx. Our data provide the first evidence for the existence of excitatory, 5-HT$_3$-like, receptors in nematodes and the first indication that receptors of this type are valid targets for pesticides.

Molecular mechanisms of phosphine toxicity and the genetics of resistance

PR Ebert, Q Cheng, N Valmas, SJ Zuryn, U Cha'on, DI Schlipalius, PJ Collins, Y Mau, W Chen, A Whan, YH Huang, HS Chiu
Department of Zoology and Entomology, University of Queensland, St Lucia, QLD 4072, Australia, p.ebert@uq.edu.au

Phosphine (PH_3) is the only globally significant fumigant available to protect stored grain from insect infestation. Phosphine is a somewhat hydophobic reducing compound that can complex with biologically significant metal ions, partially disrupt mitochondrial function and induce cytotoxic levels of oxidative stress. Despite a complex array of potential modes of action, strong resistance (600X) to this compound in the pest insect, *Rhyzopertha dominica*, is achieved with resistance alleles at only two loci, neither of which negatively affects fitness. Phosphine resistant mutants generated in the model organism, *C. elegans*, have an unusually long lifespan. One of these mutants is completely resistant to the toxic effect of hyperoxia in conjunction with an otherwise sublethal exposure to phosphine. Mutant and wild type nematodes exhibit no differences in terms of phosphine induced changes to either mitochondrial morphology or ATP levels. The mutant, however, appears to be protected from phosphine induced oxidative damage to lipids. Surprisingly, genome-wide microarray analysis in *C. elegans* does not implicate mitochondrial dysfunction or oxidative stress as the primary causes of phosphine toxicity. Rather, the stress response appears to mimic the expression profiles associated with the lifespan extension mutant, *daf-2*, as well as the unfolded protein response induced by denatured proteins.

Pyrethroid insecticide resistance and treated bednets efficacy in malaria control

AA Enayati, J Hemingway
School of Public Health, Mazandaran University of Medical Sciences, Sari, Iran. Ahmadali_enayati@yahoo.com or muaae@mazums.ac.ir

Metabolic and k resistance mechanisms were characterized in An. stephensi and this easily colonized species was used to evaluate the efficacy of ITNs. Bioassays performed on 4th instar larvae showed a resistance ratio of 182. The resistance was partially suppressed by PBO (54%) and DEF (51%) or both (68%). Biochemical assays revealed that esterases, monooxigenases and glutathione S-transferase levels were 1.72, 1.86 and 1.88-fold respectively in the DUB-S compared to the susceptible strain Beech. The overall permethrin metabolism rates by DUB-S mosquitoes measured by HPLC were 1.5-fold more than by Beech strain. The classic k mutation was detected in II6 of the para-type sodium channel gene from DUB-S strain. Bioassays performed on the resistant DUB-S mosquitoes using different pyrethroid-treated bednets showed that except for deltamethrin and a-cypermethrin treated bednets, the rest of the tested pyrethroid-treated bednets at standard WHO recommended doses did not produce adequate mortality rates. The deterrency test performed on susceptible and resistant An. stephensi showed that there are significant differences between the entry rates of susceptible and resistant mosquitoes into the exposure tube containing permethrin treated bednet. These data show that when mosquitoes have both k-type and metabolic resistance mechanisms, the efficacy of pyrethroid-treated bednets is questionable.

Update on the honey bee genome project

JD Evans and the Honey bee Genome Sequencing Consortium
USDA-ARS Bee Research Lab, Beltsville, MD USA 20705, evansj@ba.ars.usda.gov

Along with their longstanding importance for agriculture, honey bees (*Apis mellifera*) have been important models for behavior, physiology, ecology, and genetics. They play a considerable role in evolutionary comparisons across insects and in attempts to understand the forces that lead to, maintain, and challenge insect societies. A aft sequence for the honey bee genome was funded in 2002 by the U.S. National Institutes of Health, and Department of Agriculture, following a 'white paper' competition to identify compelling eukaryotic sequencing targets. The project began that year at the Baylor College of Medicine Human Genome Sequencing Center (www.hgsc.bcm.tmc.edu), with input from individual scientists and the Sanger/Wellcome Trust. The current assembly (version 1.1, January 2004) reflects 1.25 Gbp of mainly short-insert (shotgun) sequences, giving an estimated 6.0-fold coverage of the 210 Mbp genome. The assembly is comprised of 11,600 scaffolds (N_{50} = 223 kbp) containing 30,074 contigs (N_{50} = 19 kbp). Approximately 95% of known EST's, cDNA's and markers are in this assembly. Current plans are to incorporate reads from an AT-biased library and an existing BAC library and to generate cDNA's useful for gene calling. An updated assembly and an initial gene list are anticipated by the time of this meeting.

EST analysis of genes expressed in the different tissues of the spruce budworm, *Choristoneura fumiferana*

QL Feng, T Ladd, SC. Zheng, L Li, D Buhlers, PJ Krell, BM Arif, A Retnakaran
Great Lakes Forestry Centre, Canadian Forest Service, 1219 Queen Street East, Sault Ste. Marie, Ontario, Canada P6A 2E5. qfeng@nrcan.gc.ca

More than 35,000 sequence reads have been generated from five cDNA libraries of the epidermis, midgut, fat body, whole larvae and cell line of the spruce budworm, *Choristoneura fumiferana*. These expressed sequence tags (ESTs) have been assembled into approximately 8000 unigenes using Phrap program. Annotation of these sequences has been conducted against the protein database Swiss-Prot/TrEMBL and the GenBank of NCBI. The unique sequences have been classified for their molecular function, cellular location, and biological process using the Gene Ontology classification system. A spruce budworm EST database has been established and is available to the scientific community. These annotated EST sequences will serve as a resource base for gene mining, comparative analysis and genome mapping. The ESTs have also being used for developing cDNA microarrays, which will be used to study the global gene expression in the spruce budworm in response to different stresses. This project is supported by funds of Genome Canada and Canadian Biotechnology Strategy.

Implementation and impact of transgenic Bt cottons in Australia

GP Fitt
CSIRO Entomology and Australian Cotton Cooperative Research Centre, Long Pocket Laboratories, 120 Meiers Rd, Indooroopilly, Queensland, 4068, Australia. Gary.Fitt@csiro.au

Bt cottons (INGARD®) expressing the CryIAc endotoxin, were commercialised in Australia in 1996/97 through an industry agreed deployment strategy which limits use to 30% of total cotton. A comprehensive management strategy minimises the risk of Bt resistance in *Helicoverpa armigera*, the target pest. In 6 years of commercial use Bt cottons have reduced pesticide applications for *Helicoverpa* by an average of 50%, providing major environmental benefits. Fibre quality has not been affected, while in some cases yields have increased. Despite early difficulties with variable performance, growers have rapidly adopted the technology and will gain long-term benefits through enhanced environmental sustainability, as Bt cotton is used in environmentally sensitive areas. Perhaps more importantly Bt cottons show great potential for IPM systems where a combination of soft approaches yields considerable benefits. That single gene Bt cotton has not been a "magic bullet" is fortunate in demonstrating that Bt cottons need to be introduced within an IPM system and supported by rigorous resistance management strategies. Two-gene Bt cottons expressing Cry 1Ac and Cry 2Ab (Bollgard II) have now been commercialised and will replace INGARD® in 2004/5. BGII provides enhanced efficacy and further reductions in pesticide requirement with associated environmental benefits. BGII also bring reduced resistance risk, but will remain part of a conservative resistance management strategy similar to that for INGARD varieties.

Pleiotropic effects of insecticide resistance genes in an aphid pest on vulnerability to attack by parasitoid wasps

SP Foster, I Denholm, W Powell
Plant and Invertebrate Ecology Division, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, UK. stephen.foster@bbsrc.ac.uk

Studying the phenomenon of insecticide resistance provides a rare and valuable insight into the fundamental processes underlying evolution as resistance often appears over short timescales in human terms. In effect, this process represents a classic case of 'forced evolution' and as a result can produce resistance mechanisms that have negative pleiotropic effects on fitness in the absence of insecticides. The paper describes experiments done at different spatial scales measuring the vulnerability of insecticide-susceptible and –resistant peach-potato aphids (*Myzus persicae*) to attack by the parasitoid, *Diaeretiella rapae*. It also discusses the potential impact of the findings on Integrated Pest Management strategies utilising beneficial insects.

Insect AChE

D Fournier
IPBS 205 route de Narbonne 31077 Toulouse, France, fournier@ipbs.fr

Two genes encode acetylcholinestesterase (AChE) in insects, but only one seems to be expressed in the synapse of the central nervous system. Protein is a dimer anchored to the presynaptic memebrane via a glycolipid. Structure has been solved for the *Drosophila* enzyme, the active site is buried 20 Å inside the protein, at the bottom of a narrow gorge. This structure results to complex kinetics resulting from the traffic of substrate and products in the active site gorge. Another consequence of this structure is the sensitivity to insecticide: insect AChE is more sensitive to insecticide than its vertebrate counterpart. This property has been used to design biosensors to detect insecticide residues and the enzyme has been engineered to improve its capacity of detection. Extensive use of insecticides resulted in insecticide resistance. Several mutations have been evidenced. They often combined in the same site resulting in an enzyme more resistant and with a broader spectrum of resistance. Mutations affected enzyme efficiency : they decrease or increase the limitating step of substrate hydolysis, deacetylation and decreases enzyme stability. This alteration of enzyme has been compensated in most of strains by an overproduction of the enzyme.

First season of methoprene application mirroring Fire Ant Control Centre treatment program has not had any prompt deleterious effects on the native soil invertebrate assemblage.

TN Fuessel, KP Plowman, CH Wild,

School of Environmental and Applied Science, Griffith University Gold Coast Campus, PMB 50 Gold Coast Mail Centre , Queensland 9726.

t.fuessel@griffith.edu.au

In response to the accidental introduction of the invasive ant *Solenopsis invicta* (Buren) to Brisbane, Australia, an eradication program was mounted. This program employs a range of chemicals including the insect growth regulators methoprene and pyriproxifen, which though specific to invertebrates and intended solely for *S. invicta*, may have deleterious effects on other invertebrates. The impact of Methoprene on soil invertebrates and nutrient cycling is being evaluated using a control-impact study conducted in eucalyptus woodlands where *S. invicta* is absent. Methoprene is applied to treatment sites following Fire Ant Control Centre procedure, with 3 applications of 2 kg/ha each treatment season (November to April). Soil samples are collected: before treatment; and one month after each subsequent treatment over two treatment seasons (Nov 2002-May 2004). Soil invertebrates are extracted and sorted to morphospecies to form a community dataset for each site. Due to their numerical dominance, and also importance for processes such as decomposition and nutrient cycling, only the mite component of the invertebrate community will be reported here. Results at the completion of the first treatment season indicate that the application of Methoprene is not associated with a decrease in any of the diversity parameters. Community data are also analysed using ordination techniques to investigate whether the actual species composition is influenced by methoprene application.

Large-insert BAC libraries for fundamental studies in Lepidoptera

MR Goldsmith, C Wu, HB Zhang

Biological Sciences Department, University of Rhode Island, Kingston, RI 02881-0816, mki101@uri.edu and Department of Soil and Crop Sciences and Institute for Plant Genomics and Biotechnology, Texas A&M University, College Station, Texas 77843-2123, USA

The tobacco hornworm, *Manduca sexta*, the tobacco budworm. *Heliothis virescens*, and the Müllerian mimic, *Heliconius erato*, are well-established lepidopteran models for studying fundamental problems in olfaction, neurobiology, and development (*M. sexta*), evolution of insecticide resistance and plant host specialization (*H. virescens*), and wing pattern mimicry (*H. erato*). We have constructed two separate BAC libraries for each species using *Bam* HI and *Eco* RI partial digestion. Average insert sizes of *Bam* HI and *Eco* RI libraries are 152 kb and 165 kb for *M. sexta*, 171 kb and 150 kb for *H. virescens*, and 175 kb and 153 kb for *H. erato*, with <5% non-recombinant clones. Genome coverage totals an estimated 12.9x for *M. sexta*, 16.3x for *H. virescens* and 15.4x for *H. erato*. We are screening the libraries with well-conserved single-copy genes to better estimate genome coverage and obtain BAC clones to use as anchor loci for comparative studies. All libraries are publicly available at http://hbz.tamu.edu. We are indebted to L. Riddiford, F. Gould, and O. McMillan for insects, and M. Cornwall and N. Pierce for vouchering specimens. Supported in part by NSF grant no. IBN-0208388 to MRG, HBZ, and CW.

Functional genomics of the midgut of the cotton bollworm, *Helicoverpa armigera*

KHJ Gordon, PD East
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia, karl.gordon@csiro.au

The Lepidopteran insect, *Helicoverpa armigera,* or cotton bollworm, is a major pest of agriculture worldwide. Many control strategies involve orally-transmitted control agents that target the larval midgut. A functional genomics study of this organ has the potential to increase understanding of its molecular and cellular biology and to identify new targets for pest control. We have undertaken an EST project to identify genes important for midgut function, growth and development and gene/enzyme pathways involved in insect-plant and insect-pathogen interactions. Sequence analysis of midgut cDNA libraries now covers ~5,000 ESTs each from young (2nd and early 3rd instar) and from 5th instar larvae. Clustering yielded a unigene set of ~3,900 contigs. Searches against the UniProt (EBI) database and model organism proteomes yielded confident Gene Ontology annotation for ~55% of the contigs. These include genes associated with key midgut functions: digestive hydolases; nutrient and ion transport and pH maintenance; a range of detoxification enzymes and genes forming the peritrophic membrane or involved in midgut cell proliferation, differentiation and adhesion. Many have not previously been identified in lepidopteran systems. Additionally, comparison with silkworm ESTs identified likely orphan lepidopteran genes. Microarrays based on the non-redundant gene set are being established for expression iling studies.

Pesticide resistance in Brazil and IRAC-BR activities: current situation and perspectives

PCRG Marçon, AC Santos, F Orsi, RNC Guedes, C Omoto
IRAC-BR, Caixa Postal 168, Mogi Mirim, SP 13.800-970, Brazil, guedes@ufv.br

Recognition of pesticide resistance problems in Brazil dates of the late 1960s, but it was not followed by further studies until the 1990s, when the interest was renewed due to reports of insect-pest control failures. The establishment of the Brazilian Insecticide Resistance Action Committee (IRAC-BR) in 1997 was a reflex of this concern and provided new impetus to pesticide resistance studies in the country. The major activities of the IRAC-BR have been centered on institutional, research and educational programs. The institutional program is based on the promotion of the Committee and its activities, while the research program establishes priorities and provides support for projects of interest. At present, the research effort is centered in two long-standing projects, *Tuta absoluta* in tomatoes and *Spodoptera frugiperda* in maize/cotton, and several other shorter-term projects. The educational program provides basic training in Insecticide Resistance to a diverse public. Annually, IRAC-BR offers short-courses, workshops, lectures and round-table discussions in different regions of the country. IRAC-BR also sponsors a National Research Award, in two categories, undergraduate and graduate research projects. This award was created to stimulate creativity, positive criticism and human resource formation in Insecticide Resistance Management in Brazil. These initiatives from IRAC-BR have been well received in Brazil and the fruits from this effort are beginning to ripen.

Esterases mediate resistance to biological insecticides in *Helicoverpa armigera*

RV Gunning, ME Balfe, GD Moores
Tamworth Agricultural Institute, RMB 944, Calala Lane, Tamworth, NSW. 2340 Australia, robin.gunning@agric.nsw.gov.au

The cotton bolloworm *Helicoverpa armigera* is a serious pest of cotton and other summer crops in Australia, where it has a long history of insecticide resistance to most insecticides. Particularly critical for Australian agriculture was the evolution of pyrethroid resistance. Pyrethroid resistance which was found to be largely due to overproduction of specific esterase isoenzymes (R_m 0.24 - 0.33), which sequester and hydolyse pyrethroids. Modern pest resistance management strategies have incorporated new biological insecticides with novel modes of action. Such biological insecticides are spinosad and *Bacillus thurlingiensis* toxins and as well insecticidal proteins of B thurlingiensis which have been incorporated into genetically engineered plants. Nonetheless, there is an enduring threat of resistance. *H. armigera* has already developed resistance to spinosad and some CRY toxins and in this paper we report esterase mediated resistance mechanisms.

A microsomal esterase confers insecticide resistance in *Spodoptera littoralis*

O Gurkan, P Jewess, G Moores
Rothamsted Research, Harpenden, Herts UK AL5 2JQ and Ankara University, Faculty of Agriculture, Plant Protection Dept. Ankara, Turkiye.
Oktay.gurkan@bbsrc.ac.uk

Spodoptera littoralis (Lepidoptera: Noctuidae) (Boisduval), the Egyptian cotton leafworm, is a major pest of cotton and vegetable crops in Mediterranean Europe and Africa. A field strain collected from cotton at Adana in Turkey was found to have a resistance factor of 8-fold against chlorpyrifos by leaf dip bioassay. Preliminary studies of AChE sensitivity against chlorpyrifos-oxon indicated no evidence of insensitive AChE. An enhanced microsomal esterase was revealed that correlated with the observed resistance when compared to a susceptible standard strain. We report here on the purification and kinetic parameters of this microsomal esterase.

Transgenic corn and rootworm: ecology, evolution and management.

CA Guse, DW Crowder, DW Onstad
607 E. Peabody Champaign, IL USA 61820, cguse@uiuc.edu, (217) 265-5008

The western corn rootworm in North America depends almost exclusively on corn for larval survival and adult nutrition. Two-year crop rotations were very effective at controlling rootworms since oviposition historically only occurred in corn. In recent years however, crop rotation has failed in the corn-belt east of the Mississippi river. Adults in this region lay eggs in fields other than corn and because of rotation these eggs hatch in corn the following year. The change in the behavior of adult rootworms resulted in the increased use of insecticides and a renewed interest in developing ecologically sound control strategies. We report on a series of modeling efforts that examined how land use lead to the evolution of behavioral changes in adults and how landscape diversity and weather patterns contribute to the dispersal and ultimate distribution of this rotation resistance variant in North America. We then examine a variety of control options combining cultural practices with transgenic crops and other crop technologies to simultaneously manage rotation resistance and the risk of developing resistance to transgenic corn. The results were sensitive to landscape diversity, toxin dose, expression of resistance, initial allele frequency and density-dependent larval survival.

EST-cDNA clones were mapped based on RFLP in the silkworm, *Bombyx mori* L.

W Hara
NIAS, Ohwashi1-2, Tsukuba Ibaraki, 305-8634, Japan, whara@affrc.go.jp

We have developed the genetic analysis by using molecular markers based on restriction fragment length polymorphism (RFLP) in the silkworm, *Bombyx mori*.. In the silkworm there is no crossover on female chromosomes, so a (RF02 x RF50) female was crossed to a RF02 male and from this BC_1 segregant more than 250 ug individual DNAs were prepared and used to know their genotypes. Every clone gave homozygous or heterozygous genotype for each individual and the patterns for each clone of 15 BC_1 segregants could be identified from each other. After the 28 patterns for every chromosome were made, every new clone was easily to know their linkage group from the genotyping of 15 individuals. After linkage analysis, all clones were mapped by using the 100 segregants of the cross between a (RF02 x RF50) male and a RF02 female. From all of the genotypes, non-recombinant individuals are those with either all A, homozygous, or B, heterozygous, but recombinant individuals have both A and B. The linear order of clones is known after data is sorted and distance between clones determined by counting the recombinants. Now about 300 cDNA clones have been mapped on molecular genetic map.

Molecular tools for reconstructing the past and predicting the future of insecticide resistance

C Hartley, R Russell, A Devonshire, D Yeates, J La Salle, R Newcomb, J Oakeshott
CSIRO Entomology, GPO Box 1700, Canberra ACT 2600 Australia

We have been using the tools of modern biotechnology to reconstruct the past and predict the future course of the evolution of metabolic resistance to organophosphorus (OP) insecticides in the higher dipterans *Lucilia cuprina* (Calliphoridae) and *Musca domestica* (Muscidae). Resistance in both species is due to mutations that convert a carboxylesterase enzyme into a catalytically inefficient but physiologically protective phosphotriesterase. There are a pair of allelic mutations in each species which give resistance to structurally distinct sets of OPs. The two mutations involve the same substitutions in the same residues of orthologous proteins in the two species. In order to reconstruct the history of the resistance we have been using PCR to clone and sequence the gene involved from preserved museum specimens over an 80 year temporal transect. This transect goes back over 20 years before the first use of OP insecticides. We find that at least one of the resistance alleles existed in natural populations before the introduction of the pesticides. In order to predict the future course of resistance we have been using the tools of directed *in vitro* evolution and rational enzyme design in attempts to improve the catalytic efficiency of the extant natural mutants. We have now been able to recover *in vitro* mutants which are catalytically superior in the degradation of OPs.

The management of cotton aphid (*Aphis gossypii* Glover) in Australian cotton

GA Herron, LJ Wilson
NSW Agriculture, PMB 8, Camden 2570, Australia, grant.herron@agric.nsw.gov.au

Until recently, cotton aphid, *Aphis gossypii* Glover, has been a persistent but readily controlled secondary pest of Australian cotton. However, during the 1998-1999 cotton-season, control failures linked to resistance were reported for organophosphate and carbamate insecticides, with some populations controllable only with diafenthiuron. Since then resistance hotspots have developed annually over eastern Australia that have only been controllable with new chemistries. The reasons for this are complex and include seasonal differences in rainfall patterns affecting over wintering host availability for aphids and a reduction in insecticide use, particularly endosulfan, with the coincident introduction of transgenic cotton. In response, aphid management has been multi-faceted and based on a complex integrated pest management (IPM) approach. This includes an Integrated Resistance Management Strategy (IRMS) that has recently been altered to better manage the selective aphicide pirimicarb. This useful IPM chemical is usually quickly lost to high-level target site resistance but we aim to manage it through improved tactical product use.

Chemical control of western flower thrips in Australia

GA Herron, SM Broughton, AD Clift
NSW Agriculture, EMAI, PMB 8 Camden NSW 2570, Australia, grant.herron@agric.nsw.gov.au

Insecticides are the main method used by commercial growers to control Western flower thrips (WFT) *Frankliniella occidentalis*, **in Australia. However, as has occurred overseas, WFT are resistant to a number of insecticides and insecticide groups. Furthermore, the current field application rates of many insecticides used in Australia may be too low to be effective. This would increase selection for resistance, because insecticides are being applied at sub-lethal doses. To test this, we carried out a series of field trials. Crops tested included ornamentals, tomatoes, lettuce, strawberries, cucumber and capsicum. Six key chemicals (abamectin, acephate, dichlorvos, endosulfan methidathion and pyrazophos) were evaluated. All field trials were integrated with insecticide resistance monitoring to remove the confounding effects of chemical resistance. Field trials confirmed that many application rates used for WFT were too low to be effective. Resistance monitoring showed that abamectin, methiocarb, and pyrazophos are the only chemicals where resistance was not detected. Low-level resistance was detected against acephate, dimethoate, endosulfan, fipronil, methamidophos, methidathion and spinosad. Increasing levels of resistance were detected against chlorpyrifos, dichlorvos and maldison.**

The GMO guidelines project - developing the science in risk assessment of transgenic plants

A Hilbeck, *D Andow*
Swiss Federal Institute of Technology, Geobotanical Institute, Zürichbergstrasse 38, CH-8044 Zürich, Switzerland. Email: angelika.hilbeck@env.ethz.ch

The GMO Guidelines Project (www.gmo-guidelines.info) has developed a conceptual framework for a methodology of case-specific ecological risk assessments of genetically modified plants. It consists of a generic framework that is constructed on five scientific sections and incorporates many different scientific disciplines: 1) Problem Formulation and Options Assessment (PFOA), 2. Transgene Expression and Locus Structure (TELS), 3. Biodiversity and Non-target Impacts, 4. Gene Flow and its Consequences, 5. Resistance Evolution and Management. The generic framework of the GMO-Guidelines is comprised of a risk assessment model, which is driven by systematically structured, detailed scientific questions. The model can be applied to any case and the information and data for answering each question tailors the assessment to the specific context yielding a case- and country-specific risk assessment. We applied the framework to three case examples: Bt-maize/Kenya, Bt-cotton/Brazil and Bt-cotton/Vietnam. In our presentation, we will briefly present the major outcomes of these case studies. Several unique features of the Project: a) We work collaboratively with scientists from developing countries and jointly conduct the case study risk assessments. Thereby, we build scientific capacity and build confidence in their own scientific capabilities; b) We frame risk assessment in a multi-stakeholder deliberative process of PFOA.

Modification of sucrose synthesis in GM aspens: effects on leaf-beetle preference.

J Hjältén, A Lindau
Department of Animal Ecology, Swedish University of Agricultural Sciences, SE-901 83 Umeå, Sweden. E-mail: joakim.hjalten@szooek.slu.se

GM forest trees potentially pose ecological problems beyond those faced by transgenic agricultural crops because: forest trees are essentially undomesticated which makes escape of transgenics to the wild more probable and trees also have long life spans, dominate the forest ecosystems and define the structure of many communities. Therefore, it is of outmost importance that we gain basic knowledge of the potential ecological effects of transgenic tree species. The aim was to determine if genetic modifications of aspens, not primarily intended to influence natural enemies, will lead to changes in the plants nutritional quality and secondary chemistry, thus effecting interactions between natural enemies (insects) and GM trees. We used GM (*Populus tremula x tremuloides*) aspens modified with respect to increased sucrose-synthesis (ZEA SPS), resulting in increased mesophyll sucrose concentration, dry mass and growth. Two different lines (different degrees of up regulation) were used and unmodified wild-type aspen served as controls. We used two common leaf feeding chrysomelid beetles, *Lochmeae caprea* and *Phratora vitellinae* in cafeteria test. *Phratora vitellinae* utilized transgenic aspens marginally less than the wildtype whereas no difference was found for *Lochmeae caprea* preference. The relationship between these results and plant primary and secondary chemistry and its implication for plant-herbivore interactions is discussed.

Biorational insecticides – important components in pest management of cotton, vegetable and ornamentals, an overview

AR Horowitz, I Ishaaya

Department of Entomology, Agricultural Research Organization, The Volcani Center, Gilat Research Station, MP Negev 85280, [2]Bet Dagan 50250, Israel, hrami@volcani.agri.gov.il

There have been efforts to develop biorational insecticides with selective properties to act on biochemical sites present only in the target arthropods and not in non-target organisms. This approach has led to the development of insecticides such as the neonicotinoids (which affect nicotine acetylcholine receptors), the benzoylphenyl ureas (BPUs) and buprofezin (which inhibit chitin synthesis), and the juvenile hormone (JH) mimics and ecdysone agonists. Compounds originating from natural products, which act on GABA gated chloride channel, glutamate receptors and the chloride channels (such as the avermectins and the spinosyns) and at the mitochondrial level (chlorfenapyr) with much more association to the insects than mammals, have been developed and used successfully to combat diverse insect pests and spider mites. Additional new groups of insecticides include the phenylpyrazoles (fipronil), the pyridines (pymetrozine) and the oxadiazines (indoxacarb), which act on GABA receptors, on the nerves controlling the salivary pump and on the sodium channel, respectively. All the above, are considered biorational, or "low risk" insecticides, which have relatively low detrimental effect on the environment and its inhabitants, rendering them important potential components in IPM programs. The selectivity of these biorational insecticides to beneficials and resistance evolution in key pests will be discussed.

Selection of insecticide resistant strains of African malaria vector mosquitoes

RH Hunt, M Coetzee
School of Animal Plant & Environmental Sciences, University of the Witwatersrand, 1 Jan Smuts Avenue, Johannesburg 2001, South Africa.
maureen.coetzee@nhls.ac.za

Insecticide resistance in the major African malaria vector mosquitoes seriously impacts on control operations in many countries. In 1999/2000, South Africa experienced its worst malaria epidemic in over 50 years, due to the return of pyrethroid resistant *Anopheles funestus*. The situation is confounded by cross-resistance to carbamates in *An. funestus* and low level resistance to DDT and pyrethroids in the other southern African vector *Anopheles arabiensis*. Resistant strains of both species have been established and laboratory investigations into the mechanisms of the resistance carried out. Only a metabolic mechanism appears to be responsible for the pyrethroid resistance in *An. funestus*. In *An. arabiensis*, however, two mechanisms have been found in populations from different parts of Africa, one a knockdown (*kdr*) type resistance and the other a metabolic mechanism. The possibility of cross-resistance to other classes of insecticides is discussed.

Actions of clothianidin and related neonicotinoids on recombinant and native nicotinic acetylcholine receptors

M Ihara, K Matsuda, DB Sattelle, K Komai
Graduate School of Agriculture, Kinki Universitiy, 3327-204 Nakamachi, Nara 631-8505, Japan, gc196005@nara.kindai.ac.jp

Imidacloprid and related neonicotinoids are insecticides acting selectively on insect nicotinic acetylcholine receptors (insect nAChRs). Among neonicotinoids, imidacloprid has pyridine and imidazolidine moieties, whereas clothianidin lacks both moieties. Since it was conceivable that such structural differences could result in different actions of these two insecticides on nAChRs, we have investigated, using two-electrode voltage-clamp electrophysiology, the agonist actions of clothianidin and imidacloprid on *Drosophila* SAD-chicken b2 hybrid nAChR expressed in *Xenopus laevis* oocytes. Also, we have used whole-cell patch-clamp electrophysiology, to study clothianidin actions on native nAChRs in the TAG neurons from male adult American cockroaches as well as in the mushroom body neurons from *Drosophila melanogaster* larvae. Clothianidin was found to activate not only the recombinant SADb2 hybrid nAChR but also native insect nAChRs with a greater efficacy than that of imidacloprid. Structure-agonist action relationship analysis suggested that opening of the imidazolidine ring is likely to account for the greater agonist efficacy of clothianidin compared to that of imidacloprid.

Novaluron (Rimon), a novel IGR – cross-resistance, selectivity and importance in pest management

I Ishaaya, S Kontsedalov, A Barazani, AR Horowitz
Department of Entomology, Agricultural research Organization, The Volcani Center, Bet Dagan 50250. vpisha@volcani.agri.gov.il

Novaluron, 1-[chloro-4(1,1,2-trifluoro-methoxyethoxy)phenyl]-3-(2,6-difluorobenzoyl)urea, a novel benzoylphenyl urea acts by both ingestion and contact. It is a powerful suppressor of lepidopteran larvae such as *Spodoptera littoralis* and *Helicoverpa armigera* (by ingestion) and whiteflies such as *Bemisia tabaci* (by contact). The compound has translaminar activity thereby affecting leafminers such as *Liriomyza huidobrensis*. Its residual activity under field conditions ranges between 10 and 30 days depending on environmental conditions. Artificial rain at a rate of 40 mm/h applied 5 and 24 h after novaluron treatment in a cotton field had no appreciable effect on the potency of novaluron on *S. littoralis* larvae. Novaluron has no appreciable cross-resistance with the juvenile hormone mimic pyriproxyfen or with the neonicotinoids. Hence these compounds can be used as components in insecticide resistance management for controlling whiteflies and other insect pests in cotton and field crops. Novaluron has no appreciable effect on parasitoids and phytoseiid mites, and probably has a mild effect on other natural enemies. Hence, it can be considered an important component in IPM programs.

The susceptibility of *Aedes aegypti* from northern Queensland to synthetic pyrethroids

CC Jansen, SC Barker, WG Brogdon, SA Ritchie, SP Frances, RD Cooper
Australian Army Malaria Institute, Weary Dunlop drive, Gallipoli Barracks, ENOGGERA, QLD, 4051, Australia, Cassie.Jansen@defence.gov.au

Aedes aegypti is the only mosquito vector of the dengue virus in northern Queensland. Despite complete reliance upon synthetic pyrethroids to control adult *Ae. aegypti* during dengue outbreaks, little is known regarding the susceptibility of *Ae. aegypti* from northern Queensland to these insecticides. Insecticide exposure bottle assays and biochemical microplate assays were conducted to examine the susceptibility of *Ae. aegypti* to synthetic pyrethroids. The susceptibility of five strains of *Ae. aegypti* from northern Queensland to five commonly used synthetic pyrethroids was compared with that of an insecticide-susceptible laboratory strain. All strains tested were fully susceptible to the synthetic pyrethroids used by mosquito control authorities in northern Queensland (lambda-cyhalothrin and deltamethrin). However, some wild strains showed significantly reduced susceptibility to permethrin, bioresmethrin and alpha-cypermethrin. Biochemical microplate assays were used to measure the activity levels of two types of enzymes (β-esterases and monoxygenases) that often confer resistance to synthetic pyrethroids. Elevated esterase activity was detected in three wild strains relative to the reference strain, but elevated oxidase activity was not detected in any of the mosquito strains. The presence of resistant traits in wild populations of *Ae. aegypti* demonstrated here supports the need to establish a resistance monitoring programme in northern Queensland to ensure the continued success of dengue outbreak control.

Identification and sequence analysis of the chromosomal region containing *nsd-2*, a densovirus-resistance gene in *Bombyx mori*

K Kadono-Okuda, J Nohata, K Yamamoto, S Sasanuma, M Sasanuma, R Eguchi, W Hara, K Mita
Insect Genome Laboratory, National Institute of Agrobiological Sciences, 1-2, Owashi, Tsukuba, 305-8634, Japan, Kadono@affrc.go.jp

Bombyx mori densovirus (BmDNV) multiplies in the columnar cell nuclei of the mid gut epithelia in the silkworm, *Bombyx mori*. It is classified into 2 types, DNV-1 and DNV-2. Some silkworm strains were identified as resistant against DNV-1 and/or DNV-2. So far four non-susceptibility genes have been reported, namely; *nsd-1*, *Nid-1*, *nsd-2* and *nsd-Z*. However, none of them have yet been isolated as responsible genes. Studies on these genes are useful in understanding the mechanism of non-susceptibility in relation to the viral invasion and multiplication. We identified four closely linked cDNA markers with *Nid-1* and *nsd-2*. By taking advantage of *Bombyx* genome information, the BAC contigs covering these cDNA markers were expanded by screening of the BAC library with BAC end sequences, fingerprinting and shotgun sequencing of BAC clones. At the same time, backcrossed F_1 segregants were selected by virus nonsusceptibility and the linked boundary of the chromosome was defined by sequence analysis.

The use of surface plasmon resonance in characterisation of metabolic resistance

F Kemp, *GD Moores*
Reading University, Whiteknights, Reading, UK RG6 6AH c.f.kemp@reading.ac.uk

Insecticide resistance can be the result of target-site insensitivity, metabolic resistance, or both. In general, target-site insensitivity can be readily determined by direct assays on the receptor or target involved. Metabolic resistance can often be harder to characterise, often being implicated indirectly by synergism studies or the use of model substrates. These may or may not accurately reflect the 'true' interaction between pesticide and the degradative enzyme. The use of BIAcore surface plasmon resonance technology allowed the direct interaction of insecticides with a purified esterase to be measured. Additionally such interactions are measured in real time, allowing a unique insight into the binding between resistance-associated esterase and xenobiotics.

Bt-maize and *Trichogramma* wasp – two compatible strategies in control of European corn borer (*Ostrinia nubilalis*)

F Kocourek, K Ríha
Research Institute of Crop Production, novská 507 – Prague 6 – Ruzyně, 161 06, Czech Republic,
kocourek@vurv.cz

The efficacy of *Bt* maize and Trichogramma wasp (Tw) against *O. nubilalis* was tested in two field trials in 2002 and 2003. The hybrids of maize MON 810 (Bt-maize), Monumental (isolinie) and Raissa (local variety) were used. Tw was applied as preparation Trichocarp. Plant injury before harvest on untreated plot ranged from 0.75 to 2.5 per plant in 2002, and 0.22 – 1.4 in 2003. Biological efficacy of *Bt* maize was 100%, the biological efficacy of Tw ranged from 35 to 69%. The increase of yield on *Bt* maize plot reached 21 - 27% in 2002, and 7 – 15% in 2003 and on plots treated by Tw ranged from 0.6 to 17 in both years. The content of four mycotoxins in grain of maize ascertained by ELISA will be presented. Mathematical model of population dynamics of *O. nubilalis* in strips of maize treated by Tw in comparison with untreated strips will be presented. Tw can be applied in insect resistant management (IRM) of European corn borer. Strips of non-transgenic maize hybrid protected by Tw can be used as a refugee to decrease spread of Bt-resistance. The work was funded by the Ministry of Agriculture of the CR project no. QD 1360.

Fluorescence PCR techniques for detecting mutations in the sodium channel gene and for analysis of family 6 oxidase genes conferring pyrethroid resistance in *Aedes aegypti*

AE Lenhart, WG Brogdon
CDC DPD/ENT, 4770 Buford Hwy. MS F-42, Atlanta, GA 30341 USA

Multiple mutation sites in transmembrane segment 6 of domain II of the sodium channel gene confer pyrethroid resistance in *Aedes aegypti*. Existing strategies for identification of genotypes using PCR are often difficult to use with routine success, especially in the case of heterozygotes. We sought to develop more robust PCR methods based on fluorometric PCR and primer mismatch PCR that remove much ambiguity in scoring results. Here we describe several approaches to making the scoring of resistance genotypes a more straightforward and reproducible procedure. Data are shown for *Aedes aegypti* populations from several continents expressing varying degrees of pyrethroid resistance, as well as for the two mutations known from *Anopheles gambiae*. Elevated expression of P450 oxidases can also confer pyrethroid resistance in *Aedes aegypti* populations. A conserved repeat motif in the downstream P450 reductase binding site of *Aedes aegypti* family 6 P450 genes was used as a probe for quantitative analysis of oxidase copy number and expression. Oligonucleotides were selected for conserved regions of sequence (across the *Culicidae*) and for specific oxidase sequence variants. Through fluorescence PCR analysis, this allowed a comparison of oxidase copy number and expression as well as comparison to homologous sequences in other *Aedes*, *Culex*, and *Anopheles* species.

Biokinetics in insecticide discovery

R Lind
Syngenta, Jealott's Hill International Research Centre, Bracknell, Berkshire, RG42 6EY, UK, rob.lind@syngenta.com

Biokinetics is the study of uptake, distribution, metabolism and excretion of xenobiotics and is an important factor to address in the development of new chemical insecticides. Methods have been developed within Syngenta to address these factors on whole insect systems, and the plants upon which insects feed, to gain an insight into biokinetic processes. An understanding of these factors allows iterative cycles of chemical synthesis to improve biokinetic properties which ultimately lead to increased biological potency. Furthermore, biokinetics has played a major role in understanding the translation of in vitro biochemical signals to in vivo biological potency. Conversely this can occur the other way round when a propesticidal compound is tested and again biokinetics can be used to ascertain the conversion of the parent to the active primary metabolite. This was recently exemplified in cyanotropane insecticidal chemistry which demonstrated potent biological activity on sucking pests (hemiptera) but had very weak micromolar activity on the insect nicotinic acetylcholine receptor (nAChR). Biokinetics proved the rapid conversion of the parent to a stable metabolite in insects which had high nanomolar affinity to the insect nAChR thus linking the in vivo to in vitro potency of this chemical series.

Genetic variation and phenotypic plasticity in *Leptinotarsa decemlineata* under different selection pressures

L Lindström, MSc S Boman, A Grapputo, A Lyytinen, J Mappes
Department Of Biological And Environmental Science, Po Box 35, Fi-40014 University Of Jyväskylä, Finland, lilema@cc.jyu.fi

Invasive pest species provide us an opportunity to study genetic variation linked to selection pressures in natural populations. As pests are invading new areas they face new temperature regimes as well as human induced selection by pesticides. Different countries use also different varieties of cultivated crop species, which may retard insect performance. All these selection pressures are expected to shape the life history traits of a species. Finland is still free of the Colorado potato beetle *Leptinotarsa decemlineata* but on the boarder of its range. To assess beetles potential to invade Finland we compared the life-history traits of four European populations (Italy, Poland, Estonia, Northern Russia). Adult size varied very little between populations when reared on two different temperature regimes. However, developmental times differed among populations suggesting that there may be enough genetic variability for the beetle to adapt further to cooler climates. The frequency of alleles conferring resistance to permethrin was highest in Polish, and declined for Estonian and Russian populations, which suggests that the Polish population has experienced highest pesticide selection. However, resistance to aziphos-methyls was in overall high and similar in all populations. Finally, host plant variety affected little the adult size and the developmental time.

Insecticide choice in alfalfa hay may protect water quality

RF Long
UC Cooperative Extension, 70 Cottonwood St. Woodland, CA 95695 USA, rflong@ucdavis.edu

Some insecticides used for controlling Egyptian alfalfa weevil, *Hypera brunneipennis,* have been detected in California's surface waters and are of concern due to their impact on water quality and toxicity to some aquatic life. To assess the impact of insecticide choice on water quality, we collected tail-water samples from on-farm alfalfa sites in the northern Sacramento Valley, CA over a 3-year period. Samples were collected during irrigation after organophosphate and pyrethroid sprays were applied. We found significant differences between insecticide classes in the mortality of *Ceriodaphnia dubia* (water flea) a test organism used to detect pesticides in water. Nearly all sites where organophosphate insecticides were used resulted in 100% water flea mortality in a 24-hout test of tail-water samples. The pyrethroid-treated sections of the same fields exhibited insignificant water flea mortality nor were any pyrethroids found to a detection limit of 50 ppt. The pyrethroids used in this study provided significantly better control of Egyptian alfalfa weevil than the organophosphates with no significant differences in beneficial insect counts. Although water runoff does not always occur in alfalfa fields, insecticide choice may be an important tool for protecting water quality in this crop.

Resistance traits of genetically modified silver birch (*Betula pendula*) against insects

P Lyytikäinen-Saarenmaa, L Vihervuori, H Pasonen, A Pappinen
Department of Applied Biology, PO Box 27, FIN-00014 University of Helsinki, Finland, Paivi.Lyytikainen-Saarenmaa@helsinki.fi

Genetic modification has recently been applied to forest trees, aiming to improve productivity, quality and resistance to insect pests and diseases. We introduced a sugar beet chitinase gene into silver birch, using the *Agrobacterium* mediated gene transfer. Chitinases have been characterised as defense related proteins, particularly in plant/fungus interactions. Fifteen transgenic birch lines showing varying levels of sugar beet chitinase 4 expression and a wild type birch were applied in a field test. Birch seedlings were planted in an agricultural field according to a randomized block desing in 2000. We conducted an inventory of spatial and temporal distribution of insect species and damages caused by herbivorous insects on birch seedlings. Systematic sampling of transgenic and wild type trees was carried out early, middle and late in the growing season 2003 using four randomized field trial blocks. Furthermore, we studied the effect of the quality of partially defoliated birch foliage on performance of *Orgyia antigua* (Lymantridae) larvae in the laboratory. Transgenic and wild type trees were artificially defoliated in nine field trial blocks. This study has been a part of a risk assessment project aiming to provide new information on the biological interactions between genetically modified trees and other organisms.

Effects of neem (*Azadirachta indica* A. Juss) on rice bug, *Leptocorisa chinensis* (Dallas)

DL Ma, Y Suzuki, H Takeuchi, T Watanabe, M Ishizaki
Dept. of Entomology & Nematology, National Agricultural Research Center, 3-1-1 Kannondai, Tsukuba 305-8666 Japan, madeling@affrc.go.jp

Ovicidal, ovipositional, nymphicidal effects of neem (*Azadirachta indica* A. Juss) on rice bug, *Leptocorisa chinensis* (Dallas), were tested under laboratory and caging conditions. Neem oil alone and azadirachtin (Aza) at 60-180 ppm did not show ovicidal effect on D7. However, a high mortality was observed on D10 in treatment with the mixture of neem oil and abamectin at a low rate and moderate mortalities in treatments of Aza at high rates > 180 ppm. Neem extracts did not significantly affect the survival of adults and the damage to rice when used as ovipositional deterrents. Treatment of 1-3 instars showed that the mixture of neem oil and abamectin achieved the best results in increasing the mortality and delaying the nymphal development, followed by treatments of Aza in a rate-dependent manner. Toxicity of Aza to various instars was also nymphal-age and observation-time dependent. No second instars in rice survived to three weeks when two sprays of Aza at 60 ppm were applied. Two sprays of Aza at 60 ppm and 1.4% neem oil significantly increased rice yield by 23-44%. Egg number was moderately reduced on Aza treated plants. Neem may be integrated into an existing IPM package for *L. chinensis*.

Overview on environmental impact of Bt-corn (Event Bt 176) on non target organisms

B Manachini, GC Lozzia
Agricultural Entomology Institute, Celoria, 2–20133MI ITALY, barbara.manachini@unimi.it

Field studies were conducted in Italy to assess the potential impact of transgenic *Bacillus thuringiensis* corn on non target organisms. Bt corn was modified to express the Cry1Ab toxin against the lepidopteran pest *Ostrinia nubilalis.* We monitored above-ground herbivores, predators, and parasitoids as well as soil-related organisms such as Carabidae and Nematoda. Community structures and degree of biodiversity were compared between transgenic and isogenic crops. No significant impact of Bt-corn on plant-dwelling organisms was observed. However, remarkable differences were found in the case of *Lydella thompsoni*, a parasitoid of *O. nubilalis*. Contrasting results were detected for soil organisms. The Carabidae assemblages were similar, and any differences appeared to have no correlation with Bt maize. The biodiversity of the Nematoda was quite low for both types of crops and no significant differences were found for the majority of the cases. However, Nematoda assemblages were significantly different in Bt than isogenic crops planted in clay-rich soils. These results indicate that we should not neglect taxa of agro-ecosystems before releasing transgenic crops or any other xenobiotics.

Increased efficacy of conventional insecticides against greenhouse pests by the use of piperonyl butoxide (PBO).

MJ Verdu, GD Moores, A Cervera, G Bingham, J Catalan, MD Garcera, S Young, N Lopez, R Martinez-Pardo.

Cateático de Fisiología, Dto. Biol. Func. Antrop. Fis. F. CC. Biológicas, Universidad de Valencia. (Campus de Burjassot), Moliner 50. Burjassot. 46100. Valencia. España mtnezp@uv.es

The Tobacco Whitefly, *Bemisia tabaci* (Gennadius) and Western Flower Thrip, *Frankliniella occidentalis* (Pergande) are serious insect pests of agricultural and horticultural crops throughout the world. They can cause damage through both direct feeding and also through transmission of virus. The primary strategy for control for both species remains chemical sprays. However, both have the potential for fast development of resistance due to short generation time, high fecundity, and a haplodiploid breeding system. As a result, high resistance has evolved to conventional insecticides. Results of *in vitro* assays indicated efficacious use of piperonyl butoxide could substantially reduce or nullify the metabolic resistance mechanisms conferring resistance in these species. Subsequent field trials where a pyrethroid (lambda cyhalothrin) and an Insect Growth Regulator (pyriproxyfen) were applied following a pre-treatment of piperonyl butoxide, reflected the *in vitro* findings.

Biofumigation: plant cellular disruption and water achieves high toxin levels in soil

JN Matthiessen, B Warton, MA Shackleton
CSIRO Entomology, Private Bag 5 PO, Wembley WA 6913, Australia, John.Matthiessen@csiro.au

Some brassicas are potentially large sources of isothiocyanate (ITC) toxins, in the same chemical family as the methyl isothiocyanate produced by the widely used broad-spectrum pseudo-fumigant pesticide metham sodium. Endeavours to harness this potential in the form of biologically active green manures for IPM is dubbed 'biofumigation'. Recent laboratory studies have shown that ITC concentration in soil increased 100-fold with a combination of disruption of plant tissue at the cellular level (achieved by freezing and thawing) and high levels of moisture. Analytical determination of ITCs in soil following manipulation of *Brassica* green manure crops showed that similar improvements in the concentration of these compounds could be achieved in the field. It was crucial to thoroughly pulverise plant tissue with a club-type mulcher running at high speed. A blade mulcher tended to chop the plant tissue into fragments without liquefying it. Leaving the pulverised mulch on the surface and immediately watering it heavily achieved the greatest ITC concentration in soil. It is evident that the intrinsic water content of brassicas is insufficient to allow maximum hydrolysis of the precursor glucosinolates to ITCs. Addition of water boosts this process and carries the ITCs into the soil.

The crucial role of calcium in enhanced biodegradation of soil-applied pesticides

JN Matthiessen, B Warton, MM Roper
CSIRO Entomology, Private Bag 5 PO, Wembley WA 6913, Australia, John.Matthiessen@csiro.au

Enhanced biodegradation occurs where particular, but otherwise entomologically innocuous, soil bacteria are selected by repeated use to catabolise soil-applied pesticides. It is a subtle process akin to resistance in reducing soil-borne pest control efficacy. It is more widespread than is generally recognised, possibly because of its indirect mode of action, counter-intuitive mechanism and probable confusion with resistance. Extremely severe enhanced biodegradation of the widely used broad-spectrum soil-applied pesticide metham sodium occurs in Australia in intensive horticulture, particularly on sandy soils. Highly resilient spore-forming bacteria are the cause. Pesticide persistence in affected soil was just seven hours, but 15 days in similar soil never exposed to metham sodium and in affected soil sterilised by autoclaving. A positive correlation has often been reported between the risk of onset or degree of enhanced biodegradation and soil pH. However, high agricultural soil pH is often associated with greater calcium concentration through liming (adding calcium carbonate) soils with pH below agronomically desirable levels. We have found that high soil pH alone is insufficient to exacerbate enhanced biodegradation. Rather, a powerful synergy is established when high levels of calcium occur in the same soil. Reassessment of soil pH targets and adjustment methods less reliant on calcium-rich alkalis offer scope to reduce the risk of enhanced biodegradation.

Ethanedinitrile: a promising replacement soil fumigant for methyl bromide

JN Matthiessen, Y Ren, SW Mattner
CSIRO Entomology, Private Bag 5 PO, Wembley WA 6913, Australia, John.Matthiessen@csiro.au

Methyl bromide, a long-used powerful broad-spectrum soil fumigant, is scheduled for withawal from soil use in 2005 under the Montreal protocol. Many highly intensive horticultural industries with extreme market-iven or mandated sanitation demands face significant challenges in maintaining equivalent plant protection efficacy with alternatives. Most current alternatives have a narrower activity spectrum, greater risk of phytotoxicity entailing economic penalty in longer plant-back times, are susceptible to enhanced biodegradation (a concept alien to the methyl bromide experience) or are generally less forgiving for robust use in the highly diverse and variable field environment. CSIRO Entomology has identified and taken patent protection on ethanedinitrile (C_2N_2) (EDN) as a potential soil fumigant. Its chemical properties place it at no risk as an ozone-depletor or greenhouse gas and it is safer to use than methyl bromide. Laboratory and preliminary field tests have shown that it offers equal, if not greater, spectrum of activity and potency than methyl bromide, and an extraordinarily rapid action and rate of dissipation that promises extremely short plant-back times and little prospect that enhanced biodegradation will impede efficacy with longer-term use.

Insect resistance traits in the near future

T Meade, *GD Thompson, NP Storer.*
Dow AgroSciences, 9330 Zionsville Rd., Indianapolis, IN 46268, meade@dow.com

Since their introduction nearly 10 years ago, insect resistance (IR) traits have become a significant feature of the crop protection landscape. In spite of the rapid adoption of this technology, there are relatively few IR traits currently in the marketplace, and they are only available in two major crops (maize and cotton). A limited number of new IR traits are in the product development pipelines of the major crop protection companies with projected product launches within the next 5 years. What is known about these new IR traits will be discussed. The discovery and development process for IR traits will also be discussed in the context of identifying barriers to the introduction of new IR traits.

Efficacy of a spinosad suspension concentrate formulation for controlling chewing and sucking lice on cattle under field conditions

C Jones, LL Smith, DE Snyder, DE Hutchens, Z Cui, D Mowrey, LD Firkins, AJ Paul, JA Meyer
2001 West Main Street, Greenfield, Indiana, 46140, USA, meyerje@lilly.com

Field studies were conducted with cattle in Wisconsin and Illinois between January and April, 2000, to determine the efficacy of 0.04% spray and 2 mg/kg pour-on treatments of a spinosad suspension concentrate formulation against chewing and sucking lice. Positive control substances included in the study were Co-Ral® EC (5.8% coumaphos) and CyLence™ Pour-on (1% cyfluthrin). Animals in the negative control group remained untreated. All lice species were visually sampled on each animal at weekly intervals after treatment, for eight weeks. Individual louse counts were summed over each examination site for each species. A repeated measures analysis using a mixed model (SAS PROC MIXED), was conducted for data pooled across both study sites. Both spinosad treatments and CyLence™ Pour-on provided excellent efficacy (98-100%) against *Bovicola bovis* over the entire study period; Co-Ral® EC efficacy dropped below 90% from Weeks 6-8. The efficacy of the spinosad spray treatment against *Linognathus vituli* was >93% for the entire study and >88% for the spinosad pour-on treatment. Co-Ral® EC was >90% efficacious against *L. vituli* during Weeks 1-7, while CyLence™ Pour-on only exceeded 90% for Weeks 3-7. *Solenopotes capillatus* were found only at the Wisconsin site; all treatments were highly efficacious throughout the study period.

Progress of *Bombyx* genome project in Japan

K Mita, M Kasahara, S Sasaki, Y Nagayasu, T Yamada, H Kanamori, N Namiki, M Kitagawa, H. Yamashita, Y. Yasukochi, K. Kadono-Okuda, K. Yamamoto, M. Ajimura, G. Rvikumar, M Shimomura, Y Nagamura, T Shin-I, H Abe, T Shimada, S Morishita, T Sasaki
Genome Research Department, National Institute of Agrobiological Sciences, Tsukuba 305-8634, Japan, kmita@nias.affrc.go.jp,

In Lepidoptera, the genome information had been quite limited so far. Now the situation changed quickly, since National Institute of Agrobiological Sciences (NIAS) is performing the *Bombyx* genome project including *Bombyx* whole genome shotgun sequencing, cDNA collection and construction of physical map systematically in collaboration with many groups, and the explosive accumulation of *Bombyx* genome information will be expected. We will present the recent progress on our *Bombyx* genome works.
a)EST db: Recently, *Bombyx* EST db, "SilkBase*"*, was transferred to "KAIKObase" http://sgp.dna.affrc.go.jp,, where EST db is combined with genome and map information as the integrated database.
b)Linkage map: About 2,000 genetic markers were mapped in 28 linkage groups under the efforts of several groups. The high density map was made public as "BombMap" in KAIKObase.
c) BAC library: Three BAC libraries prepared by different restriction enzymes are available.
d) EST microarray: EST microarray containing 6,000 non-redundant ESTs was available for functional studies.
e) Genomic sequence: NIAS carried out *Bombyx* WGS, whose data will be public in KAIKObase of NIAS HP shortly.

Reduced sensitivity of acetylcholinesterase in green rice leafhopper, *Nephotettix Cincticeps* Uhler, resistant to organophosphorus and *N*-methyl carbamate insecticides

Y Kato, T Tanaka, T Miyata
Laboratory of Applied Entomology, Graduate School of Bioagricultural University, Chikusa-ku, Nagoya, 464-8601 Japan, tmiyata@agr.nagoya-u.ac.jp

Green rice leafhopper (GRLH) showed resistance to various organophosphorus and *N*-methyl carbamate insecticides. Major resistance mechanism is a reduced sensitivity of acetylcholinesterase (AChE) to these insecticides. A hydophilic form of AChE was purified from *N*-methyl carbamate susceptible (SA) and highly *N*-methyl carbamate-resistant (N3D) strains of GRLH. Both of purified AChE from SA and N3D strains displayed the highest activities towards acetylthiocholine (ATCh) at pH 8.5. In the SA strain, the optimum concentration for ATCh, propionylthiocholine (PTCh), and butyrylthiocholine (BTCh) were about $1x10^{-3}$, $2.5x10^{-3}$, and $1x10^{-3}$ M, respectively. However, in the N3D strain, substrate inhibition was not identified for ATCh, PTCh, and BTCh to $1x10^{-2}$ M. The V*max* value in the N3D strain was 1.75- and 3.15-fold higher for ATCh and BTCh than that in the N3D strain. However, it was 1.13-fold lower for PTCh. The increased activity of AChE in the N3D strain is due to the qualitatively modified enzyme with a higher catalectic efficiency. AChE from the N3D strain was 65-fold less sensitive than SA strain to inhibition by propoxur. In contrast, AChE from the N3D strain 65-fold more sensitive to inhibition by monocrotophos than AChE from the SA strain. This indicated negatively correlated cross-insensitivity of AChE to propoxur and monocrotophos.

Large scale field trials in the USA with Bt cotton

WJ Moar, M Eubanks, B Freeman, S Turnipseed, J Ruberson, G Head.
Dept. of Entomology and Plant Pathology, Auburn University, Auburn, AL 36849,USA moarwil@auburn.edu

Field studies were conducted in 2000-2002 to compare arthropod populations between Bollgard$^{\text{Ò}}$ and conventional cotton season-long in Alabama, Georgia, and South Carolina. For each region, three or four paired fields were evaluated weekly, with each pair consisting of a Bollgard$^{\text{Ò}}$ field and a conventional cotton field (treated for lepidoptera when necessary). Insect species sampled included *Heliothis virescens*, *Helicoverpa zea*, *Spodoptera frugiperda*, *Spodoptera exigua*, *Trichoplusia ni*, *Pseudoplusia includens*, phytophagous stink bugs and plant bugs, cotton aphids, *Solenopsis invicta*, *Geocoris* spp., *Orius* spp., spiders, parasitic wasps, green and brown lacewings, and *Nabis* spp. Most results show that there were no significant differences for any arthropod population between a particular Bollgard$^{\text{Ò}}$ field and the corresponding conventional cotton field. However, the most amatic significant differences occurred in South Carolina when comparing conventional cotton sprayed with at least several applications of insecticides to control primarily *H. zea*, and Bollgard$^{\text{Ò}}$that was not treated for *H. zea*. In these instances, there were significantly more non-target arthropods in the Bollgard fields than in the conventional fields. These results demonstrate that the use of Bollgard$^{\text{Ò}}$usually has no impact on non-target arthropod populations, and when compared with cotton treated with insecticides for lepidoptera, results in significantly more non-target arthropods.

Molecular diagnosis of *para*-locus mutations in head lice (*Pediculus humanus capitis*) from around the world: their role in resistance to synthetic pyrethroids?

A Murrell, M Ashrafi, WG Brogdon, M Picollo, SC Barker
Department of Microbiology and Parasitology, and Institute for Molecular Biosciences, The University of Queensland, Brisbane 4072, Australia.
a.murrell@uq.edu.au.

Throughout the world head lice (*Pediculus humanus capitis*) infest people, and the pediculicides used to treat them do not always work. One group of chemicals applied to treat head lice are the synthetic pyrethroids, and resistance to these chemicals has been detected in lice in many parts of the world using the World Health Organisation (WHO) mortality assay. The genetic basis for resistance in lice to synthetic pyrethroids is hypothesised to be due to mutation in the *para*-orthologous sodium channel α-subunit (*para*-locus); where most of the sodium channel gene mutations that are known to be associated with knockdown resistance in insects are located. A number of point mutations have been detected in the *para*-locus of synthetic pyrethroid-resistant lice. We sequenced a region of the *para*-locus where two of these mutations have been previously found, in lice from Australia, Argentina, France, Guatemala, Thailand, Panama and the U.S. We observed the occurrence of these and other mutations and the correlation between genetic data and WHO mortality assays for many individual lice. We also developed a possible genetic test for resistance, a polymerase chain reaction restriction fragment length polymorphism (PCR-RFLP) assay to quickly and accurately diagnose individual lice as heterozygous or homozygous for genetic change to the *para*-locus.

Using genomic tools to isolate and characterise olfactory genes from the tortricid pest, *Epiphyas postvittana*

R Newcomb, M Jordan, C Turner , D Stanley, A Authier, A Kralicek, L Gatehouse, R Crowhurst, D Greenwood
HortResearch, Private Bag 92169 Auckland, New Zealand rnewcomb@hortresearch.co.nz

With completion of the *Drosophila* genome, efforts have turned to insects of major economic interest for whole genome sequencing. However in the short-term whole genome sequencing will still remain beyond the reach of many projects working on individual insect species. Tools such as EST sequencing and proteomics can contribute to finding genes/proteins involved in targeted processes and create useful information for comparative genomic analysis. We are using these approaches to identify genes involved in the detection of odorants, particularly sex pheromones, from the horticultural tortricid pest, *Epiphyas postvittana*. Potential odorant binding proteins, odorant receptors and odorant hydolases have been isolated from ESTs derived from male antennae. Comparison of male and female antennal proteins on 1-D and 2-D gels reveals proteins both up and down-regulated in males relative to females, and mass spectrometry reveals some of these proteins correspond to genes from the EST collection. These techniques have given us quick access to potential olfaction genes. Functional studies of these genes to examine expression in antennae, protein structure and function, and involvement in olfaction using expression in insect cell lines and RNAi in whole insects will be described.

Expressed sequence tags from the brown planthopper, *Nilaparvata lugens* and its tissue-specific genes

H Noda, S Kawai, Y Koizumi, J Wang, Q Zhang, K Mita
National Institute of Agrobiological Sciences, Owashi, Tsukuba, Ibaraki 305-8634, Japan, hnada@affrc.go.jp

A total of about 35,000 expressed sequence tags (ESTs) were produced from various tissues and stages of *Nilaparvata lugens*, one of the serious pests of rice plant. cDNA libraries were made from two stages of eggs, fourth instar nymphs, two stages of adult ovary, testis, male midgut, female midgut, female salivary glands, female head, female thorax, female abdomen, male head and thorax, and male abdomen. There were more than 8,000 non-redundant ESTs, potentially representing unique genes. Eleven ESTs were found only from the female abdomen and ovary, and five out of the eleven were expressed only in the mature ovary. At least ten ESTs were testis-specific. Nucleotide sequences of truncated region of these cDNAs were determined by 5' and 3' RACE. BLAST search disclosed that the sequences of many gonad-specific genes were dissimilar to those in the databases. The ESTs were also used for determining whole mitochondria genome sequence, because the mitochondrial gene sequences were contaminated in the EST data. *Nilaparvata lugens* mitochondria genome size was 17,251 bp.

Prospects and potential pitfalls associated with the use of transgenic corn for fall armyworm management

GS Nuessly, BT Scully, MG Hentz, R Beiriger
Everglades Research and Education Center, UF/IFAS, 3200 E. Palm Beach Rd., Belle Glade, FL, USA, 33430-4702, GSN@IFAS.UFL.EDU

Transgenic corns that produce Bt toxins have been available for control of European corn borer in the Midwestern USA for several years. While the Bt-event in sweet corn is well expressed and also provides essentially 100% control of fall armyworms, the event in field corns provides only 60 to 85% control of this migratory, polyphagous pest. Despite the reduced potential for fall armyworm control, these transgenic products provide substantial yield gains over traditional field corns for grain and silage. With the recent development of sub-tropically adapted, Bt-enhanced field corns, acreage of Bt-corn grown for silage has spread south into the insect's overwintering region of Florida. IRM stewardship agreements standardized and enforced by the EPA to limit resistance development encourage growers to plant a proportion of their acreage to non-Bt corn reservoirs dependent upon their location within the U.S. cotton growing belts. Corn growers are increasingly pressed to produce high yields with low inputs to compete in the marketplace and are pushing to reduce or eliminate the reservoirs. These and other issues, including non-compliance and season-long availability of Bt-enhanced corn and cotton, will be examined for their potential for selection of Bt-resistance and its area wide implications for fall armyworm control.

Cost economics of Bt cotton cultivation in irrigated ecosystem

BV Patil, M Bheemanna, BK Suresh, SG Hanchinal, V Anand Kumar
Regional Agricultural Research Station and College of Agriculture, Raichur-584 101, Karnataka, India, E-mail: bvp2001@rediffmail.com

Bollworms, *Helicoverpa armigera* (Hubner), *Earias vittella* (F.) and *Pectinophora gossypiella* (Saunders) have made cotton cultivation uneconomical. Transgenic cotton hybrids with in built δ endotoxin reduces pest problem and cost of cultivation. Studies were undertaken at Regional Agricultural Research Station (RARS) and in farmers' field. MECH-162 Bt and non Bt during 2002-03 and MECH-184 Bt and non Bt during 2003-04 and local hybrid (NHH-44) were cultivated. Sprays were imposed as and when the pest population/damage crossed ETL. Totally 3, 4 and 4 sprays during 2002-03 and 3, 12 and 12 sprays during 2003-04 were imposed on Bt, Non Bt and NHH-44 hybrids respectively in RARS, whereas, in farmers' field 4, 9, and 9 sprays during 2002-03 and 6, 12 and 12 sprays during 2003-04 were imposed on Bt, Non Bt and NHH-44 hybrids respectively. Incidence of bollworms only in Bt cotton MECH-162 and 184 was much below ETL. More good opened bolls and less bad opened bolls per plant were recorded with significantly higher seed cotton yield in Bt cotton as compared to non Bt and local hybrid. Bt cotton hybrids recorded 35 to 45 percent increase in net it over local hybrid making it commercially viable and itable.

Wound-inducible expression in transgenic plants after insect attack

MR Perera, *MGK Jones*
Plant Biotechnology Research Group, School Of Biological Sciences And Biotechnology, Wa State Agricultural Biotechnology Centre, Murdoch University, Perth, WA 6150, Australia. mperera@murdoch.edu.au

Promoters of genes that are induced by microbial pathogens, wounding and treatment with wound-signalling compound could be valuable in regulating the expression of resistance genes when plants are attacked by insects or pathogens. A plant expression vector pMP4 was developed using a GUS/GFP fusion construct driven by a *Shpx6b* peroxidase gene promoter (J. Manners, UQ) from a tropical forage legume *Stylosanthes humilis*. This construct was introduced into insect susceptible tobacco using *Agrobacterium tumefaciens*. Expression of *gus* and *gfp* reporter genes in T_1 transgenic tobacco leaves after infestation/treatment with chewing insects, sucking insects, the plant defense regulator MeJa, and mechanical wounding were investigated. *Gus* reporter gene levels were also assayed to quantify expression and the results were consistent with the observed histological patterns of expression. The results show that the *Shpx6b* promoter switches on the expression of linked genes after damage by insect herbivores, and could be useful in regulating the expression of heterologous genes for insect and /or pathogen resistance in transgenic plants.

Appraisal of cross resistance potential to neonicotinoid insecticides by *Bemisia tabaci*

N Prabhaker, SJ Castle, NC Toscano, TJ Henneberry
Dept. of Entomology, University of California, Riverside, CA 92501, USA, nscastle@earthlink.net

Resistance that occurs to a particular insecticide is often assumed to extend to all members of the class. However, structural differences among compounds may affect vulnerability to degradation by metabolic enzymes, or differences in target site receptors may influence susceptibility to specific insecticides, thereby mitigating cross-resistance effects. Neonicotinoids are an important class of insecticides used worldwide against *B. tabaci* and many other insect pests. Populations from southern Spain resistant to imidacloprid have also shown cross-resistance to thiamethoxam and acetamiprid. To further assess the expression of cross-resistance to neonicotinoid insecticides, *B. tabaci* populations from California and Arizona were monitored periodically to determine their susceptibilities to acetamiprid, dinotefuran, imidacloprid, and thiamethoxam. In addition, two imidacloprid-resistant strains were tested for cross-resistance potential. Field strains expressing different levels of resistance to imidacloprid did not always show cross-resistance to other compounds. For example, a population from Arizona collected in November 2003 had an LC_{50} of 115ppm to imidacloprid in a leaf-uptake bioassay, but only 8 and 9 to dinotefuran and thiamethoxam, respectively. The resistance factor was even greater in a strain from Guatemala that yielded an LC_{50} of 653ppm to imidacloprid, but only 29 to dinotefuran. Implications for cross-resistance between neonicotinoids among the various strains are examined.

Developing protocols for field evaluations of non-target organisms in Bt crops

JR Prasifka, *RL Hellmich*
Genetics Lab c/o Insectary, Iowa State University, Ames, IA 50011, USA, prasifka@iastate.edu

Transgenic crops containing insecticidal genes from Bacillus thuringiensis (Bt) bacteria offer unprecedented power to combat agricultural pests, but concerns about their possible unintended effects remain. Laboratory research suggests accidental exposure or indirect effects of Bt toxins may negatively impact non-target species, though this result is rarely seen in field studies. However, such field research sometimes employs methods inappropriate for evaluating Bt crops, which may have relatively small effects on a select number of species. Nonetheless, simple modifications to experimental protocols and analysis could greatly increase the value of field tests of non-target effects. A synthesis of existing data may guide choices of appropriate indicator taxa, needed replication, and optimal sample timing. Current statistical methods may also allow for more powerful analysis of time-series community data. Field experiments assessing the effects of plot size on community and species-level tests of non-target effects may allow for research plots which are both practical and realistic. Overall, such changes will improve researchers' power to detect differences, positive or negative, between Bt crop production and alternate management practices. However, methods developed for current Bt corn varieties should be adaptable to studies of new cultivars, non-Bt management practices, and other cropping systems.

Studies on detection and characterization of organophosphate-resistance in *Anopheles culicifacies* sibling species in Madhya Pradesh, Central India

K Raghavendra, AK Mishra, SK Chand, G Goswami, N Singh, SK Subbarao
Malaria Research Centre (Icmr), 22 Sham Nath Marg, DELHI-110054, India, kamarajur2000@yahoo.com

Field studies carried out in villages in two blocks in Chhindwara district indicated presence of malathion resistance in *Anopheles culicifacies,* the principal vector of malaria in this area, in the absence of use of malathion spraying for malaria control. *An. culicifacies* s.l. was found 36-86% resistant to malathion but was susceptible to other organophosphate, carbamate and synthetic pyrethroid insecticides. Selection of malathion-resistance in *An. culicifacies* appears to be due to insecticides used in plant protection. Biochemical assays indicated non involvement of general esterases and insensitive acetylcholinesterase in conferring malathion-resistance. Synergist-malathion bioassays indicated the involvement of specific malathion carboxylesterase (MCE). ASPCR assays have revealed prevalence of species B (73%) and species C (27%) and exhibited diferential susceptibility to malathion. The observed percent susceptibility to malathion in species B was 68% while in species C it was 13% These results will be presented in detail and the implication of development of resistance owing to selection by agricultural pesticides will be discussed.

Sugarcane borer (Lepidoptera: Crambidae) resistance management studies in Louisiana

TE Reagan, FPF Reay-Jones, J Ottea, C McAllister, W Akbar.
Department of Entomology, Louisiana Agricultural Experiment Station, Louisiana State University Agricultural Center, Baton Rouge, LA 70803, USA.
treagan@agctr.lsu.edu

During the last decade, sugarcane borer (SCB), *Diatraea saccharalis* (F.) management in Louisiana has been impacted by cultural practice changes emphasizing early planting initiated in August, and the increasing dominance of a high yielding borer-susceptible variety (LCP 85-384) now approaching 88% of the planted acreage. Insecticide foliar sprays for SCB control rose from 0.2 applications per season in 1994-95 to 1.8 applications per field in 2002-03. Due to the growing popularity of the ecdysone agonist, tebufenozide (Confirm®), insecticide resistance monitoring efforts were begun throughout the sugarcane industry in 2002. Increases in LC_{50} values from traditionally low insecticide use areas have ranged up to 2.6 fold in areas averaging more than one application per season. In one area of heavy tebufenozide use, LC_{50} values remained high despite discontinuance of selection pressure. Resistance management studies will be discussed in relation to broader SCB management issues.

Twenty years of insecticide resistance management in the Australian cotton industry.

LC Rossiter, *R Gunning*
Australian Cotton Research Institute, NSW Agriculture, Locked Bag 1000, Narrabri, NSW 2390. Email: louise.rossiter@agric.nsw.gov.au

The Australian Cotton industry has been guided by an Insecticide Resistance Management Strategy (IRMS) for twenty years. Since its introduction in the 1983/84 cotton season to combat widespread pyrethroid resistance by the primary pest of cotton *Helicoverpa armigera*, it has been modified and expanded to encompass an increased number of chemical groups, embrace integrated pest management and account for a wider range of insect pests. Compliance to this voluntary strategy is near to 100 % by the cotton industry, and in recent years the grains industry has become involved in the strategy providing a more co-ordinated attempt across multiple farming practices to manage resistance and maintain the chemicals available for pest control. This paper shall provide an overview of the IRMS, its evolution over the last twenty years, the principles involved and why uptake by the industry has been so successful. The current status of insecticide resistance by the primary pests of cotton shall be discussed, as well as the future of the IRMS, including the possible impact of transgenic cotton on the pest complex and insecticide resistance management.

Global status of insecticide resistance mechanisms in *Helicoverpa armigera*

DA Russell, KR Kranthi, T Martin, Y Wu, M Ahmad, G Devine, I Denholm
NRI, Chatham Maritime, Kent, UK. E-mail derek.russell@latrobe.edu.au

The cotton bollworm *Helicoverpa armigera* (Hübner) has displayed an enormous potential to resist almost all the insecticide molecules used against it thus far. Amongst the range of mechanisms that confer resistance, enhanced metabolic detoxification has been found to be the most important. Recent evidence showed that increased oxidative breakdown of pyrethroids was found to be associated with pyrethroid resistant strains from West Africa, India, China, and Pakistan. Thus far, at least four cytochrome p450 genes CYP6B2, CYP6B6, CYP6B7 and CYP4G8 have been implicated in pyrethroid resistance. Pyrethroid resistance due to enhanced esterases, reduced penetration and nerve insensitivity was reported from India, China, Pakistan, Thailand and Australia. Several genes associated with nerve-insensitive resistance were explored for specific structural changes, but the mutations generally associated with sodium channels and GABA chloride channels in other insecticide resistant species were not found in *H. armigera* and those that were reported previously in the intracellular segment linking repeat domains III and IV of the para-homologous sodium channel gene, that were associated with nerve insensitive *H. armigera* larvae, were not confirmed. Insensitive acetylcholinesterase and or unique esterase isozymes were found to be associated with resistance to organophosphates and carbamates. Resistance diagnostic kits based on the unique resistance associated isozymes, have been made in India.

Resistance issues in Bt cotton in India and China

KR Kranthi, DA Russell, Y Wu
Natural Resources Institute, Chatham Maritime, ME4 4TB, UK, d.a.russell@gre.ac.uk

Genes for resistance to Cry toxins being selected in the field *in Helicoverpa armigera* by Bt cottons may not be necessarily those which are also being found in laboratory selections. Resistant individuals are present in the field at frequencies of between one in $0.42x10^{-3}$ and one in $1.3x10^{-3}$ in India and China. There appears to be both a recessive target site mechanism and a dominant enzymatic degradation mechanism. Currently the former seems likely to be more important in Chinese field populations and the latter in Indian populations with important implications for resistance management strategies. A simulation model was produced taking account of the biology of the pest, the local cropping pattern, initial resistance gene frequency, dominance, mode of inheritance, relative survival rates of RR, RS and SS individuals on Bt and non-Bt hosts throughout the year and other variables. Factors of importance in determining the time to a filed resistance gene frequency of 0.5 in the two countries are different. Where resistance is semi-dominant, in-crop refugia were of little value in delaying resistance development. However even fitness costs as low as 5% doubled the time to significant resistance in most scenarios. Integrating other artificial mortality factors at times of peak pest presence was the simplest effective strategy for delaying resistance in systems where >40% of the cotton is Bt transgenic. The likely impact on resistance development of the range of dual gene combinations currently being commercialised in the two countries has been modeled and is discussed.

Survival and development of *Spodoptera frugiperda* and two of its natural enemies on Bt transgenic maize

CJ Sanders, TH Schuler, JK Pell, GM Poppy, A Raybould
Rothamsted Research, Harpenden, Herts, UK; University of Southampton, Southampton, Hants, UK;
christopher.sanders@bbsrc.ac.uk

This paper reports effects of conventionally-bred partially resistant and transgenic maize hybrids on *Spodoptera frugiperda* (herbivore), *Campoletis sonorensis* (parasitoid) and *Beauveria bassiana* (entomopathogenic fungus). *Spodoptera frugiperda* larvae fed maize expressing the Bt toxin Cry1Ab had an increased development time and reduced pupal weights compared to larvae fed conventionally-bred resistant and susceptible maize hybrids. *Campoletis sonorensis* cocoon and adult weights were significantly reduced by 15-30% when reared in hosts fed Bt maize. The extent of this effect varied with the weight of host at oviposition, its subsequent development and host weight at parasitoid emergence. Resistant maize, whether transgenic or conventionally-bred, may increase the susceptibility of *S. frugiperda* to *B. bassiana*, as larvae develop more slowly than on susceptible maize, with greater time intervals between moults. This increases the time for *B. bassiana* spores to germinate and invade the host through the cuticle before they are shed during moulting. Alternatively, resistant plants may induce an immune response in *S. frugiperda*, reducing susceptibility to fungal attack. Results of ongoing experiments on this interaction will be presented.

The *Diabrotica* genetics consortium: a paradigm for global cooperation in research

TW Sappington
USDA-ARS, CICGRU, Genetics Lab, ISU, Ames, IA 50011, USA, tsapping@iastate.edu

The evolution and spread of insecticide- and rotation resistance, the introduction and spread of the western corn rootworm (*Diabrotica virgifera virgifera*) in Europe, and the recent large-scale commercial deployment of rootworm-active *Bt* corn in North America have generated a growing sense of urgency among scientists involved in rootworm genetics research. These are all complex problems, with a number of researchers in several countries working on various aspects. In the last year, a group of more than 35 scientists from 25 different institutions in the U.S., Canada, France, and Germany have come together to form the *Diabrotica* Genetics Consortium. The main role of the Consortium is to facilitate communication among those working on related problems, both to avoid unnecessary overlap of effort and to reveal opportunities for synergism through cooperation/collaboration. It is founded on the principle that open communication of research goals, activities, findings, and future plans is in the best interest of all concerned and in the best interest of advancing science. The scientists comprising the Consortium are committed to sharing information and ideas in an atmosphere of mutual trust, respect, and sensitivity to the essional needs of one another in accord with the highest ideals of scientific endeavor.

Induction and transmission of Bt-tolerance in the flour moth *Ephestia kuehniella*

O Schmidt, MM Rahman, HLS Roberts
Insect Molecular Biology, University of Adelaide, Glen Osmond, SA 5064, Australia.
otto.schmidt@adelaide.edu.au,

The use of *Bacillus thuringiensis* endotoxins to control insect vectors of human diseases and agricultural pests is under threat from the possible evolution of resistance in major pest species. In addition to high levels of resistance, produced by receptor insensitivity, several cases of tolerance to low to medium levels of toxin have been reported in laboratory colonies of lepidopteran species. Since the molecular basis of some of these cases of tolerance to the toxin are not known, we explored alternative mechanisms. Here we present evidence that tolerance to a Bt-formulation in a laboratory colony of the flour moth *Ephestia kuehniella* can be induced by pre-exposure to a low concentration of the Bt-formulation and that the tolerance correlates with an elevated immune response. The data also indicate that both immune induction and Bt-tolerance can be transmitted to offspring by a maternal effect and their magnitudes are determined by more than one gene.

Effects of reduced prey choice caused by GM plants on a predatory insect

TH Schuler[1], A Clark, GM Poppy, I Denholm
[1]Division of Plant and Invertebrate Ecology, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, UK; tanja.schuler@bbsrc.ac.uk

Bt plants are highly toxic to certain pest species. Predatory insects may be affected by the reduced abundance of target pests if sufficient alternative prey is not available. This paper will present experiments investigating such indirect effects under laboratory conditions. Lacewing (*Chrysoperla carnea*) larvae were released into large cages containing Bt and wildtype plants previously infested with a constant number of diamondback moth (*Plutella xylostella*) eggs but different numbers of aphids (*Myzus persicae*). No *P. xylostella* larvae survived on Bt plants but aphid populations reached high densities on both plant types. Lacewings recovered from Bt plants at the end of the experiment did not differ in weight from ones recovered from wildtype plants. At the highest initial aphid densities there was also no difference in the proportion of lacewings surviving on the two plant types. Significantly fewer lacewings were recovered from Bt plants than from wildtype plants as initial aphid numbers were reduced. Interestingly, however, numbers of *C. carnea* recovered from wildtype plants were only significantly correlated with numbers of surviving *P. xylostella* at the highest aphid densities. Possible roles of escape behaviour of *P. xylostella* as well as cannibalism between *C. carnea* larvae in these interactions will be discussed.

The effect of spinosad on different developmental stages of Colorado potato beetle *Leptinotarsa decemlineata* (Say) (Col.: Chrysomelidae)

M Mohammadi Sharif , *MJ Hejazi*
Department of Plant Protection, Faculty of Agriculture, Tabriz University, Tabriz, 51666-4888, Iran. msharif@tabrizu.ac.ir

The Colorado potato beetle (CPB) *Leptinotarsa decemlineata* is a major insect pest of potatoes. In this study we investigated the effect of spinosad on egg, larval and adult stages of CPB. A strain of CPB was collected from Ardabil, where this pest was reported for the first time from Iran in 1984; and was reared in greenhouse conditions. Bioassays were conducted using eggs, neonates, 1st, 2nd, 3rd and 4th instar larvae as well as adults. In preliminary experiments, no ovicidal effect was observed. The concentrations used for treating the larval stages and adults ranged from 1-80 ppm. To estimate the LC values, each treatment was replicated 4 times. Bioassays were conducted at 26 ± 1 °C and 16:8 (L:D) h photoperiod in transparent plastic containers. The mortalities were recorded 24 hrs after treatment. Based on probit analysis of the data, LC_{50}s were 2.1, 3.2, 4.6, 6.5, 20.2 and 12.0 ppm and the estimates for LC_{90} values were 8.0, 12.9, 17.0, 30.1, 67.8 and 30.2 ppm for neonates, 1st, 2nd, 3rd and 4th instar larvae and the adults, respectively. If spinosad also performs well in the field, this insecticide will be a suitable candidate for CPB management programs in the region.

Laboratory selection for resistance to Bt toxins in the European corn borer: potential and limitations

BD Siegfried, HAA Siqueira, AP Alves, EJG Pereira, NP Storer
202 Plant Industry Building, Department of Entomology, University of Nebraska Lincoln, NE 68506-0816. bsiegfried1@unl.edu

Transgenic maize hybrids expressing toxins from *Bacillus thuringiensis* have been available for managing European corn borer (*Ostrinia nubilalis* Hübner) populations since 1996. However, there is concern that this technology will result in widespread resistance to Bt toxins. The "high dose-refuge strategy" is the currently accepted method for managing resistance in *O. nubilalis* and has become a requirement of registration for all transgenic events. However, this strategy is based on a number of assumptions that are difficult to validate until resistance is identified and characterized. Resistant strains resulting form laboratory selections provide a potential tool to assess these assumptions in the absence of field derived resistant populations. However, such laboratory experiments are limited by their inability to reflect the selection intensity imposed on a field population exposed to transgenic plants. Our laboratory has been selecting *O. nubilalis* by exposure to Bt toxins incorporated into an artificial diet since 1998. A number of different colonies that vary with regard to the nature of the resistance, degree of dominance, number of genes and ability to survive on transgenic plants have been developed. The relevance of these strains in terms of their ability to improve and refine resistance management recommendations will be discussed.

Insecticide mode of action classification: a key to insecticide resistance management

CA Staetz
Insecticide Resistance Action Committee (IRAC International) (FMC Corporation), P.O. Box 8, Princeton, New Jersey, 08543, USA,
charles_staetz@fmc.com

The Insecticide Resistance Action Committee (IRAC) has developed a classification scheme for insecticides (and acaricides) that is based on mode of action (MoA). Experience has shown that effective insecticide resistance management (IRM) strategies seek to minimise the selection for resistance for any one type of insecticide or acaracide. In practice, alternations, sequences or rotations of compounds from different MoA groups provide a sustainable and effective approach to IRM. This ensures that selection for resistance through the use of compounds in the same MoA group is minimised. It is recognized that insecticide resistance can also result from enhanced metabolism by enzymes within the pest, reduced penetration of the pesticide into the pest or behavioural changes of the pest. These resistance mechanisms are not linked to any site of action classification, but are specific for individual compounds or chemical groupings. Despite this, alternation of compounds from different chemical classes remains an entirely viable resistance management technique because such a practice will always minimise selection pressures. This presentation describes the mode of action classification scheme and its use in IRM.

Insecticide resistance surveillance of disease vectors in Peru

JD Stancil, *C Flores Mendoza*
NMRCD, UNIT 3800, APO, AA 34031, USA, stancil@nmrcd.med.navy.mil

Vector-borne diseases, such as malaria and dengue, are significant public health problems in many countries of South America, including Peru. While environmental modifications and infrastructure improvements to reduce vector populations are the ideal, the reality in many areas of the world is that insecticides play a crucial role in vector suppression. Resistance to these insecticides can potentially interfere with vector control operations. In Peru, there is little information concerning insecticide resistance in *Anopheles darlingi* or *Aedes aegypti*, the principal vectors of malaria and dengue, respectively. Utilizing the CDC bottle bioassay, personnel from the U.S. Naval Medical Research Center Detachment, Lima and the Peruvian Instituto Nacional de Salud, have conducted over 3,300 assays of over 70,000 *An. darlingi* and *Ae. aegypti* mosquitoes to establish diagnostic concentrations for 8 insecticides representing 3 chemical classes. In addition to the assays, a workshop was held to train 22 technicians from 11 regional reference laboratories in Peru on the CDC bottle bioassay methodology. The goal of these assays and training is to ultimately establish a national insecticide resistance monitoring program and assist the Peruvian health authorities in implementing effective vector control programs.

Mechanisms underlying mite outbreaks following imidacloprid applications: effects on mite fecundity and natural enemy communities in landscapes.

A Szczepaniec, M Raupp
4112 Plant Sciences Bldg., Univ. of MD, College Park, MD 20742, USA , ada0708@umd.edu

Imidacloprid, a chloronicotinoid insecticide has become one of the most widely used products for insect control. It provides excellent control for many pests; however, following the elimination of the primary pest, secondary infestations of mites have been observed. The mechanisms underlying this phenomenon are thought to include alterations in mite fecundity levels stimulated by sublethal levels of the insecticide (hormoligosis), and disruption of natural enemy communities. To investigate the effect of imidacloprid on beneficial insects, we examined the influence of the insecticide on longevity and survival of a general predator, *Orius insidiosus*, and abundance and diversity of natural enemies on imidacloprid treated plants. Hormoligosis in boxwood mite (*Eurytetranychus buxi*) was also investigated. *Orius insidiosus* was shown to be negatively affected by imidacloprid in plants. However, the study of insect diversity and abundance indicated that beneficial insect communities differed only slightly between imidacloprid treated and untreated sites. Moreover, we were able to create increased densities of mites and attendant damage in the absence of predators. The results of the study suggest that the mechanisms leading to increased mite populations involve several aspects of mite and natural enemy ecology and, possibly, changes in mite or plant physiology.

Delayed resistance to Bt crops: is Arizona's story unique or universal?

S Morin, JA Fabrick, MS Sisterson, L Antilla, M Whitlow, Y Carrière, TJ Dennehy, BE Tabashnik.
Department of Entomology, University of Arizona, Tucson AZ, 85721, USA. brucet@ag.arizona.edu

Transgenic cotton producing *Bacillus thuringiensis* (Bt) toxin Cry1Ac that kills pink bollworm, *Pectinophora gossypiella*, has accounted for more than half of Arizona's cotton since 1997. Despite the wide use of Bt cotton and surprisingly high frequency of pink bollworm resistance to Cry1Ac detected in 1997, Bt cotton has remained extremely effective against pink bollworm. Laboratory bioassays show that the frequency of resistance to Cry1Ac did not increase from 1997 to 2003. Field-based estimates also show sustained efficacy during this period. In laboratory-selected strains with up to 3,100-fold resistance to Cry1Ac and survival on Bt cotton plants, resistance is linked with three recessive mutations in the gene encoding a cadherin protein that binds Cry1Ac. DNA-based monitoring of field-sampled individuals using the polymerase chain reaction (PCR) indicates that the frequency of the three identified resistance alleles remains low. Other examples of delayed resistance to Bt crops have been reported from Australia, China, and elsewhere in the USA. Factors delaying pest resistance to Bt crops include refuges of non-Bt crops, low initial resistance allele frequency, recessively inherited resistance, fitness costs, and incomplete resistance. The success of Bt crops exceeds expectations of many, but does not preclude future resistance problems.

Construction of transgenic *Bombyx white egg-1* mutant introduced kynurenine 3-monooxygenase gene

I Kobayashi, G Quan, K Uchino, K Kojima, T Kanda, T Shimada, T Tamura
NIAS, Owashi1-2, Tsukuba, Ibaraki 305-8634, Japan, ttamura@affrc.go.jp

Bombyx white egg 1 mutant (*w-1*) is characterized by the white colour egg and eye. It was known that the mutant kynurenine 3-monooxygenase gene possesses a partial in the exons. To understand an effect of complementation of wild type *KMO* gene, we introduced *KMO* cDNA with the promoter of native *KMO* or cytoplasmic actin gene (*A3*). We obtained three transgenic lines with A3 promoter and one line with the native promoter. The adult eyes of these lines turned to be brown and the eggs laid by the transformed females were also brown. The analysis by RTPCR showed that the lines with *A3KMO* gene accumulated the transcript in the mid gut, fat body and Malpighian tubes. A line with *KMO* promoter expressed it only in the fat boy and Malpighian tubes. The strength of eye and egg colour in the transgenic line was proportional to the *KMO* expression level. Interestingly, the transgenic larvae with *A3KMO* gene changed the larval skin colour more brownish. These results suggest that the morphological change in *w-1* mutant is caused by a deletion of *KMO* gene. The mutant and *KMO* gene can be used as a host and marker for a construction of transgenic silkworm.

Presence of avidin and aprotinin in the bodies and frass of *Spodoptera litura* (Lepidoptera: Noctuidae) larvae feeding on transgenic tobacco plants.

LA Malone, JH Todd, JT Christeller, RM Marshall, EPJ Burgess, BA Philip
HortResearch, Mt Albert Research Centre, Private Bag 92169, Auckland, New Zealand, jtodd@hortresearch.co.nz

To determine whether herbivorous insects and their frass could be environmental sources of novel proteins from transgenic plants, *Spodoptera litura* larvae were fed on transgenic tobacco leaves expressing either the biotin-binding protein, avidin, or the protease inhibitor, aprotinin. Control larvae received non-transgenic tobacco. Samples of 20 larvae each were taken on Days 5, 6 and 7 and two samples of frass on Days 6 and 7. Insects in all treatments grew significantly between Days 5 and 7, but the avidin-fed larvae were significantly smaller and produced less frass than the others on Day 7. All insects produced more frass on Day 7 than on Day 6, but the mass of frass produced per mg insect did not vary from day to day. Both novel proteins were present in larvae at lower concentrations than in the transgenic leaves they had fed upon. Unbound avidin was found in the samples of avidin-fed larvae and their frass. Aprotinin was detected in all larval and frass samples from insects fed aprotinin-tobacco. Unbound aprotinin accounted for only a portion of that found in larvae and in frass.

Bollgard® II cotton, tested for the first time in West Africa, shows excellent lepidopteran control and potential for improved cotton production

O Hema, O Traoure, D Sanfo
Programme Coton / INERA 01 B.P. 208 Bobo- Dioulasso 01 Burkina Faso

Field studies were conducted in Burkina Faso during the 2003 cropping season to evaluate the efficacy, against lepidopteran insects, of cotton expressing two endotoxins of *Bacillus thuringiensis* subsp. *kurstaki* (Berliner), commonly known as Bollgard® II cotton. Bollgard® II, treated against sucking and piercing pests only, was compared, in two research stations, to local varieties treated against lepidopteran insects and sucking pests. Our data showed that Bollgard® II cotton provided control of major lepidopteran species that attack cotton in Burkina Faso. The average number of bollworm larvae per plant over time was significantly different between transgenic cotton (treated against sucking pests only) and a local variety (treated against lepidopteran insects and sucking pests). The average number of *Helicoverpa armigera* larvae per Bollgard® II plant was reduced by 92% when compared to the local varieties. Bollgard II and the local spraying regimen were similarly highly effective in reducing foliar feeding lepidopterans. The difference in damage by lepidopteran insects, resulted in fewer abscissions of floral and fruiting bodies and higher numbers of bolls per plot in the Bollgard® II cotton. In Frako-Bâ and Kouaré evaluation sites, Bollgard® II cotton rendered a yield 13% and 19% higher, respectively, than the commercial local variety.

Bt crops in Argentina: efficacy and resistance management

GW Videla.
Dorrego 487 (2700) Pergamino, Argentina. guillermo.w.videla@la2.monsanto.com

Bt crops began to be de-regulated in 1998 (Bt Cotton: MON 531; Bt Corn: E 176, and MON 810). In 2001, Bt 11 was also authorized. Both Bt crops have steadily increased their acreages. Last season, 45 % of the corn area was planted with Bt corn, and 20% of the cotton was Bt. Bt corn produces Cry1Ab protein, and Bt cotton produces Cry1Ac protein. Corn and cotton producing areas do not significantly overlap, and the only lepidopteran pest in common for both crops in the country is *Spodoptera frugiperda.* Target pests for Bt-cotton are: *Alabama argillacea, Heliothis virescens/Helicoverpa gelotopoeon* complex, and *Pectinophora gossypiella.* For Bt-corn, the target species is *Diatraea saccharalis.* The Insect Resistant Management (IRM) group proposes strategies for the management of Bt crops, based on local and external experiences. Research is conducted by third party entomologists from Universities, and National Research Institutes. Mainly, the the strategy is based on a required refuge (non-Bt crop), which is 20% for Bt-cotton, with the possibility of insecticidal-non-Bt applications as needed, according to economic thresholds. For Bt-corn, the requirement is 10% refuge without any insecticides for the target pest. IRM strategy also considers studies such as baselines, emergency plans, monitoring, and continuous studies related to the size of the refuge, that will be discussed during the presentation.

Altered gene expression levels linked to fenvalerate resistance in cotton bollworm, *Helicoverpa armigera*

CW Wee, DG Heckel
CESAR-Centre for Environmental Stress and Adaptation Research, Department of Genetics, University of Melbourne, Victoria 3010, Australia
(c.wee@pgrad.unimelb.edu.au)

The ANO2 strain of *Helicoverpa armigera* is 50-fold resistant to the pyrethroid insecticide fenvalerate; largely due to a single gene, *RFen1*, on Linkage Group 13. The cDNA-AFLP technique was used to search for changes in gene expression levels controlled by or linked to *RFen1*. Larvae from a segregating backcross family were genotyped at a linked marker locus, enabling prediction of their fenvalerate resistance status without exposure to insecticide. mRNA was isolated from individual larvae and used to make cDNA, which was processed for AFLPs (double restriction digestion, ligation to adapters, amplification by two rounds of PCR, and resolution of labelled fragments on a sequencing gel). 256 different primer combinations were tried and a total of 426 bands showing differences between resistant and susceptible groups were identified. Three were cytochrome p450s, with similarity to *Depressaria pastinacella* CYP6AE1 and *Helicoverpa armigera* CYP4S1 and CYP4AP1. The latter was upregulated whereas the other two were down-regulated in the resistant group. In addition, two carboxylesterases were down-regulated and one was up-regulated in the resistant group. Currently, real time RT-PCR is being used to verify the results and full length sequences of these potential detoxification genes are being sought using rapid amplification of cDNA ends (RACE).

Bt: Organic production – new life for the oldest commercial biopesticide.

ME Whalon
Department of Entomology and Center for Integrated Plant Systems, Michigan State University, East Lansing, Michigan, USA. E-mail: whalon@msu.edu
Fax: 517-353-5598

The Organization for Economic Cooperation and Development predicts that biopesticide may grow to 20% of the world's pesticide market by 2020. Biopesticides represent approximately 1% of the world pesticide market, and Bt products represent > 75% of biopesticides sold. Other organizations like the World Health Organization, Food and Agriculture Organization and European Commission are also predicting dramatic growth for biopesticides over the next 10-20 years. Sprayable Bt formulations have penetrated cotton, fruit and vegetable, aquatic and other insecticide markets in the US, EU and the world. Organic producer dependence on Bt for worm and, in a more limited fashion, beetle control globally. In fact, many organic workers claim that Bt is more important to the organic community than to other producers because conventional producers have a greater array of management tools to choose from. With organic produce sales increasing steadily worldwide, Bt use and resistance management should be an important consideration in any system that anticipates frequent application, but especially in organic production systems where use can be extreme. Fortunately, the organic formulation of Spinosad™--a fermentation macrocyclic lactone product, is changing management practices in many cropping systems and this may change Bt's organic market dominance. In addition, new insect growth regulators and other novel modes of action may be entering the organic market in the next few years providing new opportunities to implement truly integrated management programs in organic production.

The international arthropod resistance database and newsletter: a report

M Whalon, R Hollingworth, D Mota-Sanchez
Michigan State University, East Lansing , MI 48823, USA. Whalon@msu.edu

A number of resources related to resistance management have been cultivated at Michigan State University in the USA. This presentation will highlight these developments and how resistance workers all over the world can access and participate. The first of these is the Resistant Pest Management Newsletter (RPM News), which has a worldwide circulation of roughly 2,500 resistance workers in academia, industry, and government. It provides information on ongoing changes and advances in the field of resistance management, and is produced in cooperation with the Insecticide Resistance Action Committee (IRAC), the US Department of Agriculture (CSREES) and the US Western Regional Coordinating Committee (WRCC-60). Our goal in implementing a resistance database is to help address arthropod resistance by evolving an integrated, cooperative system to effectively deliver resistance information efficiently. Our information currently resides in an electronic database at Michigan State University's Center for Integrated Plant Systems and is available via the Internet at http://www.cips.msu.edu/resistance/rmdb/. The database design features a central table of 'resistance' records with five key pieces of information: the arthropod, the pesticide, the location (country), the year, and a reference to the document reporting the case. There are secondary tables that elaborate on these five key informational groups as well as auxiliary tables to help refine the information further or link to external data sources.

Juvenile hormone bioanalogs – selectivity, importance and perspectives in insect pest management

Z Wimmer, J Kuldová, I. Hrdy, B Bennettová
Institute of Organic Chemistry and Biochemistry AS CR, Flemingovo náměstí 2, CZ-16610 Prague 6, Czech Republic. wimmer@uochb.cas.cz

Insect juvenile hormone bioanalogs (JHAs, juvenoids) have been the target of the long-term research in our team for many years. A special interest has been paid to several series of 2-(4-hydoxybenzyl)cycloalkanols for their high biological activity values obtained in screening tests to a broad variety of insect species. Even if a number of these JHAs have been proven to be stable but non-persistent under the environmental conditions, designing of ways for limited increase of their stability in environment and for modification of their physico-chemical properties had been performed. This effort resulted in designing and developing the pioneer hormonogen substances (juvenogens). The juvenogen molecule consists of a JHA, bearing convenient functionality, which can be easily transformed into another functionality by chemical means or by enzymic ways. This step results in a synthesis of a biologically inactive or low active substance, which is characterized by physico-chemical properties different from those found with the parent JHA. The new substance, a juvenogen (a hormonogen chemical species), can be prepared as a targeted species, a substance bearing physico-chemical properties designed in advance. This strategy enables to synthesize "juvenogens upon demand", which are designed for application on selected insect species under selected laboratory or environmental conditions.

UK-wide studies of biodiversity impact of GMHT crops

IP Woiwod
Plant and Invertebrate Ecology Division, Rothamsted Research, Harpenden, Hertfordshire AL5 2JQ, UK, Ian.Woiwod@bbsrc.ac.uk

By the end of 1998 four genetically modified herbicide-tolerant (GMHT) crops were nearing the end of the regulatory hurdles for commercial growing in the UK. Although human health and direct environmental effects had been assessed and they had been declared safe the question was raised about indirect environmental effects caused by more efficient weed control. The result was the Farm Scale Evaluations, one of the largest agro-environmental impact studies ever undertaken, covering plant and invertebrates at 60-70 field sites for each of 4 crops over a three year period. The background and results from these trials will be discussed in relation to wider issues about insect biodiversity in agricultural landscapes.

Current status and future prospect of Bt cotton commercialization in China

K Wu, *Y Guo*
Institute Of Plant Protection, Chinese Academy Of Agricultural Sciences, Beijing 100094, China, wkm@caascose.net.cn

Transgenic cotton that expressed a gene derived from the bacterium *Bacillus thuringiensis* (Bt) was introduced for combating *H. armigera* in 1997, and rapidly increased to 58% of the total cotton area of 4.8 million ha. in 2003. In the Yellow River cotton-farming region of Northern China, where *H. armigera* has historically caused major yield losses, Bt cotton has been exclusively planted. The pest management tactics associated with Bt cotton planting causes astic reduction in use of insecticides due to the high efficacy of the transgenic cultivars in suppression of *H. armigera* infestations, increases the abundance of beneficial insects and improves the natural control of some pests. The monitoring results indicate that movement toward Bt cotton resistance in *H. armigera* is not apparent in face of intensive planting of Bt cotton over several years, which could be associated with the migratory behavior of the insect and the natural refuges derived from the mixed planting system of cotton, corn, soybean and peanut on single- family holdings with a small scale under one half hectare.

The involvement of microsomal oxidases in pyrethroid resistance in *Helicoverpa armigera* from Asia

Y Yang, Y Wu, S Chen, GJ Devine, I Denholm, P Jewess, GD Moores
Department of Entomology, College of Plant Protection, Nanjing Agricultural University, Nanjing 210095, P.R.China, wyd@njau.edu.cn

Five contemporary strains of the bollworm *Helicoverpa armigera* Hübner from China, Pakistan and India, all with high resistance to pyrethroids, were compared with a standard susceptible strain that originated from the Cote D'Ivoire in the 1970s ('SCD'). The strong synergism of pyrethroids by PBO implied that an oxidative metabolism could be involved in pyrethroid resistance in all resistant strains. The activities of cytochrome P450 monooxygenases from midguts of final instar larvae to *p*-nitroanisole (PNOD), ethoxycoumarin (ECOD), methoxyresorufin (MROD) significantly increased in all the resistant strains when compared with the susceptible strain. This further implies that cytochrome P450 monooxygenases are involved in pyrethroid resistance in Asian *H. armigera*. Comparative *in vitro* studies of the metabolism of ^{14}C-deltamethrin by midgut microsomes of the resistant PAK and susceptible SCD strains showed that the resistant strain had a much greater capacity than the susceptible strain for the metabolic degradation of deltamethrin. This enhanced metabolic degradation occurred in the presence of NADPH which suggested an oxidative detoxification. In the resistant strains, minor increases in glutathione S-transferase activity (to the substrates CDNB and DCNB), and esterase activity (to the substrate α-naphthyl acetate) further suggested that, of the putative metabolic mechanisms, oxidases are the most important. This study provides the first evidence that cytochrome P450 monooxygenases are a major metabolic mechanism responsible for pyrethroid resistance in *H. armigera* from Asia.

Bt rice studies of ecological risk and nontarget effects in China

GY Ye, HW Yao, ZC Liu, M Chen, CY Jiang, H Cui
State Key Laboratory of Rice Biology, Institute of Applied Entomology, Zhejiang University, Hangzhou 310029, China, chu@zju.edu.cn

Bt rice has been permitted for field trials since 1998. After then, impacts of our different Bt rice lines containing *cry*1Ab or *cry*1Ab/*cry*1Ac gene with high resistance against rice stem borers and leaffoles, on the arthropod community and population dynamics of some dominant nontarget phytophages and spiders under field conditions was evaluated using different sampling methods. The results showed that our Bt rice lines generally did not have any significant negative effects on the arthropod community in rice paddy habitat, except that sometime resulting in the marked decrease in the abundance of some parasitoids of target pests such as braconids and ichneumonids. These tested lines also did not act any adverse impacts on the predation, growth and development, reproduction of two common spiders, *Pirata subpiraticus* and *Ummeliata insecticeps,* using either leaffolders or planthoppers feeding on Bt rice plants as their prey. In contrast, some Bt rice lines might not be suitable for the brown planthopper, *Nilaparvata lugens* to feed and lay eggs. In addition, no significant adverse effects were found on the survival, growth and development as well as the fecundity of the domestic silkworm, *Bombyx mori* fed with the mulberry leaves contaminated by Bt rice pollen grains.

In vivo effect of PBO on resistance-associated esterases from Australian *Helicoverpa armigera* Hübner (Lepidoptera: Noctuidae)

SJ Young, RV Gunning, GD Moores
Rothamsted Research, Harpenden, AL5 2JQ, UK graham.moores@bbsrc.ac.uk

Piperonyl butoxide (PBO) is a commercially important and successful insecticide synergist against a variety of insects in house-hold situations and against public health pests. In agriculture use has been restricted to use against the cotton bollworm, *Helicoverpa armigera* (Hübner) (Lepidoptera:Noctuidae). It has been deployed in the field to help partially restore the efficacy of pyrethroids that are currently compromised by metabolic based resistance. It has been established that PBO inhibits some insect esterases associated with insecticide resistance (Gunning *et al.*, 1998; Moores *et al.*, 1998; Young *et al.*, 2002; Young *et al* 2003). Kinetic esterase assays using *H. armigera* reveal that esterase activity was inhibited by the insecticide synergist, PBO, over a 24hr period. Esterase inhibition by PBO did not occur immediately after doseage but occurs with maximum enzyme inhibition being obtained several hours later. Laboratory analysis with *H. armigera* and pyrethroids confirmed that maximum synergism occurred at the pre-treatment times corresponding to maximum *in vivo* esterase inhibition in biochemical studies. These results were confirmed in the field when using a 5 hr pre-treatment of PBO prior to pyrethroid exposure. These results indicate that with improved temporal application of PBO, it may be possible to restore some pyrethroid efficacy in *H. armigera*. It would also be expected that partial restoration of efficacy with other conventional insecticides currently compromised by esterase based resistance mechanisms would occur.

PTD significantly synergize Bt and overcome the low resistance of diamondback moth to Cry1Ac

YJ Zhang , FS Yang , QJ Wu, BY Xu , J Zhang, DW Qiu , GR Zhu
Institute of Vegetables and Flowers, Chinese Academy of Agricultural Science, Zhongguancun South Street, Beijing 100081 China, zhangyj@mail.caas.net.cn (or youjunzhang@hotmail.com)

Protein Transduction Domains (PTD) are kinds of peptides which can automatically penetrate bio-membrane and be acted as a carrier to transfer foreign molecule into cell(Science. 1999,285(3):1569-1572.). A fusion gene,pET21b-TAT-Cry1Ac, consisting of Cry1Ac and TAT(a kind of PTD) ,as well as its control pET21b-Cry1Ac was constructed and expressed in E.coli. The toxicity of this two expressed and purified fusion proteins to Diamondback moth were determined. To the susceptible strain the LC50 of Cry1Ac and TAT-Cry1Ac are 20.55 mg/L and 4.25 mg/L; and 124.23mg/L and 12.81 mg/L to the low resistant strain. TAT-linked Cry1Ac show a synergistic ratio of 4.84 folds to the susceptible strain, 9.70 folds to the resistant strain, and restore the susceptibility of low resistant Diamondback moth to Cry1Ac. PTD show strong potential in synergizing Bt insecticidal protein and overcoming Bt resistance.

Fluctuating asymmetry of target and non-target insects in response to the stress of GM cotton

BP Zhai, N Li, XD Liu, L Meng
Department of Entomology, Nanjing Agricultural University, Nanjing 210095, P.R. China

Fitness and fluctuating asymmetry (FA) in response to the stress of GM cotton were examined among the different symmetric characters of target and non-target pests (cotton bollworm, *Helicoverpa armigera*, CB, and cotton aphid, *Aphis gossypii*) and a beneficial species (Asian lady beetle, *Harmonic axyridis*, ALB). The results indicate that non-target effects do arise from some GM cultivars. The FA values of CB in lab decreased gradually generation by generation. The light-trap catches of CB collected in northern China with different planting history of Bt-cotton (1~5 years) also exhibited a similar trend on FA. Bt-cotton and conventional cotton are equally suitable hosts for cotton aphid. The fitness and FA of ALB and cotton aphid were similarly when fed on the aphids from both Bt-cotton and conventional cotton. But the Bt+CpTI cotton present significant impacts on the fitness of cotton aphid that their intrinsic rate of increase and fecundity decrease significantly in the first and second generation. The aphids feeding on Bt+CpTI cotton showed higher FA and their feeding behavior detected by EPG is different significantly with Bt-cotton and conventional cotton. The possibility of FA as a sensitive indicator for the ecological risk and environmental stress of GM crops are discussed.

Genetic diversity study of native Iranian silkworm using ISSR markers

A Balvasi, E Bagheri-Zenouz, Z Ansari and J Nozari
PO Box 578, Sari, Mazandaran, Iran, z.ansari@umz.ac.ir

Five diverse strains of the native Iranian silkworm were analysed using the simple sequence repeat anchored polymerase chain reaction. Samples (30 larves from 3rd day of 5th instar for each population) were collected from silkworm research institute. DNA was extracted from sericigene glands by modified Suzuki method. A set of three 5'-anchored repeat primers amplified a total of 211 bands out of which 208. A denogram constructed using the UPGMA method revealed two distinct groups. Maximum unbiased genetic distance was between Pink and Gilani and Minimum was between Gilani and Baghdadi. Gilani and Baghdadi were in one group and other populations were in separated groups. Maximum and minimum gene diversity average was in Khorasani and Baghdadi respectively. Genetic diversity average for total populations was 0.3575. Average of effective number of alleles was maximum in Khorasani and minimum in Baghdadi and for whole populations was 1.5995. Maximum polymorphism was seen in Khorasani and minimum was in Limon and Baghdadi. These results suggest that ISSR method is potentially useful for study of genetic diversity of silkworm and as a mapping tool in the silkworm.

Ecology of *Helicoverpa* spp. (Noctuidae) and their parasitoids, in relation to the use of transgenic cotton and associated refuge crops.

GH Baker, GP Fitt, CR Tann
"CSIRO Entomology & Australian Cotton CRC, PO Box 1700, Canberra, ACT, 2601, Australia. Geoff.Baker@csiro.au"

Transgenic (Bt) cotton varieties provide a substantial basis for economically and environmentally sustainable insect pest management within the Australian cotton industry. Whilst the introduction of Bt cotton (in 1996) has significantly reduced pesticide use and encouraged a greater emphasis on the management of beneficial invertebrates in pest control, its impact on the overall abundance of the target moth pests, *Helicoverpa* spp., in cotton-growing regions is poorly understood. This poster will present analyses of long-term data sets from northern New South Wales and southern Queensland, including pheromone and light trapping programs, to test if populations have changed over time. In addition, the efficiency of designated refuge crops (no Bt use), which must be grown in partnership with Bt cotton to generate large numbers of *Helicoverpa* that are susceptible to Bt and thus reduce the likelihood of the development of resistance, will be discussed. Finally, the degree to which refuge crops, other agricultural crops besides cotton, and non-agricultural habitats produce significant populations of natural enemies of *Helicoverpa* will be described.

Toxicity of cascade (flufenoxuron) to natural enemies and influence upon arthropod pests in citrus orchard

SR Benvenga, S Gravena, J L. da Silva, LCS Amorim
PO Box 546, Jaboticabal, SP, 14870-990, Brazil, gravena@gravena.com.br

The toxicity of cascade (flufenoxuron 100 CE; 30 mL/100 L) and mixture with pyridaben 200 CE (50 mL), abamectin 18 CE (20 mL), acrinathrin 50 SC (5 mL), propargite 720 CE (50 mL) and dinocap 369 CE (50 mL) were evaluated to the predators mites *Euseius citrifolius* and *Iphiseiodes zuluagai* (Acari: Phytoseiidae), the ladybugs *Pentilia egena*, *Cycloneda sanguinea* and *Azya luteipes* (Coleoptera: Coccinellidae) and to the lacewings *Chrysoperla externa* and *Ceraeochrysa cubana* (Neuroptera: Chrysopidae) in citrus orchard. The density of preys was also evaluated between 3 and 60 days after the application, on a randomized blocks with 10 treatments, 5 replications and plots of 12 plants. The predators mites were evaluated on internal leaves and the leprosis citrus mite, *Brevipalpus phoenicis* (Acari: Tenuipalpidae) on fruits. The ladybugs and lacewings were evaluated on leaves infested with the scales *Selenaspidus articulatus* and *Parlatoria ziziphi* (Hemiptera: Diaspididae) around the tree canopy. Flufenoxuron in mixture was highly efficient to control *B. phoenicis*, as the standard mitecide fenbutatin oxide 500 SC (80 mL). The density of *S. articulatus* and *P. ziziphi* were similar to the check plants. The mixtures with pyridaben, acrinathrin and propargite were of low toxicity (<50% of reduction) to the natural enemies.

Microencapsulated α-cypermethrin and PBO with delayed release of active ingredient restores pyrethroid susceptibility in B-biotype *Bemisia tabaci*.

GV Bingham, R Gunning, GD Moores,
Rothamsted Research, Harpenden, Herts. , UK. Georgina.bingham@bbsrc.ac.uk

Pyrethroid resistance in B-biotype *Bemisia tabaci* field populations is primarily a consequence of overproduction of esterase isoenzymes that metabolise and sequester pyrethroid insecticides. Laboratory and field studies demonstrated that the synergist piperonyl butoxide (PBO) can potentiate pyrethroid mortality against resistant field populations in Australia. This is dependant upon a delay in applying the active (α-cypermethrin), after PBO application. PBO inhibits the esterase isoenzyme, thus regaining susceptibility, by preventing pyrethroid detoxification. A single application of a novel formulation of microencapsulated α -cypermethrin allowed time for PBO to inhibit the esterase prior to the release of pyrethroid. In laboratory bioassays, using a pyrethroid resistant field population, use of microencapsulated α-cypermethrin with PBO reduced the resistance factor from 200 fold to 5 fold. A simultaneous application of PBO and α–cypermethrin only reduced the resistance factor to 145 fold. A similar gain in efficacy was also obtained in a field trial. The microencapsulated formulation gave almost complete mortality in the sprayed area, whereas α-cypermethrin applied at the registered rate achieved no mortality. The use of this microencapsulated pyrethroid and PBO clearly has the exciting potential to restore pyrethroid susceptibility in B-biotype *Bemisia tabaci.*

Cry2Ab resistance in *Helicoverpa armigera*

LJ Bird, W James, L Masson, RJ Akhurst
CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia. lisa.bird@csiro.au

Transgenic cotton that produces Cry1Ac and Cry2Ab will be used in Australia for the management of *Helicoverpa* spp. with reduced usage of synthetic chemical insecticides, to which *Helicoverpa armigera* has already developed resistance. There is some concern about the risk of resistance to the transgenic cotton by *H. armigera*, which has a demonstrated capacity for resistance to Cry1A toxins. We tested the potential for Cry2Ab resistance in *H. armigera* by selection of field populations on artificial diet containing Cry2Ab. Independently, resistance to Cry2Ab was detected in an F_2 screen involving only 33 single pairs (1/132 alleles; R. Mahon, pers comm.), suggesting that the resistance allele may be common in *H. armigera*. Shortly thereafter, resistance was detected in our strain after only three generations of selection. Following a further four generations of selection, the resistance ratio stabilised at 80-fold, a level at which Cry1Ac-resistant *H. armigera* can complete development on Cry1Ac-cotton. Preliminary characterization of this strain will be discussed.

Biochemical and molecular mechanism of prothiofos-resistance in the diamondback moth, *Plutella xylostella* (L.)

KS Boo, BY Seo, DW Lee, BK Chung, SH Lee
Lab. Insect Physiology, Seoul National University, Seoul 151-742, South Korea, ksboo@plaza.snu.ac.kr

To understand resistance mechanism of the diamondback moth (DBM, *Plutella xylostella*) against prothiofos, a resistant strain (DBM-R) has been established from the susceptible (DBM-S) strain and maintained over 100 generations under the selective pressure of prothiofos. The activity of general esterase in the DBM-R strain was 2 times higher than that in DBM-S strain, whereas there was no significant difference in glutathione S-transferase activity. Acetylcholinesterase (AChE) of the DBM-R strain, however, showed a low affinity for acetylthiocholine iodide, and its activity was 1.2-fold higher than that of the DBM-S strain. Inhibitory kinetic analysis of the resistant AChE with paraoxon exhibited the reduced bimolecular reaction constant (k_i) by 7-fold, indicating that the resistant AChE is much less sensitive to paraoxon. The nucleotide sequences of the *AChE* gene in both strains showed polymorphism due to amino acid substitutions at several positions. In addition, *AChE* gene in genomic DNA has no intron and of different length, such as 1717- and 1917-bp from DBM-S and 1614- and 1917-bp from DBM-R, showing possibly multiple copies of *AChE* genes in their genome. These results suggest that the increased AChE activity, AChE insensitivity and polymorphisms in AChE amino acid sequence contribute to the development of prothiofos-resistance in the DBM-R strain.

Analogues of piperonyl butoxide and their efficacy against metabolic enzymes.

V Borzatta, G Bingham, E Cappacella, R Gunning, P Trincia, S Young, GD Moores.
R+D Dept., Endura SpA, via Baiona 107-111, 48100 Ravenna, Italy. vborzatta@endura.it

Analogues of piperonyl butoxide (PBO) were synthesised and structures confirmed by NMR and mass spectrometry. Homologues contained alterations to either the methylenedioxyphenol moiety or the polyethoxy side chains, and the *in vitro* efficacy of the analogues against non-specific esterases and microsomal oxidases assayed biochemically. It was confirmed from these assays that the methylenedioxyphenol ring must be intact for efficacy against microsomal oxidases, but was found to be non-essential for activity against non-specific esterases. Such analogues, therefore, are of great interest in exploiting the contribution of metabolic enzyme systems in insecticide resistance.

Insecticide defenses in *Ochlerotatus sollicitans* (Walker) (Diptera: Culicidae) larvae

S Huang, LB Brattsten
Rutgers University, Dept of Entomology, Blake Hall, 93 Lipman Drive, New Brunswick, NJ 08901 USA; Brattsten@aesop.rutgers.edu

Oc. Sollicitians is a major pest mosquito along the eastern coast of North America. It is a competent vector of the eastern equine encephalitis virus (EEEV). In New Jersey, *Oc. Sollicitians* is controlled in its larval stages by temephos (an organophosphate), which has been used as primary larvicide on the salt marshes since the 1970's, and methoprene, and in the adult stage by malathion (an organophosphate) and synergized pyrethoids. Resistance of *Oc. Sollicitians* in several localities toward these insecticides has been well documented. However, the mechanisms are unclear. *Oc. Sollicitians* populations from South New Jersey and North New Jersey still have considerable sensitivity to temephos, carbaryl and resmethrin; the southern mosquitoes are less sensitive than the northern ones. Environmental factors including salinity and water pH do not significantly affect the toxicities. Toxicity assays with synergists (piperonyl butoxide and DEF) show that cytochrome P450s and esterases are the two primary enzyme systems involved in temephos, carbaryl and resmethrin detoxification. RT-PCR and molecular cloning show that many cytochrome P450s are expressed. Comparison of the cytochrome P450 profiles between the northern and southern NJ mosquito populations will be used to identify the isoform(s) responsible for the different sensitivities to the tested insecticides.

Impact of *Bacillus thuringiensis* transgenic maize on non-target arthropod populations in the southeastern United States

T Daly, GD Buntin
"Department of Entomology, University of Georgia, Georgia Station, Griffin, GA 30223, USA, gbuntin@griffin.uga.edu"

Transgenic field maize has been genetically engineered with the gene from the *Bacillus thuringiensis* var. *kurstaki* (Bt), which secretes proteinaceous endotoxins that is toxic to certain species of lepidopteran pests. The effects of transgenic Bt maize containing the MON810 event on non-target arthropods were compared to those in conventional, near isogenic maize. The study was conducted at two locations in Georgia in 2001 and 2002 using visual counts, pitfall traps, and ear insect evaluations. The only insect whose numbers and mortality was consistently affected by the Bt maize was the corn earworm, *Helicoverpa zea* (Boddie), a target insect. There were no consistent effects of the Bt toxins on non-target phytophagous and predaceous arthropods observed in the visual counts, nor on those non-target arthropods recovered from the pitfall traps and the maize ear dissection. From these results, transgenic Bt field maize containing the MON810 event does not have an adverse effect on non-target phytophagous or predaceous arthropods.

Uptake and persistence of imidacloprid in California vineyards

FJ Byrne, SJ Castle, JL Bi, NC Toscano

"Dept of Entomology, University of California, Riverside, CA92521, U.S.A. and USDA-ARS Western Cotton Research Laboratory, Phoenix, AZ, USA. frank.byrne@ucr.edu

The glassy-winged sharpshooter (GWSS) *Homalodisca coagulata* Say has become the principal vector of the plant pathogenic bacterium *Xylella fastidiosa* Well in southern California. Strains of *X. fastidiosa* cause several economically important plant diseases, including Pierce's Disease (PD) in grapevines. The GWSS transmits this disease while it feeds on the xylem fluid of host plants. The Temecula Valley viticultural region in southern California was severely affected by a PD epidemic that began in 1996, with some wineries reporting losses of 20% to 30% of their vines. There is no cure for PD and infected vines must be removed from the vineyard. In a comparison of Admire application rates in Temecula Valley vineyards, a 16 oz. per acre treatment proved very effective at attaining xylem sap imidacloprid levels that were necessary to protect vines from sharpshooter feeding. In contrast, the same rate applied to table grapes in Coachella Valley vineyards produced levels of imidacloprid within the xylem sap that were extremely short-lived, raising concerns about the utility of this material within this region. Information about the soil type was found to be particularly important for the effective deployment of Admire applications in both regions."

Monitoring resistance to insecticides of diamondback moth and some alternate application in Thailand

P Chayopas, P Keinmeesuke, T Saito
"Plant Protection Research & Development Office, Dept. of Agriculture, Bangkok 10900,Thailand, parnpen@doa.go.th , parnpen_tu@hotmail.com"

Monitoring resistance of diamondback moth, *Plutella xylostella* L. was done in the laboratory by leaf dipping bioassay. Larvae from 4 parts of Thailand; north , north- east , central and west were tested with some insecticides and *Bacillus thuringiensis* (Bt) both var. *kurstaki* and *aizawai*. Studies in 1997-2001 , larvae from central with many vegetable growing areas ; Pathumthani (PNS)and Nonthaburi province(BBS and SNS) developed resistance to almost all insecticides used by crucifer growers such as permethrin, deltamethrin, lambda-cyhalothrin, prothiofos, enofos, abamectin, fipronil, chlofenapyr and chlorfluazuron with resistant ratio(RR) 23.19-138.27 fold compared to susceptible strain from Japan . Because of the continuous use and almost same crop grown in same area throughout the year. However, in some northern area;Sunsai, Chiengmai province (SSS) had no resistance to deltamethrin, lambda-cyhalothrin, enofos, chlorfluazuron, abamectin, fipronil, chlofenapyr and spinosad with RR 3.71-10.54 fold . Every parts showed high resistance to permethrin but did not have any Bt resistant. In 2003, alternate application trial was done in farmer's field ,growing Chinese Kale, at Bangbuathong(BBS,central part). Spinosad 2 times alternated with Bt.a 2 times each sprayed day after 2 days interval throughout the crop season gave highest marketable yield and significantly lowest number of larvae.

Cloning of vitellogenin cDNAs of the oriental fruit fly, *Bactrocera dorsalis* (Hendel), and its expression analysis

SL Chen, CP Lin, KH Lu
"Department Of Entomology, National Chung-Hsing University, 250 Kuo-Kuang Road, Taichung, Taiwan, d9036001@mail.nchu.edu.tw"

In the present research, vitellogenin (Vg) genes of the oriental fruit fly, *Bactrocera dorsalis* (Hendel) were investigated. Referring the conservation regions by alignment of several known dipteran vitellogenins (yolk proteins), a pair of degenerate primers was designed. Based on the degenerate primers, two different putative vitellogenin cDNA fragments were obtained by RT-PCR, and then the full length cDNAs corresponding to both fragments were further achieved by using 5'- and 3'-end RACE methods, cloned and sequenced. These two cDNA were named *Bdvg1* (accession No. AY368053) and *Bdvg2* (accession No. AY368054), respectively. The cDNA of *Bdvg1* was 1507 bp and contained an ORF encoding 437 amino acids, and *Bdvg2* was 1434 bp and contained an ORF encoding 440 amino acids as well. Both *Bdvg1* and *Bdvg2* were highly similar to the Vgs of relative insects such as *Ceratitis capitata*, *Anastrepha suspense*, *Calliphora erythrocephala* and *osophila melanogaster*. RT-PCR analysis revealed that both Vg genes were expressed specifically in the adult females but not in adult males, eggs, larvae and pupae. The *Bdvg1* and *Bdvg2* mRNAs were detected in the fat bodies of 1- and 2-day-old females, respectively. In addition, the Vg genes were expressed in the ovaries since day 2 after female emergence.

Diminished egg size in fenvalerate resistant strains of the diamondback moth (DBM)

XD Chen, *F Nakasuji*
"Faculty of Agriculture, Okayama University, Tsushima,Okayama 700-8530, Japan, gag14132@cc.okayama-u.ac.jp"

Female adults of *Plutella xylostella* (DBM) treated with sublethal doses of a pyrethloid, fenvalerate lay small-sized eggs. In the process of resistance development, DBM may also lay small-sized eggs under successive selection with insecticides at sublethal doses. In the present study, we conducted a selection experiment using DBM and fenvalerate. DBM was selected with fenvalerate at the dose of LD_{50} for 8 generations. The LD_{50} value rose gradually and resistance ratio became 60-folds. The egg size of the selected strains became significantly smaller than that of the non-selected strains within 2 or 3 generations and it stabilized thereafter. To investigate the genetic changes in the egg size in the selected strain, offspring of the selected and non-selected strains were individually reared at every other generation. The eggs of the selected strain were significantly smaller than those of the non-selected strain in all generation, and survival rate during the immature stages in the former was lower then that of the latter. Other life history traits did not differ between the two strains. This result the successive selection with fenvalerate at sublethal does yielded a fitness disadvantage in DBM population.

Aldicarb and its sulfoxide and sulfone metabolites residues in coffee leaves and efficacy for the control of the coffee leafminer

GI Diez-Roíguez, GC de Baptista, LRP Trevizan
"ESALQ/USP, 13418-900, Piracicaba-SP, Brazil, gcbaptis@esalq.usp.br "

Residues of aldicarb and its sulfoxide and sulfone oxidative metabolites in coffee leaves (*Coffea arabica* L. cv. Mundo Novo) were determined by gas chromatography, by using a NPD detector. The action of the insecticide on the control of the coffee leafminer, *Leucoptera coffeella* (Guérin-Mèneville, 1842) (Lepidoptera: Lyonetiidae), one of the main insect pest of coffee crops in Brazil, was also evaluated. The insecticide Temik 150 G was applied in December of 2001 at the dosages of 2.25 and 4.50 g of a.i./tree, in the State of São Paulo, Brazil. Twig samples were collected at zero, 30, 60, 90 120, 150, 180, 210 and 240 days after the application (DAA), in three heights of the trees: botton, middle height and top. Residues of the parent compound were not found in any leaf sample. Metabolites residues levels declined starting from 30 DAA, and were below the limit of quantitation (LOQ=0.5 mg.kg^{-1}), after 120 DAA, for aldicarb 2.25 g of a.i./tree and for its sulfoxide at 4.50 g of a.i./tree. The sulfone of this latter treatment, was found up to 150 DAA. Aldicarb at the higher dosage controlled coffee leafminer from 60-180 DAA; at the lower dosage was effective from 60-120 DAA.

Pirimiphos-methyl residues in wheat grain and in some of its processed products and the insecticide action on the control of the maize weevil.

E Sgabiero, GC de Baptista, LRP Trevizan, AA Franco.
" ESALQ/USP 13418-900 Piracicaba-SP, Brazil, gcbaptis@esalq.usp.br "

The degradation/persistence of residues of the organophosphorous insecticide pirimiphos-methyl was determined in wheat grain and in some of its processed products such as bran, flour, whole wheat flour and bread. The action of the insecticide on the control of the maize weevil, *Sitophilus zeamais* Mots. (Coleoptera: Curculionidae), was also evaluated. The grains were treated with the concentration of 12 $mg.kg^{-1}$ (ppm). Samples were taken at zero, 15, 30, 60, 120 and 240 days after treatment. Quantitative measurements were made by gas chromatography, using a flame photometric detector. For pirimiphos-methyl residual action studies, grain samples were taken at 15, 30 days after treatment and subsequently at monthly intervals up to one year. Treated and non-treated (control) grains were infested with weevil adults. Mortality was checked 15 days after exposure. Pirimiphos-methyl residues in grain and in wheat products opped 4 to 7 times during the sampling period. Processing operations decreased insecticide contamination in processed products: as compared to grain, bran (richer in oil) concentrated about 2.5 times more residues; whole flour had approximately the same; white flour 60% and bread 45%. The insecticide remained effective against the pest over the entire period of observation (1 year).

Action of pirimiphos-methyl on the control of the maize weevil and its residues on/in corn, popcorn grains, and in some of their processed products.

E Sgarbiero, GC de Baptista, LRP Trevizan, AA Franco.
"ESALQ/USP, 13418-900 Piracicaba-SP, Brazil, gcbaptis@esalq.usp.br"

The degradation/persistence of residues of the organophosphorous insecticide pirimiphos-methyl was determined in corn and popcorn grains and in some of their processed products such as grain, bran, hominy and corn flour from corn and prepared popcorn and grain from popcorn. The action of the insecticide on the control of the maize weevil, *Sitophilus zeamais* Mots. (Coleoptera: Curculionidae), was also evaluated. The grains were treated with the concentration of 12 mg.kg^{-1} (ppm). Samples were taken at zero, 15, 30, 60, 120 and 240 days after treatment. Quantitative measurements were made by gas chromatography, using a flame photometric detector. For pirimiphos-methyl residual action studies, samples of both types of grain were taken at 15, 30 days after treatment and subsequently at monthly intervals up to one year. Treated and non-treated (control) grains were infested with weevil adults. Mortality was checked 15 days after exposure. Pirimiphos-methyl residues were not persistent in either types of grains or their processed products. Higher residues in corn bran than in grain (1.7 time) are related to the higher oil content in that processed product. The insecticide remained effective against the pest over the entire period of observation (1 year) for both types of grains.

Effects of transgenic field corn expressing two lepidopteran-specific insecticidal proteins on the invertebrate community

GP Dively
4112 Plant Sciences Bldg., Department of Entomology, University of Maryland, College Park, Maryland, 20742, USA, gd7@umail.umd.edu

A large-scale field study during 2000-02 determined the effects of transgenic field corn expressing two Bt-derived lepidopteran-specific insecticidal proteins, VIP3A and Cry1Ab, on the nontarget invertebrate community. The experimental design compared the transgenic hybrid to a non-transgenic, isogenic hybrid with and without insecticide treatments. The abundance and diversity of foliage-dwelling and soil surface fauna were monitored by visual inspections of plants, pitfall traps, sticky cards, and litter extractions throughout the growing season and post-harvest. Aside from anticipated effects on target pest species, the transgenic hybrid had no significant negative effects on invertebrate communities. Some changes in certain taxa did occur but were linked to plant-mediated factors and the absence of feeding injury by target pest species. As expected, communities of nontarget invertebrates in the insecticide sprayed non-transgenic plots displayed significant changes in species abundance, diversity, and trophic interactions. However, communities during the third year with only non-transgenic corn were essentially the same, suggesting that disturbances associated with the insecticide may be short-lived.

Pyrethroid insecticide resistance and treated bednets efficacy in malaria control

AA Enayati, J Hemingway
"School of Public Health, Mazandaran University of Medical Sciences, Sari, Iran. Ahmadali_enayati@yahoo.com or muaae@mazums.ac.ir"

Metabolic and k resistance mechanisms were characterized in An. stephensi and this easily colonized species was used to evaluate the efficacy of ITNs. Bioassays performed on 4th instar larvae showed a resistance ratio of 182. The resistance was partially suppressed by PBO (54%) and DEF (51%) or both (68%). Biochemical assays revealed that esterases, monooxigenases and glutathione S-transferase levels were 1.72, 1.86 and 1.88-fold respectively in the DUB-S compared to the susceptible strain Beech. The overall permethrin metabolism rates by DUB-S mosquitoes measured by HPLC were 1.5-fold more than by Beech strain. The classic k mutation was detected in II6 of the para-type sodium channel gene from DUB-S strain. Bioassays performed on the resistant DUB-S mosquitoes using different pyrethroid-treated bednets showed that except for deltamethrin and a-cypermethrin treated bednets, the rest of the tested pyrethroid-treated bednets at standard WHO recommended doses did not produce adequate mortality rates. The deterrency test performed on susceptible and resistant An. stephensi showed that there are significant differences between the entry rates of susceptible and resistant mosquitoes into the exposure tube containing permethrin treated bednet. These data show that when mosquitoes have both k-type and metabolic resistance mechanisms, the efficacy of pyrethroid-treated bednets is questionable.

The effect of *Bt*-corn on soil invertebrates and decomposition rates of corn post-harvest residues under field and laboratory conditions.

J Frouz, F Kocourek
Institute of Soil Biology, Na sádkách 7, CZ 37005, České Budějovice, Czech Republic. frouz@upb.cas.cz

Effects of *Bt* corn on post-harvest residues decomposition and soil fauna, were studied in two field experiments in the Czech Republic. At each experiment location, *Bt* corn and the same cultivar of non-*Bt* corn were each planted on half of the field, and repeated at both location for three years. Field microcosms containing litter bags of *Bt* or non-*Bt* corn post harvest residues and matching field soils were exposed in matching field plots for 2 years as completely randomized blocks. Decomposition of litter bag contents and abundance of soil fauna in whole microcosms were determined. No significant effects of *Bt* corn on investigated parameters were recorded.
Either fresh post-harvest residues or post-harvest residues exposed in soil for 60 days from the above fields were used to study the effect of *Bt* corn on population growth of *Enchytraeus crypticus* (Oligochaeta: Enchytraedae) in laboratory tests. Significant (about 30%) reductions of *E. crypticus* population growth on fresh *Bt* corn litter in comparison with non *Bt* corn was observed. However, this was not observed in litter exposed in soil for 60 days. In conclusion, *Bt* corn may have a deleterious effect on decomposers in the laboratory, but these effects were minor and restricted to the initial stages of decomposition and undetectable in long-term field experiments.

Selectivity of envidor (spirodiclofen) to some natural enemies in citrus orchard.

S Gravena, SR Benvenga, JL da Silva, LCS Amorim.
PO Box 546, Jaboticabal, SP, 14870-990, Brazil, gravena@gravena.com.br

The trial was conducted from January to February of 2003, Taquaritinga, São Paulo, Brazil. The purpose was to evaluate the impact of spirodiclofen, in two dosages, on the beneficial arthropod fauna found in citrus orchard. The statistical design was based on completely randomized blocks, with 5 treatments and 4 replications and plots with 2 plants for the evaluations. The treatments were: spirodiclofen (Envidor, 20 and 25 mL/hectoliter), azocyclotin (Caligur, 50 mL/hectoliter), and acrinathrin + Hexythiazox (Rufast + Savey, 5 mL + 1.5 g/hectoliter). Each plot had 2 plants treated and insect density evaluated. The arthropod predator densities were evaluated at 0, 1, 4, 7, 14, 21, 29 and 40 days after the mitecides sprays. The toxicity classification was based upon Hassan's method: none ≤ 25%, low 26-50%, moderate 51-75%, and high 76-100%. The most abundant insect predator found was the Coccinellid ***Pentilia egena*** **(Coleoptera: Coccinellidae), and the predator mites found were** ***Euseius citrifolius*** **and** ***Iphiseiodes zuluagai*** **(Acari: Phytoseiidae). By the results and the trial conditions, it was concluded that spirodiclofen presented low toxicity to the predator insects, but due to the mitecide effect of the product, it was of moderate toxicity to the predator mites.**

Developmental rates and population growth of insecticide resistant and susceptible populations of the maize weevil, *Sitophilus zeamais*

RNC Guedes, DB Fragoso
Departamento de Biologia Animal, Universidade Federal de Viçosa, Viçosa, MG 36571-000, Brazil, guedes@ufv.br

Two experiments were carried out to assess the developmental rate and population growth of four populations of *Sitophilus zeamais*. Two of these populations are resistant to pyrethroids (Jacarezinho and Juiz de Fora), while the other two are susceptible (Bragança Paulista and Sete Lagoas). The first experiment, with progeny removal and assessment every other day, allowed the estimation of the developmental rates of the four populations. The second experiment, without progeny removal and with monthly assessments, allowed the estimation of population growth and grain loss caused by each population. Both susceptible populations and the resistant population from Jacarezinho showed similar developmental rates, population growth and grain loss. The resistant population from Juiz de Fora showed reduced and delayed emergence. This population also showed smaller rate of population growth and high mortality at high densities associated with reduced grain loss. The Jacarezinho population have been maintained without insecticide selection for over a decade suggesting that resistance is fixed in this population explaining its good demographic performance, unlike what happened with the Juiz de Fora population, which was recently collected in a grain mill. Pyrethroid resistance in the Juiz de Fora population seems unstable without insecticide selection, which will likely prevent its fixation.

Partial characterization of glutathione *S*-transferases and phosphotriesterases in pyrethroid resistant and susceptible populations of the maize weevil, *Sitophilus zeamais*

RNC Guedes, *DB Fragoso*, *MGA Oliveira*, *ST Rezende*
Departamento de Biologia Animal, Universidade Federal de Viçosa, Viçosa, MG 36571-000, Brazil, guedes@ufv.br

Glutathione *S*-transferases and phosphotriesterases from a susceptible population and two pyrethroid resistant populations (Jacarezinho and Juiz de Fora) were characterized through *in vitro* colorimetric assays. Glutathione *S*-transferases showed higher activity peaks at pH 9.0 and 30^{o}C, while phosphotriesterases showed higher activity peaks at pH 7.0 and 8.0 and 30^{o}C. The Km-values for glutathione *S*-transferases for the substrate CDNB were 1.3 and 1.7x higher in the susceptible population than in the resistant populations from Jacarezinho and Juiz de Fora, respectively. The Km-value for the susceptible population (49.47 ± 0.50 mM) was 7.2x higher than the Km-value for Jacarezinho (6.81 ± 0.24 mM), when the CDNB conjugation was fixed and the concentration of reduced glutathione varied. Similar trend was also obtained for the substrate DCNB. For phosphotriesterases the susceptible population showed a Km-value about 3x higher than the Km-value for both resistant populations. Therefore, the results obtained through the enzyme kinetics characterization of glutathione *S*-transferases and phosphotriesterases indicate higher catalytic efficiency of these enzymes in exercising their biological activity in the resistant populations. These findings suggest that enhanced metabolic detoxification is an important insecticide resistance mechanism against pyrethroids in *S. zeamais* and that glutathione *S*-transferases and phosphotriesterases are involved in this mechanism.

Partial life table of cotton aphid *Aphis gossypii* in transgenic Bt cotton field

JY Guo, FH Wan, GF Zhang, S Murphy
Institute of Biological Control, Chinese Academy of Agricultural Sciences;

Partial life tables of cotton aphid *Aphis gossypii* were studied from mid to late August, 2003 in transgenic Bt cotton NuCTON33B field, compared to those in non-transgenic cotton Simian-3 field. The experimental fields were sprayed once with 0.36 matrine (diluted 1000 times) on 28 June to control the cotton leaf bug, and there were no other chemical spray during the growing season. Four types of nylon screen bags (10, 40, 120 and 200 meshes per square centimeter, respectively) and one uncovered control were set up to determine the magnitude of mortality factors, such as the Bt protein within plants, parasitization and predation. The results showed that (1) Compared to the uncovered control, mesh bags of different sized meshes (from 10 to 200 meshes per square centimeter) all decreased the control efficiency of natural enemies on cotton aphids. (2) Death of cotton aphids in Bt cotton (NuCTON 33B) and non-transgenic cotton (Simian-3) did not differ much, which meant that Bt cotton had little effects on cotton aphid. (3) The main factors affected the population dynamics of cotton aphid were weather conditions (mainly rains) and natural enemies (including parasitoids –Aphidiidae, Aphelinidae, and predators – ladybirds and Orius). (4) The oviposition abilities of cotton aphids on Bt cotton (NuCTON 33B) and non-transgenic cotton (Simian-3) did not differ.

A microsomal esterase confers insecticide resistance in *Spodoptera littoralis*

O Gurkan, P Jewess, G Moores[1]
"Rothamsted Research, Harpenden, Herts UK AL5 2JQ. Oktay.gurkan@bbsrc.ac.uk and Ankara University, Faculty of Agriculture, Plant Protection Dept. Ankara, Turkiye"

Spodoptera littoralis (Lepidoptera: Noctuidae) (Boisduval), the Egyptian cotton leafworm, is a major pest of cotton and vegetable crops in Mediterranean Europe and Africa. A field strain collected from cotton at Adana in Turkey was found to have a resistance factor of 8-fold against chlorpyrifos by leaf dip bioassay. Preliminary studies of AChE sensitivity against chlorpyrifos-oxon indicated no evidence of insensitive AChE. An enhanced microsomal esterase was revealed that correlated with the observed resistance when compared to a susceptible standard strain. We report here on the purification and kinetic parameters of this microsomal esterase.

Cloning and sequencing of the latrophilin-like receptor from the economically important pest *Lucilia cuprina*.

M Hope, M Menzies, S Johnson, D Kemp, P Willadsen
"CSIRO Livestock Industries, Queensland Biosciences Precinct, 306 Carmody Rd, St Lucia, 4067, Australia. Shelly.hope@csiro.au"

The latrophilin/CIRL receptor in vertebrates mediates the binding of Black Widow spider venom. We have cloned and sequenced the gene encoding a latrophilin–like receptor from *Lucilia cuprina.* Our analysis predicts a protein with 70% homology to the N-terminal and 50% to the COOH terminal region of CG8639, a hypothetical gene in the *osophila melanogaster* sequence database. CG8639 was previously identified as the *D. melanogaster* homolog of the latrophilin receptor by BLAST. The *L. cuprina* latrophilin-like receptor is expressed in all developmental stages of *L. cuprina* and is localised to the neuromuscular regions of larvae by *in situ* hybridisation. It is hypothesized this receptor plays a role in signalling / signal transduction in mammalian species, but the role in insects is largely unknown.

Insecticide resistance in *Aedes aegypti* during dengue epidemics in Taiwan, 2002

EL Hsu, YL Lin
Dept of Entomology, National Taiwan University, Taipei 106, Taiwan, elhsu@ntu.edu.tw

Pest control operators were very successful in the insecticides application for mosquito control when dengue fever cases occurred in Taiwan in last twenty years. But the dengue was out of control in 2002. There were 5316 confirmed cases reported. We used 7 kinds of WHO insecticide-impregnated papers, 0.1% propoxur, 1% fenitrothion, 0.15% cyfluthrin, 0.5% etofenprox, 0.05% lambdacyhalothrin, 0.75% permethrin and 0.05% deltamethrin, to determine the insecticide susceptibility of adult *Aedes aegypti* in 2002. The resistance ratios of adult mosquitoes of the Chianjen, Lingya (2002), and Lingya (1900R) strains for permethrin compared to susceptible strains were above 312.5 folds, while those of the 4th instar larvae were 20.8, 37.5 and 102.1, respectively. Results of a synergism study on larvae resistant to permethrin showed correlations to the activities of microsomal monooxygenases and esterases.

The susceptibility of *Aedes aegypti* from northern Queensland to synthetic pyrethroids

CC Jansen, A/ SC Barker, WG Brogdon, SA Ritchie, SP Frances, RD Cooper
Australian Army Malaria Institute, Weary Dunlop Drive, Gallipoli Barracks, Enoggera, QLD, 4051, Australia, Cassie.Jansen@defence.gov.au

Aedes aegypti is the only mosquito vector of the dengue virus in northern Queensland. Despite complete reliance upon synthetic pyrethroids to control adult *Ae. aegypti* during dengue outbreaks, little is known regarding the susceptibility of *Ae. aegypti* from northern Queensland to these insecticides. Insecticide exposure bottle assays and biochemical microplate assays were conducted to examine the susceptibility of *Ae. aegypti* to synthetic pyrethroids. The susceptibility of five strains of *Ae. aegypti* from northern Queensland to five commonly used synthetic pyrethroids was compared with that of an insecticide-susceptible laboratory strain. All strains tested were fully susceptible to the synthetic pyrethroids used by mosquito control authorities in northern Queensland (lambda-cyhalothrin and deltamethrin). However, some wild strains showed significantly reduced susceptibility to permethrin, bioresmethrin and alpha-cypermethrin. Biochemical microplate assays were used to measure the activity levels of two types of enzymes (β-esterases and monoxygenases) that often confer resistance to synthetic pyrethroids. Elevated esterase activity was detected in three wild strains relative to the reference strain, but elevated oxidase activity was not detected in any of the mosquito strains. The presence of resistant traits in wild populations of *Ae. aegypti* demonstrated here supports the need to establish a resistance monitoring programme in northern Queensland to ensure the continued success of dengue outbreak control.

Design and production of a cell adhesive silk fibroin by transgenic technology

K Kojima, T Tamura, T Kanda, Y Tamada
"N.I.A.S, Owashi 1-2, Tsukuba, Ibaraki, 305-8634, Japan, kojikei@affrc.go.jp"

Silk protein of *Bombyx mori* (silkworm) has used for medical materials for years and there are attempts to apply it for a regenerative medicine. One target of that is reproduction of joint cartilage. We already reported that cartilage-like tissue could be formed by chonocyte culture into silk fibroin sponge structure. This time, we designed and produced a novel silk fibroin in order to add cell adhesive activity. Silk fibroin of silkworm is consisted mainly of three components, fibroin-H, fibroin-L and P25. To improve cell adhesion activity of silk fibroin, we designed a fusion protein, that fibroin L-chain was linked with a part of human fibronectin and EGFP (L-hFN-EGFP). And we generated transgenic silkworm in order to produce L-hFN-EGFP as a part of silk protein. The transgenic silkworm secreted L-hFN-EGFP in silk gland and also made cocoon with L-hFN-EGFP. We tested cell adhesion activity on the dish coated with L-hFN-EGFP extracted from posterior silk gland. The number of adhered cells was greater on the L-hFN-EGFP coated dish than native silk coated dish and some cells were extended their pseudopod like cells on fibronectin coated dish. These results indicate that we succeeded to modify the nature of silk as we designed.

An amino acid substitution in insensitive acetylcholinesterase of *Tetranychus* mites.

Y Kono, Y Anazawa, Y Aiki, T Kozaki, T Tomita
"University of Tsukuba, Institute of Agriculture and Forestry, Ten-nodai, Tsukuba, 305-8572 Japan. ykono@sakura.cc.tsukuba.ac.jp"

The insensitivity of the acetylcholinesterase (AChE) to organophosphate was first reported in the two spotted spider mite, *Tetranychus urticae*.and was suggested to be associated with some modification at the active site of enzyme. Recent molecular studies revealed that the insensitivity of insect AChEs was accompanied by some amino acid substitutions in its structure protein. We tried to sequence AChE cDNA in spider mites, *T. urticae* and *T. kanzawai*, and compared their sequences between a susceptible strain and an organophosphate resistant strain whose AChE was insensitive. The 687 amino acids of primary structure were deduced from the cDNA in both species. There were only three replacements of amino acid residues between AChEs of two species. In the AChE of the resistant strain of *T. urticae,* an amino acid substitution, Phe439Cis, was found. The residue is one of the acyl pocket lining components and might act an important role in the sensitibity of AChE to organophosphates. Furthermore, the amino acid 439 was changed to Trp in the resistant strain of *T. kanzawai*. The homologous amino acid substitution occurred in the insensitive AChEs of the green peach aphid and the *Culex* mosquito strongly suggests that the amino acid substitution in AChE of *Tetranychus* mites is the cause of the insensitivity.

Biochemical characterization of acetylcholinesterase in the oriental tobacco budworm, *Helicoverpa assulta*

DW Lee, BY Seo, SW Shin, KS Boo
Lab. of Insect Physiology, Seoul National University, Seoul 151-742, South Korea, 71dwlee@hanmail.net

Acetylcholinesterase (AChE), the target site of organophosphate and carbamate insecticides, plays an important role in the transmission of nerve impulse in the insect nervous system. AChE activity of the Oriental tobacco budworm (*Helicoverpa assulta*) was higher in the head than in thorax and abdomen of the adult and gradually increased through the developmental stages. The optimum pH and temperature for the purified AChE was 8.5 and 35°C, respectively. The purified AChE was composed of two different molecular forms: an amphiphilic form (68%) and a hydrophilic form (32%). The affinity for acetylthiocholine (K_m) and the activity (V_{max}) of AChE were evaluated to be 0.05 mM and 2.1×10^{-2} unit/min, respectively. The AChE of *H. assulta* belongs to the *osophila melanogaster Ace*-orthologous AChE subfamily. Its deduced protein sequence showed the highest homology to AChE of the cotton bollworm, *Helicoverpa armigera*. Six amino acid differences were identified, which suggests that there is a polymorphism in *AChE* gene in this insect.

Building Arthropodan Mitochondrial Genomes Accessible Database – AMiGA

LS Neiva, RV Santos, AM Azeredo-Espin, AC Lessinger
Laboratório de Genética Animal – Centro de Biologia Molecular e Engenharia Genética – UNICAMP – Campinas, SP, Brazil

"As mitochondrial DNA has shown to be an useful tool in phylogenetic studies, the number of completely sequenced mitochondrial genomes has greatly increased in the last few years. These sequences are available in some broad databases such as those of NCBI (http://www.ncbi.nih.gov) and in smaller and more functional organelle databases. During our work with the characterization of mitochondrial genomes of dipteran species we became aware of the usefulness of establishing a specific database for complete mitochondrial DNA sequences of arthropods. AMiGA is being constructed in a relational database system (MySQL) with the use of stantard query language (SQL) and populated with sequences and taxonomic information from NCBI databases. AMiGA aims to offer up-to-date sequences with useful tools for managing mitochondrial data. A web interface will provide to the public free access to nucleotide and protein sequences, including the sequence of the non-coding regions, physical maps, related reasearch institutions and scientific articles. It will be possible to access any of these data for any group of selected species. Codon usage and base frequencies will also be available. With AMiGA we hope to improve the access to arthropodan mitochondrial genomic data and to provide effective tools for researchers working in this field."

Esterase isoforms in the western flower thrips (*Frankliniella occidentalis*), and their inhibition by piperonyl butoxide

N López-Soler, A Cervera, GD Moores, MD Garcerá, R Martínez-Pardo
"Departamento de Biología Funcional y Antropología Física, Universitat de València, Moliner 50, 46100 Burjassot, Valencia, Spain. neus.lopez@uv.es"

We have studied the esterase banding pattern of several field and laboratory selected *Frankliniella occidentalis* (Pergande) stains. Some of the stains were collected on different locations at the SE of Spain and showed different levels of insecticide resistance. Others have been selected for resistance against some of the insecticides regularly used for western flower thrips control. Esterase isoforms of individual thrips have been separated by polyacrilamide gel electrophoresis, and stained for esterase activity with the model substrate a-NA. The banding patterns obtained from field and laboratory-selected insects have been compared with a standard susceptible strain. In addition, the effect of the metabolic synergist piperonyl butoxide (PBO) on esterase activity has been investigated. Gels incubated with 1 mM PBO showed a decrease in the intensity of all esterase bands. The inhibitory effect of PBO on a-NA activity was also evident from microplate reader assays of insect homogenates, and suggests the possibility of its use in the management of *F. occidentalis* resistance associated with esterase activity.

Tolerance to the *Bacillus thuringiensis* endotoxin Cry1Ac in a laboratory *Helicoverpa armigera* strain is based on immune induction, which is transmitted by a maternal effect.

G Ma, HLS Roberts, N Featherstone, M Sarjan, RT Roush, R Akhurst, O Schmidt
"Insect Molecular Biology, University of Adelaide, Glen Osmond, SA 5064, Australia. otto.schmidt@adelaide.edu.au, "

We crossed resistant insects from a laboratory strain of *Helicoverpas armigera* with susceptible insects and examined Bt-tolerance in neonates. We noticed significantly higher tolerance in offspring from resistant females crossed with susceptible males (RxS), compared to those from susceptible females crossed with resistant males (SxR). Tolerance in RxS offspring was not as high as for the resistant line, and for SxR offspring tolerance was somewhat higher than in the susceptible line. This suggests that in addition to a genetic element, Bt-tolerance in this strain is transmitted by a maternal effect. To investigate the possible mechanism of Bt-tolerance, we examined the induction of immune responses in susceptible larvae by a sub-lethal dose of Bt-toxin. One protein of 89 kDa in size was induced within two hours of exposure to the toxin. Protein concentration peaked after 6 hours and then declined to low levels by 21 hours. The protein has similarities to *osophila* proteins that act as pro-coagulants. These experiments indicate an immune induction of specific larval proteins, which may be involved in coagulation reactions in the hemolymph and gut lumen.

Resistance to Cry2Ab toxin in Australian populations of *H. armigera*

RJ Mahon, KM Olsen. KA Garsia
CSIRO Entomology, GPO Box 1700 Canberra ACT 2601. Rod.Mahon@csiro.au

Cotton expressing Cry1Ac toxin (Ingard®) has been grown in Australia for seven seasons. Ingard and limited quantities of two-toxin (Cry1Ac & Cry2Ab) varieties (Bollgard II®) were grown during the 2003-04 summer. Henceforth Ingard will be withawn and only Bollgard II will be available. The major Lepidopteran pest in the region is *Helicoverpa armigera*, a species with a demonstrated ability to evolve resistance to insecticides deployed against it. Resistance to Cry1Ac remains rare. This rarity was expected to enhance the prospect that Bollgard II would be resilient to the evolution of resistance. Recently a preliminary survey was conducted to detect alleles in *H. armigera* that confer resistance to Bt toxins. Only 132 alleles were examined in F_2 tests, however one was found that conferred high-level resistance (RR > 1000) to Cry2Ab. The frequency (1/132 = 0.008) was surprisingly high, as Cry2Ab has not been deployed in any transgenic crop grown in Australia. Preliminary analyses indicate the resistance is likely to be the result of a single gene, and that the resistance is largely recessive. From a resistance management perspective, the recessive nature is valuable; however modelling suggests the allele may be sufficiently common to increase in frequency through selection for homozygotes.

Heat stress breaks down the protective role of genetically engineered peas against the pea weevil (*Bruchus pisorum*)

M J de Sousa-Majer, NC Turner, DC Hardie, TJV Higgins
Department of Environmental Biology, Curtin University of Technology PO Box U1987, Perth, WA 6845, Australia. Email: M.Majer@curtin.edu.au

Recent studies have conclusively confirmed, through glasshouse and field experiments, that transgenic peas with the a-AI-1 inhibitor expressed in their seeds effectively control the pea weevil. Field trials with transgenic peas (a-AI-1 Laura line12–41) indicated that, relative to the non-transgenic plots, population growth rates of weevils were reduced by 97–98% in the transgenic plots. Also, germination tests of post-harvested field pea seeds from 1999 and 2000 show 90-99% germination for transgenic and 28-66% for non-transgenic seeds. Transgenic and non-transgenic plants were subjected to heat stress treatments under controlled conditions in a growth cabinet. The level of a-AI-1 was reduced on average by 36.3% in transgenic peas at 32/27°C compare to those grown at 27/22°C. Transgenic and non-transgenic pods of plants grown at 27/22°C and 32/27°C were inoculated with pea weevil eggs to evaluate whether the reduction in level of a-AI-1 in the transgenic pea seeds reduced the efficacy of the inhibitor. At the higher temperatures, 39% of adult pea weevil emerged, compared with 1.2% in the transgenic peas grown at the lower temperatures, indicating that heat stress reduced the protective capacity of the transgenic peas. It is possible that the transgenic peas may confer less effective protection in warmer regions. The temperatures used in the current experiments were consistent with the maximum temperature observed in the field, but the peas were exposed to a constant high temperature of 32°C for 12 h per day, whereas maximum temperatures in the field only occur for a short period around midday. If mean daily temperatures are at, or over, 27°C during flowering, growers may need to use insecticidal sprays to control pea weevils.

Insecticide resistance and *Culex pipiens* in Britain

C Mehmet, A Curtotti, CA Malcolm
School of Biological Sciences, Queen Mary, University of London, Mile End Rd, London, E1, 4NS.

The importance of the *Culex pipiens* complex in the transmission of West Nile virus (WNV) has been further emphasised with the discovery of the ubiquitous hybrid 'bridge vector' forms of *Culex pipiens* in the US. In Britain and Europe the situation is different, but to what extent needs further investigation. In Britain, mosquitoes are rarely a pest and not normally subjected to control measures. Insecticide resistance is therefore expected to be absent unless the mosquitoes are immigrants, or the progeny of a mating with an immigrant, or they have been subjected to insecticide inadvertently. We report here examples of two, or possibly all three, of these scenarios. Organophosphate resistance mediated by overproduced non-specific esterases (ONSEs) has been studied extensively in *Culex pipiens* s.l. and therefore the origin and spread of many specific haplotypes is well known, most famously the A2B2 haplotype. Our discovery of this haplotype in a population of *Cx. molestus* in Scotland therefore marked these insects as being derived from immigrants. In contrast, multiple ONSE haplotypes observed in populations of *Cx. pipiens* from east England, where agricultural use of insecticide is very high, appear to be novel.

Characterisation of insensitive acetylcholinesterase in the cotton bollworm, *Helicoverpa armigera*

N Javed, G Devine, GD Moores
"Rothamsted Research, Harpenden, Herts, UK. AL5 2JQ Graham.Moores@bbsrc.ac.uk"

Intensive use of organophosphates (OP) and carbamate insecticides over the past 50 years has lead to the development of resistance in many agriculturally important pest species, including the cotton bollworm *Helicoverpa armiegra* (Hubner). The enzyme acetylcholinesterase (AChE EC 3.1.1.7) is responsible for termination of nerve impulses at the post-synaptic membrane by breaking down the neurotransmitter, acetylcholine. AChE is the target-site for OP and carbamate insecticides which act by phosphorylating or carbamylating the active site of the enzyme to form 'transition state' intermediates that no longer attack and hydrolyse the AChE. The dephosphorylation or decarbamylation steps (k_3) either do not occur or are very slow such that the enzyme is not significantly regenerated. The subsequent accumulation of ACh leads to the continuous firing of the nervous system and ultimately, to the eventual death of the organism. AChE activity was detected using a fluorometric assay, and the sensitivity towards a range of carbamate and OP insecticides assayed.

Inhibition of *Helicoverpa armigera* esterase activity following *in vitro* exposure to piperonyl butoxide (PBO).

SJ Young, RV Gunning, GD Moores
Rothamsted Research, Harpenden, AL5 2JQ, UK graham.moores@bbsrc.ac.uk

Helicoverpa armigera is often considered the most economically important pest of cotton world-wide. In Australia, high levels of esterase-based resistance ensure widespread control difficulties. It has recently been discovered that piperonyl butoxide (PBO) is capable of inhibiting the resistance-associated esterases in this species. It was found that 4 hrs was the time taken for maximal inhibition of this esterase. It was also found that maximal mortality coincided with maximal esterase inhibition.

Overcoming pyrethroid resistance in *Bemisia tabaci* (Gennadius) (Hemiptera: Aleyrodidae) b-biotype with novel microencapsulated formulations of α-cypermethrin and piperonyl butoxide (PBO)

K Krüger , RV Gunning, GD Moores
Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, UK

Bemisia tabaci populations in many parts of the world are resistant against a range of insecticide classes, including pyrethroids. Piperonyl butoxide (PBO), a pyrethroid synergist, inhibits the non-specific esterases responsible for pyrethroid resistance in *B. tabaci* b-biotype. Recent studies in Australia have shown that splitting the application of the two compounds by applying PBO five hours before the pyrethroid application leads to effective *B. tabaci* b-biotype control. In order to overcome the problem of having to split the two applications, novel microencapsulated formulations containing α-cypermethrin and PBO have been developed. The efficacy of two of these novel formulations containing different ratios of the active compounds was evaluated against *B. tabaci* b-biotype on cotton plants under laboratory conditions in South Africa. Before spray application, the number of adults did not differ significantly between different treatment areas. Twenty-four hours after application, the novel treatments resulted in 92% and 78% control compared with 48% control for the α-cypermethrin and 36% control for the PBO treatments. The results indicate that the use of the microencapsulated formulations in the field has the potential to be highly effective in overcoming pyrethroid resistance and controlling the *B. tabaci* b-biotype.

Does the diamondback moth (DBM) population upsurge under insecticide application at sublethal dose?

F Nakasuji, Y Fujiwara, N Sota
"Faculty of Agriculture, Okayama University, Tsushima, Okayama 700-8530, Japan, nakasuji@cc.okayama-u.ac.jp"

Physiological resurgence and/or hormoligosis frequently induced after application of insecticide at sublethal doses. Treatment of a carbamate, methomyl and a pyrethloid, fenvalerate to *Plutella xylostella* (DBM) at sublethal doses causes hormoligosis through increasing fecundity. More eggs were laid by treated female adults than those without insecticides at $LD_{12.5}$ or LD_{25}. However, the eggs laid by treated females at LD_{25} and LD_{50} were significantly smaller in size than those laid by untreated females. The reproductive effort (fecundity×egg size) did not differ between treated females and untreated ones. The treatment of a sublethal dose (LD_{50}) against the parent trended to affect the development and survival rate of offspring at immature stages. This adverse effect was apparent under harsh conditions of physical environment. The hatchability of smaller eggs laid by treated females at LD_{25}, tended to be lower than those by untreated females, and the difference was significant at humidity less than 30%. The survival rate of immature stages from the smaller eggs was significantly lower and development tended to prolong more than those from the normal sized-eggs at temperatures higher than 20°C. Therefore, it is doubtful that the outbreaks occur always through insecticide hormoligosis in particular under harsh field conditions.

Non-target effects of Bt cotton: natural enemy abundance and function

SE Naranjo
USDA-ARS, 4135 E. Broadway Rd., Phoenix, AZ, USA 85040, snaranjo@wcrl.ars.usda.gov

Transgenic cottons expressing the insecticidal proteins of *Bacillus thuringiensis* (*Bt*) have been widely adopted by cotton producers throughout the USA to control lepidopteran pests. Beginning in 1999, a five year study was conducted in Arizona, USA to examine the comparative effects of *Bt* cotton on non-target organisms, with special emphasis on natural enemy abundance and the community function of the natural enemy complex. Combined analyses over all years indicate that the abundance of several natural enemy taxa, including some spiders, *Hippodamia convergens*, and *Nabis alternatus* were significantly reduced in *Bt* cotton compared with non-*Bt* cotton. In all cases, population reductions were less than 10%. However, the overall function of the natural enemy community, measured as rates of predation and parasitism on two key pests (*Pectinophora gossypiella* and *Bemisia tabaci*) of cotton in the western USA were unaffected in *Bt* cotton. Retrospective statistical power analyses indicated that sample sizes of the combined multi-year dataset were consistently sufficient to detect differences as small as 4-5% with greater than 80-90% power at a 95% level of probability. Results demonstrate that long-term and multi-factor studies are required to examine meaningful non-target effects in the field.

Preliminary construction of BAC contigs covering the chorion locus of *Bombyx mori*.

J Nohata, K Yamamoto, YK Park, K Kadono-Okuda, T Kanda, T Tamura, T Shimada, K Osoegawa, P deJong , K Mita, MR Goldsmith
"National Institute of Agrobiological Sciences, Tsukuba, Japan; nontan@nias.affrc.go.jp "

The chorion gene locus of *Bombyx mori* has been extensively studied morphologically, genetically, biochemically and genomically until 1990 by the Kafatos lab and colleagues. The chorion is composed of more than 100 proteins, which are encoded by six closely related gene families, ErA, ErB, A, B, HcA and HcB, that map in two clusters on the chorion loeus of chromosome 2. (review: Eickbush and Izzo, 1995). Recently, our group has been engaged in the analysis of the *Bombyx* genome using modern genomic tools. And resources, in the present study, we are focusing on the construction of BAC contigs covering the chorion gene locus of chromosome 2 by the following strategy: (1) identifying chorion-specific EST markers by EST analysis of a follicle cell cDNA library, (2) screening BAC clones from a *Bombyx* BAC library by chorion-specific EST markers, and (3) constructing BAC contigs by fingerprinting and use of FPC software. Fingerprinting of 200 BAC clones screened by chorion gene products gave three main BAC contigs. By end-walking and PCR verification using BAC-end sequence, we could edit three BAC contigs into one contig spanning about 1 Mb which includes early, middle and late chorion gene families.

Activity of the new acaricide (etoxazole) on the citrus leprosis mite, *Brevipalus phoenicis* (Geijskes, 1939) (Acari: Tenuipalpidae) in field and laboratory conditions.

FJ Celoto, G Papa, M Rotundo, HR Mosca, LRP Trevizan
Unesp/Dept. Fitossanidade. Av. Brasil Centro 56, Zip: 15385-000 Ilha Solteira/SP/Brazil, gpapa@bio.feis.unesp.br

Etoxazole (S-1283 11% SC) is a new molecule acaricide belonging to a new chemical group (Diphenyloxazoline). Etoxazole's modes of action is through the inhibition of the normal molting process, ovicidal egg activity and present a sterilizing effect on adult females. The experiment was conducted at Ilha Solteira/SP/Brazil. The activity of the etoxazole was evaluated on adults, larvae and eggs of *B. phoenicis* in field and Laboratory conditions. Etoxazole (1.1; 1.6; 2.7 and 5.5 g a.i. /100 L of water); hexythiazox (1.5 g a.i. /100 L of water) and flufenoxuron (3 g a.i. /100 L of water) were applied in field in a citrus orchard, variety Pera. The same acaricides and doses were used at Laboratory through the application on citrus fruits, demarcated with an arena of 2.5cm of diameter, containing adults, larvae and eggs of *B. phoenicis*. The results showed that etoxazole starting from the dose of 2.7 g i.a. /100 L of water showed: low direct activity on adults; mortality of 100% on larvae; viability of eggs inferior to 5%; adults infested on applied fruits in field until 42 days after treatment, it produced eggs, however, the emerged larvae die soon after the emergency.

Effect of new acetamiprid formulation (tablet) on the control of the whitefly *Bemisia tabaci* (Biotype B) (Hemiptera: Aleyrodidae) and *Aphis gossypii* (Hemiptera: Aphididae) in melon.

M Rotundo, G Papa, FJ Celoto, EP Prado, LRP Trevizan
Unesp/Dept. Fitossanidade. Av. Brasil Centro 56, Zip: 15385-000 Ilha Solteira/SP/Brazil, gpapa@bio.feis.unesp.br

The increasing search for safer alternatives for pests control, which are less aggressive for the environment, has brought a significant development of new insecticide formulations, with possibilities of use in agricultural pest management and contributing to a safer and more efficient way of pest control. The objective of this work was to evaluate the performance of the new formulation (tablet) of acetamiprid that is being developed for use in the transplant of vegetables to avoid the applications sequential of spray insecticides. The experiment was installed in field conditions, in Ilha Solteira/SP/Brazil, in melon. The treatments consisted: acetamiprid tablet applied on the soil in the bottom of the hole during the transplant of the seedlings (one tablet per plant); acetamiprid tablet associated to weekly applications of fenpropathrin and acetamiprid tablet associated the foliar application of acetamiprid. The evaluations were accomplished until 45 days after the transplant, by counting the number of nymphs of the whitefly and the number of aphids in 10 leaves per plot. The analysis of the results showed that the application of one tablet per transplanted plant was efficient in the control of the whitefly and aphids until 45 days after the transplant in melon.

Larvicidal activity of lignans identified in *Phryma leptostachya* var. *asiatica* Roots against three mosquito species

IK Park, SC Shin, CS Kim, HJ Lee, YJ Ahn
"Division of Forest Insect Pests and Diseases, Korea Forest Research Institute, Seoul 130-712, Republic of Korea. E-mail: parkik1@foa.go.kr"

The insecticidal activity of materials derived from the roots of *Phryma leptostachya* var. *asiatica* against third instar larvae of *Culex pipiens pallens, Aedes aegypti*, and *Aedes togoi* was examined. The biologically active constituents of *P. leptostachya* var. *Asiatica* roots was characterized as the leptostachydrol acetate and 8'-acetoxy-2,2',6-tetramethoxy-3,4,4',5'-dimethylenedioxyphenyl-7,7'-dioxabiclo[3.3.0]octane by spectroscopic analysis. The insecticidal activities of leptostachydrol acetate against *Culex pipiens pallens, Aedes aegypti*, and *Aedes togoi* were 100, 98.6 and 100% at 10 ppm. 8'-acetoxy-2,2',6-tetramethoxy-3,4,4',5'-dimethylenedioxyphenyl-7,7'-dioxa-biclo[3.3.0]octane showed weak or no insecticidal activity against three mosquito species at 10 ppm. The LC_{50} values of leptostachydrol acetate against *Culex pipiens pallens, Aedes aegypti* and *Aedes togoi* were 0.41, 2.1 and 2.3 pm, respectively.

Naturally occurring *Phryma leptostachya* var. *asiatica* root–derived compound merit further study as potential mosquito larval control agents or as lead compounds.

Bioefficacy of bifenthrin (talstar) 10 EC against chilli insect pests in irrigated ecosystem

BV Patil, M Bheemanna, A Hosamani
"Regional Agricultural Research Station and College of Agriculture, Raichur – 584 101, Karnataka, India. E-mail: bvp2001@rediffmail.com"

Chilli (*Capsicum annum* L.) I s an important commercial crop damaged by mite, *Polyphagotarsonemus latus* (Banks.), thrips, *Scirtothrips dorsalis* (Hood) and fruit borer, *Helicoverpa armigera* (Hub.) which occurs simultaneously. Bifenthrin (Talstar) 10% EC an insecticide cum acaricide was tested for two seasons at 40, 60 80 and 100 g a.i/ha along with slandered checks on chilli insect pests. Based on economic threshold level (ETL) five sprays were undertaken. Talstar at 80 g a.i/ha was found to be optimum and effective in reducing above pest population/damage below ETL level and recorded higher green chilli fruit yield.

Fenpropathrin (meothrin) 30 EC: an ideal insecticide in chilli (*Capsicum annuum* L.) insect pest management

BV Patil, M Bheemanna, K Thulasiram

"Regional Agricultural Research Station and College of Agriculture, Raichur-584 101, Karnataka, India. bvp2001@rediffmail.com"

Yellow mite, *Polyphagotarsonemus latus* (Banks), thrips, *Scritothrips dorsalis* (Hood) and fruit borer, *Helicoverpa armigera* (Hubner) are the economically important pests on chilli crop. Any insecticide molecule having efficacy against above pests fits very well in the management. Fenpropathrin (Meothrin) 30 EC an insecticide cum acaricide was evaluated for two seasons during 2001-02 and 2002-03 at 50, 75, 100, 150 and 200 g.a.i./ha along with three standard check insecticides and an untreated control on chilli variety Byadagi kaddi. In another trial Meothrin was integrated in the schedule four times at different intervals and positions. Based on economic threshold level (ETL), five sprays were undertaken. Pooled data of two seasons indicated that Meothrin at 75 g.a.i./ha was found to be optimum and effective in reducing mite and thrips population below ETL upto seven days and Meothrin at 100 g.a.i./ha was found effective against fruit borer, *H. armigera.* Spray sequence of Meothrin at 75 g.a.i./ha followed by oxydemeton methyl 25 EC at 200 g.a.i./ha, Meothrin 30 EC at 100 g.a.i./ha, dicofol 18.5 EC at 475 g.a.i./ha and Dipel 8L at 1000 ml/ha was found to be ideal as it recorded significantly lower pest population and higher green chilli fruit yield.

Fenpropathrin (meothrin) 30EC: an ideal insecticide in brinjal (*Solanum melongena* L.) insect pest management

BV Patil, M Bheemanna, A Hosamani

"Regional Agricultural Research Station and College of Agriculture, Raichur-584 101, Karnataka, India. bvp2001@rediffmail.com"

Among the many pests damaging brinjal or egg plant, *Solanum melongena* L. leafhoppers, *Amrasca biguttula biguttula* Ishida, whitefly, *Bemisia tabaci* Gennadius, spider mites, *Tetranychus* spp. and shoot and fruit borer, *Leucinodes orbanalis* Guenee are the major ones in this locality. Insecticide having effect on all the pests is the urgent need of the farmers. Fenpropathrin (Meothrin) 30 EC an insecticide cum acaricide was evaluated for two seasons during 2001-02 and 2002-03 at 50, 75, 100, 150 and 200 g.a.i./ha along with three standard check insecticides and an untreated control on brinjal hybrid MEBH-11. In the second trial, Meothrin was integrated in the schedule five times at different intervals and positions. Based on economic threshold level (ETL), six sprays were undertaken. Results indicated that Meothrin at 100 g.a.i./ha was found to be optimum and effective in reducing all the pests. Spray sequence of oxydemeton methyl 25 EC at 200 g.a.i./ha followed by Meothrin at 75 g.a.i./ha, Dipel 8 L at 800 ml/ha, Meothrin at 100 g.a.i./ha, Dipel 8L at 1000 ml/ha and Meothrin at 100 g.a.i./ha was found to be ideal as it reduced pest population significantly and recorded higher fruit yield.

Insecticide mode of action classification: a key to insecticide resistance management

A Porter,
Bydland, Lettoch Road, Pitlochry, Perthshire, PH16 5AZ, Scotland, aporter@intraspin.com

The Insecticide Resistance Action Committee (IRAC) has developed a classification scheme for insecticides (and acaricides) that is based on mode of action (MoA). Experience has shown that effective insecticide resistance management (IRM) strategies seek to minimise the selection for resistance from any one type of insecticide. In practice, alternations, sequences or rotations of compounds from different MoA groups provide a sustainable and effective approach to IRM. This ensures that selection for resistance through the use of compounds in the same MoA group is minimised. It is recognized that insecticide resistance can also result from enhanced metabolism by enzymes within the pest, reduced penetration of the pesticide into the pest or behavioural changes of the pest. These resistance mechanisms are not linked to any site of action classification, but are specific for individual compounds or chemical groupings. Despite this, alternation of compounds from different chemical classes remains an entirely viable resistance management technique since such a practice will always minimise selection pressures. This poster describes the mode of action classification scheme and its use in IRM.

Impact of piraclostrobina on beneficial arthropod pests, predators and entomopathogens in citrus orchard.

M Pozzan, S Gravena, SR Benvenga, JL da Silva, N de Araújo Junior.
PO Box 34, Monte Azul Paulista, SP, Brazil, 14730-000, marcos.pozzan@montecitrus.com.br

The present study was done to evaluate the impact of 2 applications of Comet (300 and 600 g of commercial product/100 liter), within a 60 days interval, compared to Recop (Copper Oxide) and Derosal (Carbendazim) upon arthropods and entomopathogens in citrus orchard. The populations of Citrus Rust Mite, *Phyllocoptruta oleivora,* Citrus Leaf Miner, *Phyllocnistis citrella,* Japanese Bayberry Whitefly, *Parabemisia myricae,* Rofous Scale, *Selenaspidus articulatus,* Black Parlatoria Scale, *Parlatoria ziziphus,* the predator mites of the Phytoseiidae and Stigmaeidae families and the predator insects of the Coccinellidae and Chrysopidae families were evaluated about the possible effects on their population densities after the fungicide sprayings. The results showed that: (1) Comet, can induce resurgence of the Citrus Rust Mite only sixty days after the second spraying; (2) Comet, Recop and Derosal do not have any influence on the predator insect and mite populations; (3) Comet, Recop and Derosal do not have any influence on the Leaf Miner and the Japanese Bayberry Whitefly and (4) Comet, Recop and Derosal have little influence on the population increasing of Rofous and Black Parlatoria Scales.

Use of image analysis to correlate insecticide symptomology and mode of action

A Rees, *RJ Lind*
Syngenta, Jealott's Hill International research centre, Bracknell, Berks, RG42 6EY, UK, Anne.Rees@syngenta.com

Today's competitive pesticide market demands the discovery of insecticides with novel modes of action. Recently, insecticide discovery has been transformed by the advent of imaging technologies, leading to a new way of studying insect symptomology that is inherently linked to the mode of action of insecticides. This study used a contact exposure of known insecticides to the larval stages of the Tobacco Budworm *Heliothis virescens* and symptoms were recorded by capturing images using a CCD camera and subsequent image processing. Timelapse video and quantitative measurements of locomotion were recorded over a time period of up to 24hours after exposure. A preliminary study using neurotoxic compounds with a range of mode of actions was investigated. The results showed that it was possible to differentiate between different insecticides by their symptoms, although this was not clear in every case where the end physiological effects were the same. This approach has potential to be employed to generate a library of symptomology profiles of known modes of action to which novel insecticides can be compared to aid the discovery of new chemical classes.

Field performance of thiacloprid against the tobacco flea beetle *Epithrix hirtipennis* (Melsheimer)

L Sannino, F Piro, M Contiero
Istituto Sperimentale per il Tabacco, Via P. Vitiello 66, 84018 Scafati, Italy. luigi.sannino@tin.it

The efficacy of thiacloprid for controlling the tobacco flea beetle *Epithrix hirtipennis* (Melsh.) (Coleoptera Chrysomelidae) was assessed in replicated field experiments in 2002 and 2003. In both years treatments included two doses of thiacloprid (81 and 101 ml ha^{-1} a.i.), a treated control (imidacloprid at the rate of 89 ml ha^{-1} a.i.) and an untreated control. In 2003 thiametoxam (50 g ha^{-1} a.i.) was an additional treatment. The 2002 trial crop, flue cured at a density of 27,700 plants ha^{-1}, received one application, while the 2003 trial crop, burley at a density of 47,500 plants ha^{-1}, received two applications at two weeks interval. Insecticide preparations were sprayed at normal volume at the rate of 1000 L ha^{-1}. Live beetles on ten plants in two central rows per plot were counted as response at intervals until one month after the applications. In both trials the number of live insects decreased to near zero in the first few days after all insecticide treatments and rose afterwards approaching the untreated control level in about two weeks. On average thiacloprid reduced counts in comparison with imidacloprid: by 11% and 17% in 2002 and by 60% and 78% in 2003 (lower and higher dose, respectively). Thiametoxam also reduced counts by 50% over imidacloprid.

Pyrethroids residual effect on *Anopheles* sp. mortality rates in the Brazilian Amazon.

R La C Santos, AS Fayal, AEF Aguiar, RB Baia, DRV Bertran, MM Póvoa.
"SQN 310 Bloco A 204 Brasília DF Brazil, 70.756-010 roseli.lacorte@funasa.gov.br"

We had evaluated the efficacy of four pyretroids on the *Anopheles* mortality rates in order to verify their effect in indoor residual spraying in Amazon, Brazil, as a contribution to the malaria vector control program. The field work was carried in Pará State, Brazilian Amazon. Houses were treated with cypermethrin at a rate of 125mg i.a./m^2, deltametrina 25mg a.i./m^2, lambdacyalothrin 30mg a.i./m^2 and etophemprox 200mg a.i./m^2 . The entomological follow up was conducted during a five months period. The results showed that the insecticides had effect on *Anopheles* populations varying between 2 to 5 months depending on the insecticide. The mortality rates were variable according to the type of wall and insecticide. Insecticide applied in wood and non-plastered brick surfaces were more stable and lasted more than on bricks plastered ones. Labdacyalothrin showed shorter effect than the other insecticides, lasting up to 2 months. Etophemprox showed at least 3 moths effect and it was very effective in non-plastered brick surfaces. There was no statistic difference between the effect of deltametrina and cypermethrin in all surfaces tested and the duration of the effect was satisfactory up to 3 months.

Are opportunities for biological control of leafrollers in apples afforded by newer, selective insecticides?

"M Sarvary, H Reissig, J Nyrop"
Department of Entomology, NYSAES, Cornell University, Barton Hall, Geneva, NY 14456 USA

Insect species which, in natural systems are regulated at low densities by natural enemies are often at high densities in commercial apple orchards because insecticides decimate natural enemies and/or commercial orchards provide a rich and abundant resource for herbivores. It was also thought that the orchard habitat, due to its relatively low diversity, was less than optimal for many natural enemies. Recent experiments indicated that orchards are quite adequate habitats for the natural enemies. To determine the potential for the Obliquebanded leafroller (OBLR) biological control in commercial apple orchards, studies were conducted in 2003-2004 to assess parasitism and predation in orchards treated with conventional insecticides and with novel, more selective compounds. To eliminate the potentially lethal effects of insecticides trees were artificially infested with sentinel larvae using newly developed methods. Larvae were exposed for 48 hours and natural enemy inflicted mortality was recorded. Appropriate statistical methods were used to compare natural enemy levels and species diversity in the two insecticide regimes. Both the treatment and the geographical location of the orchard influenced mortality levels. *Actia interrupta* (Tachinidae), *Onchophanes americanus* (Braconidae) and *Exochus albifrons* (Ichneumonidae) were identified as dominant parasitoid species. Predacious insect species were also identified using different collecting methods.

Impact of genetically modified maize pollen containing a *Bacillus thuringiensis* toxin on honey bees *Apis mellifera*

EA Schlüns, . Neumann, HH Kaatz
Inst. f. Zoologie, Martin-Luther-Universität Halle Wittenberg, Hoher Weg 4, Halle (Saale), 06099, Germany, kaatz@zoologie.uni-halle.de

Maize pollen can be the major protein source for honey bees which are important pollinators in many ecosystems. Genetically modified maize containing a gene from *Bacillus thuringiensis* (Bt), that confers resistance to the European corn borer *Ostrinia nubialis*, may have a negative effect on non-target insects. We have investigated the maize variant Bt176 (Novartis) with the insecticidal Bt-toxin CryIAb regarding chronic long-term effects on honey bees. The test colonies received pollen treated with active toxin, whereas the control group received untreated pollen. Both experimental groups did neither differ significantly in mortality of adult bees nor in the number of open and sealed brood cells/colony during the six week trial period. This also applies for foraging activity for pollen and sugar water, brood development, brood rearing activity and the weight of newly emerged bees. In a second experiment, when an infection with the microsporidium *Nosema apis* occurred in the colonies, the bees of the Bt-group died significantly earlier and foraged less than the control group bees. Bees suffering from an microsporidian infection are more susceptible to CryIAb. Presumably both, toxin and pathogen, coacting can cause an enhanced destruction of the epithelial cells of the gut. However, the results indicate that the Bt-Toxin CryIAb is not toxic to healthy bees.

Performance of the Colorado potato beetle on plants with reduced and enhanced insect resistance

HM Hussein, F Sehnal
Institute of Entomology, Academy of Sciences, Branišovská 31, 370 05 České Budějovice, Czech Republic: Sehnal@entu.cas.cz

Lectins belong to the battery of substances by which plants counteract attacks of insect herbivores. The gene encoding snowop lectin GNA (*Galanthus nivalis* agglutinin) was introduced into the genome of several crops with the aim to increase their resistance to insect pests. We examined performance of the Colorado potato beetle (CPB), *Leptinotarsa decemlineata*, on the GNA-potatoes in comparison with the parental non-transgenic cultivar and with a potato depleted of the lipoxygenase LOX H3. This enzyme is involved in the control of jasmonic acid methylation that initiates wound signalling leading to activation of the natural plant defence against insect herbivores. CPB larvae of the penultimate (3rd) and last (4th) larval instars were fed on potato leaves freshly cut from the non-flowering plants higher than 20 cm. One plant supported whole development of one group of larvae. The leaves (only the pinnate ones) were collected from the base to the top of the plant and care was taken to inflict minimal damage. The growth of CPB larvae on the GNA-potatoes was lower than on the control potatoes. The food consumption was similar, except for the first day of the last larval instar when it was reduced on the GNA-potatoes. The biomass increment in course of the experiment and the conversion efficiency of the ingested diet were significantly smaller in insects grown on the GNA potatoes. The pupae and adults developed normally but were smaller in size and their fecundity was reduced. Unexpectedly, there was no difference in any of these parameters between the insects grown on the control potatoes and on those fed the potatoes lacking LOX H3. We conclude that GNA restrains food utilization in CPB larvae but the effect is subtle and apparently insufficient for an economically relevant suppression of the CPB populations in the field. (The study was supported by grant 522/02/1507 from the Grant Agency of the Czech Republic).

Polymorphisms of acetylcholinesterase of the diamondback moth, *Plutella xylostella* in field populations in Korea

BY Seo, DW Lee, BR Choi, SH Lee, KS Boo
Lab. Insect Physiology, Seoul National University, Seoul 151-742, Republic of Korea, madadle@hanmail.net

Various organophosphorous insecticides have been used to control the diamondback moth (DBM) in Korea. Acetylcholinesterase (AChE) has been known to be involved in the insensitivity of organophosphorous and cabamate insecticides though point mutations. To analyze the AChE-based resistance among field populations of DBM in Korea, DBM larvae were collected from five local areas including 2 northern areas (Pyungchang and Yangyang) and 3 southern areas (Muju, Geochang and Jeju island). The characterization of *AChE* gene from each field population can be summarized as follows: (1) The *AChE* gene belongs to *osophila* type subfamily, (2) Size polymorphism of *AChE* gene: 175-, 447-, 593- and 638-amino acids, and (3) various mutations at different positions contribute to heterogeneity among field populations. These results suggest that the DBM can attain the rapid resistance to organophosphorous insecticides based on polymorphisms of *AChE* gene among field populations having different history of agrochemical treatments and various environmental factors.

Search for P450 allele associated with permethrin resistance in *Spodoptera exigua*

K Shimada, K Natsuhara, T Tanaka, T Miyata
Laboratory of Applied Entomology, Graduate School of Bioagricultural Science, Nagoya University, Chikusa, Nagoya, 464-8601 Japan, i022005d@mbox.nagoya-u.ac.jp

Cytochrome P450 enzymes (P450) play important roles in the metabolisms of both endogenous and xenobiotic compounds. P450 have been extensively studied in insects because of their importance in the insecticide resistance mechanism and the metabolism of secondary plant metabolites. The beet armyworm, *Spodoptera exigua,* were selected in laboratory with permethrin. The selected population showed 84-fold permethrin resistance. Resistance to permethrin was decreased until 12- fold when the resistant strain (TR) was pre-treated with PBO as P450 inhibitor. This suggests that P450 is related to permethrin resistance of TR. We screened fifteen P450 genes from *S. exigua* c-DNA library. Especially, CYP9A9 gene expressed 3-fold higher in the midgut and the fat body in TR than those in the susceptible strain (TS). Western blot analysis revealed that CYP9A9 gene in midgut of TR was translated 16-fold more than that of TS. However, no difference of deduced amino acid sequence of CYP9A9 was observed between TS and TR, and the possibility of gene amplification in TR was denied by sourthern blot. It is suggested the difference of regulatory gene element involved in CYP9A9 expression between TS and TR.

Role of loop C and the loop B-C interval of the nicotinic receptor a subunit in its selective interactions with imidacloprid in insects

M Shimomura, M Yokota, K Matsuda, DB Sattelle, K Komai
Department of Agricultural Chemistry, Faculty of Agriculture, Kinki University, 3327-204 Nakamachi, Nara 631-8505, Japan. gc999028@nara.kindai.ac.jp

Neonicotinoids including imidacloprid are agonists of insect nicotinic acetylcholine receptors (nAChRs). We have found that the recombinant *osophila* SAD-chicken b2 hybrid nAChR was more sensitive to imidacloprid than the chicken a4b2 nAChR, suggesting that region(s) interacting with imidacloprid are present in the a SAD subunit. The YXCC motif in loop C of the a subunits has been shown to form part of the agonist-binding sites. The X residue in this motif of SAD subunit is proline, whereas the equivalent residue of the a4 subunits is glutamate. Furthermore, insect a subunits have longer amino acid sequences between loops B and C than is the case for the corresponding region in vertebrate nAChRs. Thus, we have examined the roles of loop C and loop B-C interval region in the interactions with imidacloprid. The P242E mutation in loop C of the SAD subunit reduced imidacloprid sensitivity of the SADb2 hybrid nAChR, whereas the E219P mutation of the a4 subunit increased the imidacloprid sensitivity of the a4b2 nAChR. Deletion of the loop B-C interval region from the SAD subunit slightly enhanced the effect of the P242E mutation on the SADb2 hybrid nAChR, suggesting important roles of the regions investigated in the selective nAChR-imidacloprid interactions.

Tolerance of obliquebanded leafrollers to selected insecticides

MJ Smirle, DT Lowery, CL Zurowski
"Agriculture & Agri-Food Canada, Summerland, BC, V0H 1Z0, Canada, smirlem@agr.gc.ca"

Populations of obliquebanded leafrollers, *Choristoneura rosaceana*, were sampled from orchards in British Columbia and Washington State and assayed for tolerances to insecticides. Insecticides tested included materials with a long history of use such as azinphos-methyl, and newly-introduced materials such as spinosad, indoxacarb, and the benzoylhydrazine insect growth regulators tebufenozide and methoxyfenozide. Significant differences in response to insecticides were observed across populations. Patterns of cross-resistance were determined between azinphos-methyl and other materials. Resistance management strategies were suggested for tree fruits based on these findings.

Performance of families of *Ostrinia nubilalis* (Hubner) (Lepidoptera: Crambidae) on lyophilized corn tissue: tool for selection experiments to create resistant colonies and F2 screens

DV Sumerford, CA Abel, BS Coats, RL Hellmich, LC Lewis
USDA-ARS-CICGRU, Genetics Laboratory, c/o Insectary, Iowa State University, Ames, Iowa, 50010, USA, sumrford@iastate.edu

A method to use lyophilized corn tissue containing the *Bacillus thuringiensis* protein Cry1Ab is described for *Ostrinia nubilalis*. Tests were conducted on both laboratory and field-collected individuals to evaluate the bioassay for its potential use in selection and resistance detection procedures. Freeze-ying of transgenic corn leaves did not decrease the amount of Cry1Ab present when compared to frozen leaf tissue collected from the same experimental rows. In addition, incorporating the tissue into an *O. nubilalis* meridic diet was effective in killing larvae. Analyses of F_2 families originating from field-collected females indicated significant differences among families in the survival of F_2 larvae on a diet composed of 5% of its nutritive material as Cry1Ab tissue. After backcrossing F_2 individuals to a susceptible, laboratory colony we observed that the survival of BCF_2 families exposed to Cry1Ab tissue was dependent on the survival of the F_2 from which they originated. The BCF_2 family analysis indicates that the variation among F_2 families for survival on Cry1Ab has a genetic component. The bioassay using lyophilized tissue containing Cry1Ab therefore has great potential as a research tool for investigations of the genetic basis of resistance to Cry proteins and methods used to detect resistance to Cry1Ab.

Screening sugarcane clones for resistance to cane weevil borer in Viti Levu, Fiji.

R Tamanikaiyaroi.
FSC Sugarcane Research Centre, P.O. Box 3560, Lautoka,Fiji. rupenit@fsc.com.fj

An intensive research was conducted in Lautoka during the 2000- 2003 period to develop an appropriate method of screening sugarcane clones for cane weevil borer (Rhabdoscelus obscurus, Boisd.) resistance. Results indicated that the weevil preferred to oviposit and feed more on Mana variety more than any of the other commercial varieties screened. Using the feeding preference of the weevil larvae, a larval tray screening method based on the mean length of tunnel bored per sugarcane variety was developed. The duration of the larval tray method was 30 days using cane stalks, tin trays and borer larvae. The larval tray method showed significant correlation with field results at 5% level of significance in two different locations of western Viti Levu.

Acaritouch® EC, a novel miticide which contains a food additive as an active ingredient

Y Arimoto, K Tanaka, A Hagiwara, A Motegi, Y Ohta, Y Fujiki, H Mori
Toagosei Co., Ltd., 1-14-1 Nishi-Shimbashi, Minato-ku, Tokyo 105-8419, Japan, kentanaka@riken.jp

We have been developing pesticides focusing attention on compounds used for food and food additives because these compounds are considered safe to the environment and human beings. Our first development is KALIGREEN® SP in which the active ingredient is potassium bicarbonate. KALIGREEN® SP has been used for the control of powdery mildew in many countries. In our recent study, we have developed a new miticide ACARITOUCH® EC. The active ingredient of ACARITOUCH® EC is a propylene glycol fatty acid ester that is used commonly as a raising agent in the baking industry. We evaluated the efficacy of more than 200 different foods and food additives against adult female two-spotted spider mites, and finally found that propylene glycol fatty acid esters showed significant efficacy. The monolauric acid ester indicates the highest miticidal activity, which shows 100% miticidal effect in concentration of over 0.25 gram per litter. Since the activity against mite's eggs is weaker than the activity against the other life stages, two times applications at intervals of 5 to 7 days can enhance the effect of ACARITOUCH® EC strongly. We sell ACARITOUCH® EC for two-spotted spider mites and citrus red mites in Japan at present.

Enhanced efficacy of various insecticides against lightbrown apple moth larvae by a horticultural spray oil.

PD Taverner, K Powis
South Australian Research and Development Institute, GPO Box 397, Adelaide, SA, 5001. taverner.peter@saugov.sa.gov.au

Lightbrown apple moth (LBAM) (*Epiphyas postvittana* (Walker)) (Lepidoptera:Tortricidae) is a serious pest of fruit crops and ornamentals in Australia and New Zealand. In citrus, the larvae feed under the calyx of young fruit, resulting in scarring (halo damage), which leads to a downgrading in price. The larvae can also infest mature fruit, causing costly delays and fumigation when intercepted on consignments sent to various export markets. Horticultural sprays oils alone and in combination with insecticides have been used to control pests in citrus IPM for many years. However, organophosphate insecticides remain a critical component to the management of LBAM in export focussed citrus production. It is important to encourage the bio-rational use of these pesticides and explore the efficacy of insecticides with novel modes of action, and, potentially, less deleterious effects on the environment and beneficial insects. In this laboratory study, a high paraffin content horticultural spray oil, Brella™, significantly increased the efficacy of traditional insecticides, methomyl and chloropyrifos. Emamectin benzoate, spinosad and indoxacarb were the most efficacious of the 'novel' insecticides tested against LBAM larvae. These insecticides also showed significant enhancement when combined with Brella. The potential implications for the field control of LBAM larvae are discussed.

Resistance-associated point mutations in acetylcholinesterase gene in the cotton aphid

S Toda, S Komazaki, T Tomita, Y Kono
Dept. of Grape and persimmon, NIFTS, Akitsu, Hiroshima 729-2494, Japan, toda@affrc.go.jp

The sequences of two acetylcholinesterase (AChE) genes, *Ace1* (orthologous to *Ace* of *osophila melanogaster*) and *Ace2* (paralogous to *Ace*), from the cotton aphid (*Aphis gossypii*) were identified and compared between carbamate resistant and susceptible strains. We found no amino acid substitution in *Ace1*. On the other hand, two amino acid substitutions were detected in *Ace2*. The one substitution was found in two pirimicarb-resistant strains. This position corresponds to one of the 14 aromatic residues lining the active site gorge and located at the acyl pocket. We expected that this substitution plays an important role in pirimicarb resistance. The other amino acid substitution was located at one of the three residues which form the oxyanion hole in the active site of AChE. It remains unclear whether this substitution contributes to insecticide resistance in *A. gossypii*, although it might act a role in the sensitivity of AChE.

Action of deltamethrin on the control of the fruit small borer and its residues on/in fruits and leaves from two cultivation systems of staked tomato crops.

SPL de Carvalho, LRP Trevizan, GC de Baptista, AA Franco.
"ESALQ/USP, 13418-900 Piracicaba-SP, Brazil, lrptrevi@esalq.usp.br"

The degradation/persistence of residues of the pyrethroid insecticide deltamethrin from two cultivation systems of staked tomato crops: experimental cultivation (single line) and commercial one (double line) was evaluated on/in fruits and leaves. The action of the insecticide on the control of the fruit small borer, *Neoleucinodes elegantalis* (Guenée, 1854) (Lepidoptera: Crambidae) was also determined. The treatments, with three replications each, were: A - nine (9) applications at the dosage of 1 g a.i.100 L^{-1} of water, single line cultivation system; B - the same applied as treatment A, double line; C - control. Fruit samples were taken at (-1), zero, 3, 5 and 10 days after last application; leaf samples at (-1), zero, 1, 3, 10 and 20 days. Quantitative measurements were made by gas chromatography, using an electron capture detector. For deltamethrin residual action studies 6 evaluations of the insect pest infestations were made based on percentage of fruit damage. Deltamethrin residues were below the corresponding MRL (0.03 $mg.kg^{-1}$) in fruits from commercial cultivation system (double line) at the end of safety interval (3 days). Also, the residues were higher on/in leaves as compared to fruits. The experimental cultivation system (single line) showed, in general, higher residue levels than the commercial one, giving, in consequence, a better insect pest control.

Carbaryl residues on/in fruits and leaves from two cultivation systems of staked tomato crops and the insecticide action on the control of the fruit small borer.

SPL de Carvalho, LRP Trevizan, GC de Baptista, AA Franco.
"ESALQ/USP, 13418-900 Piracicaba-SP, Brazil, lrptrevi@esalq.usp.br."

The degradation/persistence of residues of the carbamate insecticide carbaryl from two cultivation systems of staked tomato crops: experimental cultivation (single line) and commercial one (double line) was evaluated on/in fruits and leaves. The action of the insecticide on the control of the fruit small borer, *Neoleucinodes elegantalis* (Guenée, 1854) (Lepidoptera: Crambidae) was also determined. The treatments, with three replications each, were: A - nine (9) applications at the dosage of 108 g a.i.100 L^{-1} of water, single line cultivation system; B - the same applied as treatment A, double line; C - control. Fruit samples were taken at (-1), zero, 3, 5 and 10 days after last application; leaf samples at (-1), zero, 1, 3, 10 and 20 days. Quantitative measurements were made by gas chromatography, using a mass selective detector. For carbaryl residual action studies 6 evaluations of the insect pest infestations were made based on percentage of fruit damage. Carbaryl residues were above the corresponding MRL (0.1 $mg.kg^{-1}$) in fruits from both cultivation systems at the end of safety interval (3 days). Also, residues were higher on/in leaves as compared to fruits. The experimental cultivation system (single line) always showed higher residue levels than the commercial one (double line), giving, in consequence, a better insect pest control.

The influence of a biotech cotton crop on arthropod biodiversity in a commercial-farm set-up in South Africa

WM Green, A Bennett-Nel, MJ van Jaarsveld, T Joffe, CLN du Toit
ARC - Plant Protection Research Institute, Division for Pesticide Science, Private Bag X134, Pretoria, Queenswood 0121, South Africa.
rietmvj@plant2.agric.za

Cotton production in South Africa has declined over the last five years, resulting in a national crop yield that is considerably lower than present national consumption. The National Department of Agriculture, in collaboration with Cotton SA and other role-players, is therefore currently formulating a strategic plan to stabilize and expand cotton production. The introduction of cotton as a biotech crop, which enables the commercial farmer to achieve higher yields with lower input costs, will play a large role in achieving these goals. The acceptance of cotton varieties displaying both bollworm-resistant and glyphosate-resistant characteristics in a single cotton plant (so-called stack-gene varieties) by government, industry, environmental organizations and the cotton producer will depend, amongst other factors, on the influence they will have on biodiversity. Arthropod biodiversity was therefore compared within fields treated with Roundup Ready™ and Bollgard™, conventional or non-transgenic cotton, and a stack-gene variety. Preliminary results are given to provide information about the possible impact of these genetically altered products on biodiversity, for the scientific community, industry and other interested parties.

Chitinases induce unexpected effects on *Myzus persicae* Sulzer (Homoptera: Aphididae)

J Saguez, C Vincent, A Cherqui, V Le Roux, JC Laberche, P Giordanengo
"UPRES 2084-2085, Biologie des Plantes et Contrôle des Insectes Ravageurs, Université de Picardie Jules Verne, 33 Rue St Leu, 80039 Amiens Cedex, France and Horticulture Research and Development Centre, Agriculture and Agri-Food Canada, 430 Gouin Blvd., Saint-Jean-sur-Richelieu, Qc, Canada J3B 3E6. julien.saguez@u-picardie.fr"

As it is largely present in invertebrates but absent from plants and vertebrates, chitin appears to be a selective target for pest control agents. Chitinases (EC 3.2.1.14) hydrolyse chitin in the exoskeleton during insect moulting and in the peritrophic matrix. Such properties could be used in the development of new strategies against pests. As part of a program designed to develop potato plant resistance, an insect chitinase gene from the chrysomelid *Phaedon cochleariae* was inserted in potato plants (*Solanum tuberosum* cv. Désirée) via *Agrobacterium* gene transfer. Unexpected effects (i.e. reduction of pre-reproductive period and enhancement of daily fecundity) were observed on the peach-potato aphid *Myzus persicae* when reared on the transformed potato lines. In order to evaluate direct chitinase involvement in the physiological effects observed upon aphid feeding, a bacterial (*Serratia marcescens*) chitinase was provided via artificial diets. Ingestion of bacterial chitinase by aphids reduced nymphal mortality and enhanced the intrinsic rate of natural increase of the populations. For the first time, our results document unexpected effects of chitinase which improved several biological parameters related to *M. persicae* population's growth, a major pest deprived of peritrophic matrix. They also question the relevance of a chitinase-based strategy in a potato culture protection program.

RaPID Assay® technique to test the toxicity of spinosad in the noctuid endoparasitoid *Hyposoter didymator* (Hymenoptera: Ichneumonidae).

J Morales, Pilar Medina, G. Smagghe, E Viñuela
"protección De Cultivos. E.T.S.I.Agrónomos. Polytechnic University Of Maid. 28040-Maid. Spain.
Evinuela@Pvb.Etsia.Upm.Es"

Hyposoter didymator (Thunberg) is an endoparasitoid of *Spodoptera, Heliothis* and *Helicoverpa* larvae in several European countries. The use of pesticides in IPM programmes stressing biological control implies the previous step of determining the impact on the enemies. Spinosad, a neurotoxic compound obtained from a soil actinomycete, is considered a good candidate for the control of lepidopteran pests. A quantitative enzyme immunoassay using magnetic beats (RaPID Assay®) was used to determine the amount accumulated in the body of different stages of *H. didymator* after ingestion or topical exposure at concentrations of 1000 mg a.i./l. Cocoons retained the insecticide in high amounts preventing the pupae from being contaminated. Larvae and adults accumulated very low amounts, but were lethal to them irrespective of the mode of exposure. More than a half of the insecticide that remained in the adult body was found in the ovaries. The endoparasitoid seemed to be more susceptible to the insecticide than the pest.

Insecticidal activity of the lectin from ground ivy, Gleheda

G Smagghe, M Mues, P Medina, F Budia, E Viñuela, W Peumans, EJM Van Damme

"Unidad De Protección De Cultivos, E.T.S.I.Agrónomos, Polytecnic University Of Maid, 28040 Maid, Spain, evinuela@pvb.etsia.upm.es"

The insecticidal activity of the lectin Gleheda (related to the classical legume lectins) from leaves of the ground ivy (*Glechoma hederacea*, family Lamiaceae) has been tested against the pests *Spodoptera littoralis* and *Leptinotarsa decemlineata*. In oral treatment bioassay with larvae, Gleheda affected larval growth and halted larval feeding clearly in both species. Action of Gleheda may rely on its specific carbohydrate-binding activity, so we analyzed its activity on the insect midgut (mainly consisting of a matrix of chitin and proteins), and checked the membrane for aberrations using the scanning electron microscopy. Gleheda activity was compared to that of the GlcNAc-specific wheat germ agglutinin lectin (WGA) and the chitin synthesis inhibitor diflubenzuron. Interaction of the lectin with proteins from different insect tissues (foregut, midgut, hindgut, hemolymph, Malpighian tubules and fat body) was also evaluated. The possible mode(s) of insecticidal action is discussed.

Identifying mechanisms of cyromazine resistance in *Drosophila melanogaster*

AP Van De Wouw, PJ Daborn, DG Heckel, P Batterham
Centre for Environmental Stress and Adaptation Research, Genetics Department, University of Melbourne, Parkville, Victoria 3052, Australia,
a.wouw@pgrad.unimelb.edu.au

The insecticide cyromazine is classified as an insect growth regulator. It has been used to control pest species such as the housefly (*Musca domestica*), the Australian sheep blowfly (*Lucilia cuprina*) and the pea leaf miner (*Liriomyza huidobrensis*). The physiological effects caused by cyromazine include necrotic lesions and irregular hardening of the cuticle, elongation of the larval insect body and death. The molecular mode of action of cyromazine has not been determined. Although cyromazine resistance exists in the field, mechanisms of resistance are unknown. Chemical mutagenesis studies have identified at least four genes conferring cyromazine resistance in *Drosophila* melanogaster. One of these genes, Rst(2b)Cyr, had previously been mapped to chromosome 2R. Using polymorphic molecular markers (single nucleotide polymorphisms (SNPs), restriction fragment length polymorphisms (RFLPs) and microsatellites) and recombination mapping, we have refined the location of Rst(2b)Cyr to a region of 1 map unit which contains 74 putative open reading frames. In addition to mapping approaches, affymetrix microarrays and deficiency kit screening have been used to identify potential candidate genes involved in resistance and mode of action(s) of cyromazine.

Effects of cypermethrin and chlorpyrifos residues in cattle dung on the development of the dung beetle *Copris tripartitus* (Coleoptera: Scarabaeidae)

HS Bang, JH Lee, GS Kyung, OS Kwon, YE Na, SJ Hwang
NIAST, RDA, Suwon 441-100, Korea; Banghs1@rda.go.kr

Fresh dung was collected from untreated cattle and cattle dosed with a spray-on formulation of cypermethrin and chlorpyrifos (2.1g /cow) on days 1, 3, 5 and 7 post-treatment. The dung was bioassayed using the dung beetle *Copris tripartitus* Waterhouse. Residues of cypermethrin and chlorpyrifos were sufficient to inhibit oviposition by *C. tripartitus* in day 1 dung but there was no significant effect on egg laying in dung collected at days 3-7 post-treatment in sexually matured female. But, in the second generation residues of cypermethrin and chlorpyrifos were sufficient to inhibit oviposition by *C. tripartitus* in treatment after 1 and 3 days. Although there was no significantly different effect on egg laying in dung collected at days 3-7 post-treatment in first breeding but, in second breeding, toxic effect reveal in 3 and 5 days dung treatments. Nulliparous dung beetles fed for 200days on dung collected 0, 1 and 3 days after treatment of cow with cypermethrin and chlorpyrifos show little ovarian development.

Efficiency Of Parasitoids From A Behavioural Perspective

H. Gu, Q. Wang and S. Dorn
Institute of Plant Sciences/Applied Entomology, Swiss Federal Institute of Technology (ETH), Zurich, CH-8092, Switzerland, E-mail: hainan.gu@ipw.agrl.ethz.ch

Whilst parasitoids benefit from host herbivore-induced plant volatiles, their behavioural response to these olfactory cues is variable. This variability can cause the inconsistent performance of parasitoids as natural antagonists, but it may also facilitate improvement of their efficiency in biological control through genetic manipulation. Using a model system consisting of cabbage plant *Brassica oleracea*, herbivorous insect *Pieris brassicae*, and parasitic wasp *Cotesia glomerata*, we address how genotypic differences in olfactory response influence host parasitism, and how genetic manipulation of the odour-guided behaviour can enhance the efficiency of parasitoids. Bidirectional selection resulted in two genetically diverged strains of *C. glomerata* in behavioural response to the host-induced plant volatile. Simulation experiments demonstrated that the capacity of both habitat colonization and parasitism significantly increased in the high olfactory response strain, as compared to the low olfactory response strain. Thus, the efficiency of parasitoids can be improved by genetic manipulation of relevant traits. A newly developed technique to mark parasitoids with a stable isotope makes it feasible to test this postulate in the field. The novelty of this technique allows the movement of parasitoids and the resultant parasitism to be tracked at a spatial scale.

Biological control of thrips in greenhouses: the European and Australian experience

J. Bennison and M. Steiner
ADAS Boxworth, Boxworth, Cambridge, CB3 9NN, UK, jude.bennison@adas.co.uk

Western flower thrips (WFT), *Frankliniella occidentalis* is the main thrips pest of greenhouse crops in northern Europe, although other species also occur. WFT was first recorded in the UK in 1986, in other northern European countries around the same time, but in Australia not until 1993. Successful biological control strategies have since been developed for use in Integrated Pest Management programmes on many greenhouse crops. The most widely used biological control agent used against thrips in northern Europe is the predatory mite, *Neoseiulus cucumeris*, supplemented on some crops by other mite species, predatory bugs or entomopathogenic fungi. Some crops such as sweet pepper, cyclamen and other pot/bedding plants can now be grown without the use of pesticides against thrips. UK growers using biological control do not experience severe problems with the tospoviruses *Tomato spotted wilt virus* and *Impatiens necrotic spot virus*. A recent development has been the successful commercial use of entomopathogenic nematodes, *Steinernema feltiae* against WFT on chrysanthemums and other ornamentals. Australia has far fewer biological control options, but is making progress in reducing reliance on chemicals through a similar multi-pronged approach to thrips management. Current research to improve biological control methods for thrips on various crops will be discussed.

Variability in responses of discrete laboratory populations of western flower thrips, *Frankliniella occidentalis* (Pergande) to entomopathogenic fungi

Dr S. Goodwin, Dr WG Liang, MY Steiner,
"National Centre for Greenhouse Horticulture, NSW Agriculture, Locked Bag 26, GOSFORD NSW 2250, AUSTRALIA, stephen.goodwin@agric.nsw.gov.au"

A collaborative research project was undertaken to evaluate entomopathogenic fungi against discrete populations of western flower thrips, a major pest of greenhouse and field vegetable and ornamental crops. Using a standardised laboratory bioassay technique involving a single spore deposit as a discriminating dose, entomology research laboratories in Australia, Canada and the USA are testing a range of promising fungal isolates of *Beauveria bassiana, Metarhizium anisopliae* and *Verticillium lecanii* against second instar and adult female western flower thrips. Data illustrate variability in response by different geographic strains of the target organism. Results of the research to date and future directions in the development of fungi as effective microbial control agents are presented.

Vain Hopes and Last Resorts in Field and Forest Pest Suppression

T. D. Paine
"Department of Entomology, University of California, Riverside, California 92521. USA. timothy.paine@ucr.edu"

It is tempting to look back at the techniques that have been implemented for the suppression of pests of field crops and forest systems and wonder what practitioners were thinking about. Ancient approaches relied on superstitions and divine intervention. Approaches that rely on trapping, herding, burning, barriers, or nasty combinations of highly toxic materials have been used, rejected, and resurrected. Some of these ideas worked when there were no other alternatives. Others never worked at all, but memories are short and wishful thinking or desperation can be powerful forces when the sales pitch is promising. More recently, in part because of dissatisfaction with mixed results or negative impacts of high technology, there has been a return to the spiritual approach to pest suppression and we are left wondering

Good Ideas Gone Bad in Structural Pest Control

Michael K. Rust
Department of Entomology, University of California, Riverside, CA 9252, USA michael.rust@ ucr.edu

In recent years there has been an increasing awareness of consumers of the potential negative impact of insecticides that has resulted in an interest in the use of alternative non-toxic control strategies in urban environments. In addition to the traditional sources of pest control chemicals and equipment, interest in alternative strategies has spurned a cottage industry that markets and promotes various devices, naturally occurring plant products, and remedies designed to provide safe and effective pest control. Even though many of these strategies may be based on some scientific observations, most have not undergone rigorous scientific testing. Most of these can be conveniently organized into three distinct categories: good ideas that have gone bad, bad ideas that are really bad, and bad ideas on the verge of fraud.

Mistakes and Hyperbole in Medical and Veterinary Entomology

B. A. Mullens
"Department of Entomology, University of California, Riverside, California 92521, USA mullens@mail.ucr.edu"

Many imaginative approaches and devices have been designed and marketed for control of arthropod pests of people and animals. A sampling of these will be presented, dealing with mosquitoes, head lice, fleas, and flies. A notable mistake from the historical published literature dealing with delusory parasitosis also will be addressed.

Controlling the Diamondback moth (*Plutella xylostella*) with spinosad applied to white cabbage and cauliflower seeds.

A. Ester, H. de Putter
"Applied Plant Research (PPO), PO Box 430, 8200 AK, Lelystad, The Netherlands. albert.ester@wur.nl"

Three field experiments were carried out with white cabbage (2000 and 2001) and cauliflower (2000) to assess the protection against Diamondback moth with various doses of the spinosad. The plants were raised in trays of modules filled loosely with peat-based potting compost. Batches of seed filmcoated with spinosad at doses of 12, 24, 48, 72, and 96 g a.i. per 100,000 seeds were compared with untreated seeds. Filmcoating with spinosad in the doses used, resulted in the same percentage of usable plants of both crops as the untreated seeds, about 98 % at the moment of transplanting. Seeds filmcoated with spinosad appeared to reduce the number of white cabbage plants attacked by Diamondback moth caterpillars and the number of caterpillars present on the plants for at least 11 weeks after sowing. Treatment with 48 g a.i. spinosad per 100,000 seeds decreased by about 90 % the number of cauliflower plants infested with caterpillars at least 5 weeks after transplanting, inwhich is 10 weeks after sowing. The treatment with 96 g a.i. resulted in 100 % protection against the Diamondback moth.

Integrated Sugar Beet Management Research Program and practices in Iran

M.Zarrabi ,G.A.Abdollahi, H.Salimi,S.Farzadfar, H.Baghdadi
Plant Protection Dept. - Aburihan Agril.College - Tehran University, Email:m_zarrabi_2000@yahoo.com

Up to 200000 hectares is under sugar beet culturing in 17 provinces of Iran. The average production, 35.05 tons/hectares, shows that this crop is affected by different factors. Pests' damage is one of the most important factors. A survey of this situation was conducted to evaluate the sugar beet production information, goals and problems; sources of sugar beet IPM and use of IPM practices for producing maximum yield while keeping production and protection costs as low as possible with emphasis on ICM programs. According to this survey, 15 harmful insects, 20 pathogens and 10 kinds of weeds recorded. Some of them are key pests which decrease the total production below 50%. We have been mentioned to the IPM research program as our national purpose since 1999. Following this program the IPM practices conducted in different pilots with emphasis on good monitoring of insects, weeds and diseases; use of suitable agronomic practices; improving the chemical control methods. The results show a high decreasing in poisons application in this area.

The IPM Practices for controlling the main Sugar Beet Weevils in Iran

M.Zarrabi & *A.Baghdadi*
Plant Protection Dept. - Aburihan Agril.College - Tehran University, Email:m_zarrabi_2000@yahoo.com

Fifteen weevils' species attack to sugar beet in warm and dry regions of Iran. Two species, *Bothynoderes obliquifasciatus* Germ, *Temnorhinus brevirostris* Gyll are key pests. Their adults feed from seedlings after immigration and female laid eggs individually on the upper surface of leaves which look like a block dot. The emerged larvae make a hole in leaves then fall down to cracks in soil near the roots. Larval feeding from roots occur serious damage not only by direct infestation but also by providing suitable condition for root rots. Farmers generally spray high dosage poisons every 2-3 days in early season. In this study the IPM practices conducted base upon mechanical, chemical and agronomical control methods. It included; collecting the hibernator adults from cracks near desert weeds' roots and digging a narrow canal around fields for capturing the immigrated adults in early spring; spraying the seedlings with safe poisons against the adults and eggs; Agricultural practices like early planting , suitable weeding and good irrigation program during summer. The results show decreasing in damage.

Control of mites and insects in flower bulbs during storage: short treatments with controlled atmosphere.

C.G.M. Conijn and M.E. Breedeveld,
Applied Plant Research, PO-box 85, 2160 AB Lisse, The NETHERLANDS, email: cor.conijn@wur.nl

Controlled Atmosphere (CA) treatments are an attractive method for insect and mite control in flower bulbs during storage. To minimise the risk of bulb damage, the aim of this research is focused on development of short CA treatments (24 to 48 hours) to achieve complete pest control. Specific atmospheres, low oxygen or high carbon dioxide, are needed to kill different species of mites and insects. The treatment temperature is important as well as the duration of the treatment. Higher mortality rates were found when temperatures increased (25° to 30°C). Two short CA treatments with one week interval gave better results compared with the same period in one treatment. In small scale experiments the dry bulb mite *Aceria tulipae* in tulip bulbs and the bulb scale mite *Steneotarsonemus laticeps* in Hippeastrum bulbs were killed at low O_2 concentrations (Ultra Low Oxygen, <1 % O_2). The bulb mite *Rhizoglyphus robini* in lily bulbs and gladiolus thrips *Thrips simplex* in gladiolus corms were not controlled with this method. Bulb mites and gladiolus thrips were sensitive for high carbon dioxide concentrations around 30 - 60% CO_2. Advantages of this approach could be a convenient application for bulb growers because it leaves no residues on bulbs and corms. Further research is needed to determine the effects of the CA treatments on the flower bulbs and the pests in large bulb storage rooms.

Multi-species dispensers for mating disruption of codling (*Cydia pomonella* L.) and oriental fruit moth (*Grapholita molesta* Busck) on pome fruit.

AL Il'ichev, DG Williams and LJ Gut
Primary Industries Research Victoria, Tatura, DPI, Victoria 3616, Australia. Department of Entomology, Michigan State University, East Lansing, MI, USA.
Alex.Il'Ichev@dpi.vic.gov.au

Oriental fruit moth (OFM) and codling moth (CM) are key pests of fruit grown in Victoria, Australia and in Michigan, USA. Although CM was the major pest of pome fruit, and OFM was the primary pest of stone fruit, OFM is now established as a pest of pome fruit in Victoria. In the USA and Canada OFM also damages apples, while in Chile and Argentina CM has expanded its host range to peaches. These pests have the ability to migrate and invade new host-plants and growers now need to cater for both OFM and CM together in their pest management strategies. New hand-applied dispensers for mating disruption (MD) of OFM and CM together were evaluated in counter seasonal replicated trials in Northern Victoria (Australia) and Michigan (USA). Trials were conducted for three years on randomly selected pear blocks in orchards in the Goulburn Valley, Victoria and in apple blocks in Michigan orchards where OFM and CM damaged together. Although there was a lot of variation in initial OFM and CM populations the results demonstrated that new multi-species MD dispensers performed similarly with hand applied dispensers for OFM and CM applied individually during three seasons. There were no damaged fruit found on the MD treated plots, but in the control plots without MD, fruit damage averaged at 0.2%. In general, the numbers of OFM and CM caught under all treatments were decreased at the end of the season.

First Australian trials of sprayable microencapsulated pheromone for mating disruption of oriental fruit moth (*Grapholita molesta* Busck) on peaches and pears.

AL Il'ichev, DG Williams
Primary Industries Research Victoria, Tatura, DPI, Victoria 3616, Australia. Alex.Il'Ichev@dpi.vic.gov.au

Sprayable microencapsulated pheromone products for mating disruption have an advantage in easy application with standard spray equipment and compatibility with most insecticides and fungicides. Field trials of a sprayable pheromone formulation for oriental fruit moth (OFM) mating disruption (MD) were established in 2002 for the first time in Australia and continued in 2003-04. Trials were conducted on randomly selected blocks of peaches and pears in orchards in the Goulburn Valley, Victoria. The sprayable pheromone was applied monthly for OFM control with conventional orchard spray equipment. Fruit blocks treated for MD by hand applied dispensers in the registered rate of 500 dispensers per ha were used as a standard. Fruit blocks without MD treatment, but under a conventional insecticide spray program for OFM were used as control. Preliminary results demonstrated that monthly applications of sprayable formulation on pears were as effective for OFM control as hand applied dispensers (500 dispensers per ha) if the initial level of OFM infestation was medium or low. Monthly sprayable applications on peaches were not effective enough to control medium level OFM populations. Experiments on peaches in 2003-04 with fortnightly spray intervals demonstrated no significant differences with standard hand applied dispensers. Sprayable pheromone products for MD of OFM have good potential in pheromone based IPM in Australian orchards.

Nutrient depletion in Western flower thrips affects their response to odour and visual cues

M.M. Davidson, R.C. Butler, D.A.J. Teulon
NEW ZEALAND INSTITUTE OF CROP & FOOD RESEARCH LIMITED, PRIVATE BAG 4704, CHRISTCHURCH, NEW ZEALAND, davidsonm@crop.cri.nz

The physiological state of insects, especially depletion of nutrients through starvation, is known to affect their behaviour. The effects of starvation on the walking or flying response of female Western flower thrips' to visual and/or odour cues in two types of olfactometer were examined. Thrips starved for 0, 1, 4, or 24 h were limited to walking in response to an odour cue (1 ml of 10% p-anisaldehyde) in a Y-tube olfactometer, while thrips starved for 0, 1, 4, 24, 48 or 72 h were able to fly in response to a visual cue (98 cm^2 yellow sticky trap) and/or odour cue (0.5 ml p-anisaldehyde) in a wind tunnel olfactometer. More thrips walked up the odour-laden arm in the Y-tube when starved for at least 4 h (76%) then those not starved (58.7 %) or only starved for 1 h (62.7%). In the wind tunnel experiments the percentage of thrips to fly (regardless of cue) or land on a yellow sticky trap changed significantly with starvation period ($P<0.001$). The percentage to fly or land on the sticky trap increased between those not starved (8% to fly, 7% on trap) and those starved for 4 h (83% to fly, 56% on trap) and decreased slightly between 48 (75% to fly, 39% on trap) and 72 h (57% to fly, 30% on trap).

Control of codling moth (*Cydia pomonella*) by „attract and kill" method

J Stará, F Kocourek
Research Institute of Crop Production, Drnovská 507 – Prague 6 – Ruzyně, 161 06, Czech Republic, stara@vurv.cz

The „attract and kill" method based on combination of attractant and insecticide was tested against codling moth from 2001 to 2004 in Prague – Ruzyně in experimental apple orchard. In 2001, the preparation Appeal (contained cyfluthrin 4% + codlemone 0,1%) produced by Bayer was tested on 0,34 ha plot. In 2002 - 2004 the preparation LastCall^{TM} CM (contained permethrin 6% + codlemone 0,16%) produced by IPM Technologies was tested on 1,7 ha plot. The efficacy of the tested preparations Appeal and LastCall^{TM} CM was ascertained according to level of fruit injury on experimental and untreated plot. In 2001, the fruit injury after the first generation was 15,8% on the plot treated by Appeal and 32,5% on untreated plot. The fruit injury at harvest was 6,4% and 26,3% on the plot treated by Appeal and untreated plot, respectively. In 2002, the fruit injury after the first generation was 1,1 %, on the plot treated by LastCall^{TM} CM and 19 % on untreated plot. The fruit injury at harvest was 0,2% on treated plot and 26,3% on the untreated plot. The results of 2004 will be presented.
This work was supported by the Ministry of Agriculture, the Czech Republic, project No. QD 1048.

Image Database File HANABACHI Based on the Japanese Bees

O. Tadauchi, A. Dawut and H. Inoue

Entomological Lab., Kyushu Univ., Fukuoka, 812-8581 JAPAN, tadauchi@agr.kyushu-u.ac.jp

An image database file HANABACHI (= bees in Japanese) is one of the files in KONCHU database treating species information on the Japanese, East Asian and Pacific insects. It is a species information database based on the Japanese bees including images. The HANABACHI contains image keys to the families and genera of the Japanese bees and species data. A user can also use related files, DJI (Dictionary of the Japanese Insects) and MOKUROKU (A Check List of the Japanese Insects) which are linked to the HANABACHI file. Each species record is composed of 18 items, such as a family, genus and species (or subspecies) names, Japanese name, distribution data, sex of the type, type locality, type depository, source of the original description, synonymies, morphological notes, remarks, flying season, visiting or associated flowers, parasites, references, various and distribution map. The image essentially includes the general habitus, head in frontal view, mesoscutum, propodeum and metasomal terga for each sex of the species. It is managed by a text database management system SIGMA. A user can access the database file by visiting the following URL: http://konchudb.agr.agr.kyushu-u.ac.jp/hanabachi/.

Invasive ants – knocking at New Zealand's door

R. J. Harris, A. Pascoe, M. Stanley
Landcare Research Private Bag 6, Nelson, New Zealand. harrisr@landcareresearch.co.nz

Within the last few years numerous invasive ants have been detected in New Zealand biosecurity border control areas -largely due to the instigation by MAF Biosecurity of a targeted ant surveillance programme at points of entry. These include *Solenopsis invicta*, *S. geminata*, *Paratrechina longicornis*, *Tapinoma melanocephalum* and *Anoplolepis gracilipes*. For some of the high-risk species New Zealand is too cold and they are unlikely to be significant pests. For others, like *S. invicta*, northern New Zealand is at risk. Why are these ants successful invaders? We look at their biological traits and New Zealand border interception data to highlight their success as stowaways, and also demonstrate the numerous entry pathways that exist for invasive ants. Recent changes to importation processes are aimed at picking up more stowaway organisms, and targeted ant surveillance will continue; however, with the ever-increasing importation of goods from around the globe and the continuing international spread of invasive ants, preventing future incursions will remain an ongoing challenge.

Use of mineral oil and predatory mites in the management of two-spotted mite in greenhouse roses

O. Nicetic, DM Watson and GAC Beattie
Centre for Horticulture and Plant Sciences, University of Western Sydney, Locked Bag 1797, Penrith South DC, NSW 1797, Australia. Email: o.nicetic@uws.edu.au

Two-spotted mite, *Tetranychus urticae*, is an important cosmopolitan pest that causes severe economic damage in horticultural crops. Its resistance to many synthetic acaricides has resulted in the search for alternative control approaches. A series of experiments conducted in greenhouses on commercial rose crops investigated the effectiveness of mineral oil sprays and releases of the predatory mite *Phytoseiulus persimilis* in two-spotted mite integrated pest management programs. Application of 0.5% v/v sprays of an *n*C24 horticultural mineral oil applied fortnightly gave excellent protection from when two-spotted mite mite populations were below the economic threshold of 0.5 mites per leaflet before the first oil application. If oil was applied when mite populations were above the threshold, populations were stabilised but not reduced. Application of oil to the upper parts of canopy and release of predators improved control of two-spotted mite over the release of predatory mites alone. Comparisons of the cost of three pest management programs (oil alone; oil with *P. persimilis*; oil in rotation with synthetic acaricides) with the conventional synthetic acaricide program demonstrated cost savings of around 43%, 50% and 12% for these programs respectively.

Value of remnant native vegetation to horticulture

S Rozario
Department of Primary Industries. Box 905, Mildura, Victoria 3502, Australia; shelley.rozario@dpi.vic.gov.au

There is an increasing emphasis on protection of remnant native vegetation and on constructing native vegetation shelterbelts and corridors to protect and manage biodiversity in our landscapes. This project is investigating opportunities to integrate natural resource management with arthropod pest control in irrigated horticulture in the Northern Mallee region. We also aim to increase community awareness of the role and value of native vegetation. We selected seven study sites where vineyards were adjacent to remnant native vegetation. At each site we established two transects perpendicular to the native vegetation/vineyard boundary and installed five pit-fall and five pan traps along each transect, to capture arthropods within the native vegetation and the vineyard. Traps are installed at the vineyard edge and 25 and 50 metres into the vineyard, and at the edge of the remnant native vegetation and 50 metres into the vegetation. We will collect samples from a one week trapping period four to five times a year. Samples already collected are being sorted to major groups of interest (Hymenoptera, Coleoptera, Diptera, Thysanoptera, Lepidoptera, Neuroptera, Dermaptera, and spiders, scorpions, centipedes and millipedes). Selected groups will be sorted to morpho-species to allow some analyses of diversity and functional groups.

Use of pheromones in integrated pest management in Uzbekistan

VSAbdukakharov

Institute of bioorganic chemistry, 83, Kh.Abdullaev street, Tashkent 700125, Uzbekistan, e-mail: abdukakharov@mail.ru

The Institute of bioorganic chemistry of the Uzbek Academy of Science was founded in 1973. The Institute has developed new perspectives in the fields of bioorganic chemistry, molecular biology, biotechnology, and chemical ecology. A major research emphasis is structure-function studies of substances from animals and plants. We carry out investigation of pheromones of insect pests of agriculture in Uzbekistan. Particular attention is given to practical use of pheromones. Methods have been developed for synthesis and practical use of pheromones for more than 30 species of agricultural pests in Uzbekistan. The research includes synthesis of optically active forms of pheromones with chiral centers. Investigations are also conducted on the dependence of attractiveness on structure. The Institute of bioorganic chemistry produces and sells kits containing traps and pheromone lures. These are widely used in the agricultural areas in Uzbekistan, particularly in cotton. We investigate main cotton pests – *Heliotis armigera, Agrotis segetum, Spodoptera exiqua, Lygua lineolaris.* Pests of horticulture – *Euzophera punicaeela, Choreutis nemorana, Laspeyresia pomonella, Grapholitha molesta.* Pests of forestry – *Sarrothrypus musculana, Eurytoma samsonovi.* Pests of food-stuffs – *Ephestia kuehniella, Plodia unterpunctella, Sitophilus oryzae, Cryptolestes pusillus.* Pest of silk-tree – *Glyphodes pyloalis.*

Assessing the risk of reduced-risk apple pest control programs in New York State

AM Agnello, WH Reissig, JP Nyrop, RW Straub
Dept. of Entomology, New York State Agricultural Experiment Station, 630 W. North St., Geneva, NY 14456-0462 USA   email: ama4@cornell.edu

Apple is a high value crop in the US, worth US$1.5 billion annually, and US$100 million in New York State alone. A current on-farm project in NYS is concentrating on the use of IPM systems as an alternative to broad-spectrum insecticides that have been relied upon for 40 years, to greatly reduce residues and worker exposure to organophosphate, carbamate, and pyrethroid insecticides and to evaluate, on a regional scale, reduced-risk tactics that will be effective, sustainable, economically viable, and compatible with biological control. This study addresses the effectiveness of tactics that include IGRs, botanically derived and selective pesticides, and pheromone disruption. Results after 2 years of this 4-year study show that reduced-risk insecticides are effective against many secondary pests. However, fruit damage from internal lepidopterans and apple maggot in reduced-risk orchards tends to be slightly higher than that occurring in standard blocks. This project will help determine if selective insecticides, alone or integrated with mating disruption, can provide adequate control of direct pests of fruit for which there is no allowable market tolerance for damage. It will also help identify potential new pests, as well as natural enemies, that may occur in orchards treated with these new, selective tactics.

Vegetational diversity and conservation biological control

DA Andow, NA Schellhorn, JP Harmon
Department of Entomology, 219 Hodson Hall, University of Minnesota, St. Paul, MN 55108 USA
dandow@umn.edu

The theory of multi-species interactions is rudimentary while vegetationally diverse habitats require examination of many interactions. We identify two 3-species interactions that may be crucial to understanding how natural enemies respond to vegetational diversity. We concentrate on cannibalism and intra-guild predation in a multi-predator system, and on the shared predator, apparent competition multi-prey system. *Coleomegilla maculata* [Coccinellidae] is cannibalistic and feeds on aphids, pollen and other species of coccinellids in maize fields. In one set of experiments, densities of *C. maculata* and other species of coccinellids were experimentally manipulated to evaluate the relative strengths of cannibalism and intra-guild predation and to predict if predation by the various species was redundant or complementary. By analyzing the system as a competitive system, we predicted that predation was complementary. There may be many circumstances that multi-predator systems simplify into ones structurally similar to two-species competition. In another set of experiments, densities of aphids, maize pollen and Lepidoptera eggs were manipulated experimentally to evaluate the effects of multiple prey on *C. maculata*. Unexpectedly, addition of aphid prey sometimes increased per capita predation rates on eggs. Careful examination of three-species interactions may reveal ways to integrate community interactions into a general theory of vegetational diversity.

Adoption of cotton IPM in the state of Andhra Pradesh, India

T Ramesh Babu, A Padma Raju
"Acharya N.G. Ranga Agricultural University, Hyderabad 500 030, Andhra Pradesh, India tatinenir@yahoo.com"

Cotton is an important commercial crop of Andhra Pradesh state covering an area of around one million hectares accounting to 12.5 % of the state total cropping area during *Kharif* (rainy) season. The production of cotton is limited by insect pests to an extent of 50 % despite the use of around 45 % total pesticide consumption. Since 1940s, pesticide application has been the principal approach of plant protection. The pesticide based technology packages exacerbated the pest control problem by reducing pest defenders and development of insecticidal resistance. Hence, it is imperative that Integrated Pest Management (IPM) will play a crucial role in coming decades. *Has the theory of IPM delivered a change in practice?* Certainly yes, the period of transition from conventional paradigm of insecticidal control to pest management tools is underway. The present situation is such that both research and extension activities are to be weighed equally to achieve the production targets. The technologies to ameliorate cotton pest problems, pest monitoring and transfer of technology activities of the state agricultural university, activities of the state agricultural department such as dissemination of IPM package to clientele, season long training programmes on IPM, farmers field schools, establishment of biological control laboratories, encouraging *NGO's* participation, regulation of pesticide marketing and adoption of IPM at farmer level coupled with reduction in pesticide consumption over a decade were discussed. The need for establishing cotton clinics, development of curricula and training modules, information net work, educational software package on Diagnosis and Recommendation in most user-friendly version was emphasized.

Potential use of trap cropping to control diamondback moth in cabbage

FR Badenes-Perez, AM Shelton, BA Nault
NYSAES Cornell University, Dept. of Entomology, 630 W. North St, Geneva, NY 14456 USA, frb3@cornell.edu

The ovipositional preference of the diamondback moth (DBM) *Plutella xylostella* (L.) (Lepidoptera: Plutellidae) and the larval survival of its larvae were tested on four hosts: cabbage, *Brassica oleracea* var. *capitata* L.; collards, *Brassica oleracea* var. *acephala* L.; Indian mustard, *Brassica juncea*; and yellow rocket, *Barbarea vulgaris* (R. Br.). These experiments showed yellow rocket and glossy collard as good potential trap crops. The percentage of trap crop plants necessary to make the trap crop was tested for these trap crops in six different treatments (0, 4, 8, 16, 24, and 32% of trap crop plants in relation to cabbage). Results of these studies and other ones aiming to determine factors of importance in the effectiveness of trap crops show that there is potential in the use of trap crops, particularly yellow rocket, to control diamondback moth in cabbage.

Mating disruption of several lepidopterous pests using high-emission-rate, widely spaced dispensers

TC Baker
Penn State University, Pesticide Res. Lab., University Park, PA 16802, USA tcb10@psu.edu

Widely spaced, high-emission-rate pheromone dispensers have been in commercial use for many years in both field and fruit-tree crops and allow a judicious use of pheromone while minimizing application costs for labor. This is the only type of mating disruptant formulation whose dispenser density (and amount of A.I.) per ha diminishes as the hectarage treated increases while maintaining the same dispenser grid-spacing, due to an advantage of geometry provided by widely spaced dispenser systems. The Metered Semiochemical Timed Release System ("MSTRS") evolved away from a clock-timer machine-driven 'active' release of pheromone into an entirely passive release system using polyethylene bags that maintained high-emission-rate low-point-source-density attributes. The application of this formulation against the European corn borer in Iowa reduced damage to corn by an average of 50% in replicated trials over several years. The density of bags needed to be deployed is only 25 bags per 10 hectares of corn. Merely delaying mating by females and not eliminating it entirely is responsible for the reduction in larval damage. MSTRS dispensers at a density of only 15 per hectare in cranberry marshes significantly reduced mating by free-flying black headed fire worm females. The system also is effective against the oriental fruit moth.

Population dynamics models of vegetation diversity and pesticide sprays in a broccoli-aphid agroecosystem: an alternative to ANOVA in gauging the effectiveness of IPM.

JE Banks, BM Adams, HT Banks, JD Stark

Interdisciplinary Arts & Sciences, University of Washington, Tacoma, 1900 Commerce Street, Tacoma, Washington 98402 USA banksj@u.washington.edu

We explored the interaction of vegetation diversity and selective pesticide disturbance on aphid population dynamics using an optimization approach that fits data from a factorial design field experiment to simple differential equation models. In particular, we established field plots of broccoli surrounded by (a) bare ground or (b) weedy margins, subjected to (i) no pesticide spray, (ii) low concentration pesticide spray, or (iii) high concentration pesticide spray. We fit data from weekly aphid censuses in treatment plots to exponential and logical growth models, and numerically solved an inverse problem in order to calculate time-varying birth/death rates for aphids in different treatment plots. The results of our optimization/inverse problem revealed a synergistic interaction between margin type and pesticide disturbance, corresponding to independent statistical analyses (MANOVA). This modeling approach provides a means of inferring information about mechanisms underlying population field data from factorial design experiments. Our results suggest that combinations of increased vegetation diversity and selective pesticides may act synergistically to reduce populations of target insect pests.

Biodiversity and parasitoid effectiveness: a new twist to an old story

P Barbosa, A Caldas
Department of Entomology, Plant Sciences Building, University of Maryland, College Park, MD, USA 20742

The direct positive relationship between biodiversity in agroecosystems and effectiveness of natural enemies has been an underlying assumption of agroecology. Yet recent research has suggested that although greater biodiversity may be necessary it may not be sufficient. That is, biodiversity may or may not enhance natural control depending on the nature of the biodiversity, e.g., what organisms constitute the diversity. We present the results of research that determined the traits that influence the susceptibility of macrolepidoptera to parasitism. We suggest that the extent to which species in a community exhibit traits enhancing susceptibility and the number of such species may determine if greater biodiversity leads to greater effectiveness of biological control agents.

Behavioural responses of arthropods to iso- and cycloalkanes and implications for use of horticultural and agricultural mineral oils

GAC Beattie, VL Nguyen, O Nicetic, DJ Rae, RN Spooner-Hart
Centre for Horticulture and Plant Sciences, University of Western Sydney, Locked Bag 1797, Penrith South DC, NSW, 1797, Australia,
a.beattie@uws.edu.au

Horticultural and agricultural mineral oils (petroleum spray oils) are important components of biorational integrated pest management programs. These products contain aromatics (0% to about 8% depending on oil quality), cycloalkanes and isoalkanes. Historically, emphasis has focused on their use in dilute (£ 2% v/v) aqueous emulsions to drown susceptible pests, mostly mites and scales. Recent studies have shown that a far wider range of pests can be controlled, with less oil, through the influences of spray deposits on feeding and/or oviposition behaviour. We review recent studies on tetranychid mites, thrips, whiteflies, Asiatic citrus psyllid, dacine fruit flies, *Helicoverpa* spp., agromyzid and gracillariid leafminers, and other pests, and discuss their relevance to pest and disease management programs. Possible reasons for the behavioural effects are also discussed. The effects do not depend on the aromatic content of oils. Queensland fruit fly and Oriental fruit fly respond, quite dramatically, to isoalkanes and cyloalkanes that boil within a very narrow range of temperatures. The results suggest that females perceive these molecules, or parts of them, to be naturally occurring molecules that are detrimental to the development of their larvae.

The influence of groundcover plant species on *Epiphyas postvittana* (Lepidoptera: Tortricidae) and its parasitoid *Trichogramma carverae* (Hymenoptera: Trichogrammatidae)

M Begum, GM Gurr, SD Wratten, P Hedberg, HI Nicol
Pest and Biology Management Group, Faculty of Rural Management, The University of Sydney, Orange, P.O. Box 883, NSW 2800, Australia. mbegum@orange.usyd.edu.au.

Greenhouse experiments were conducted to investigate how *Trichogramma carverae* responded to different groundcover plant species. Adults (< 24h after eclosion) were caged with different groundcover plant species to measure longevity and daily fecundity. Both male and female longevity in *Fagopyrum esculentum* and *Lobularia maritima* treatments were significantly higher than on shoots of these species from which flowers had been removed. Daily fecundity was significantly greater in the *L. maritima* with-flowers treatment than in all other treatments. There was no significant enhancement of longevity or parasitism when wasps were caged with intact *Brassica juncea* or *Borago officinalis*. Separate greenhouse experiments quantified the effect of groundcover plant species on the pest, *Epiphyas postvittana*. Both adults and larvae benefited from *F. esculentum*. This result suggests that whilst *F. esculentum* is non-selective food plant, *L. maritima* could safely be used in a vineyard to enhance *T. carverae* with minimal risk of favouring the pest.

Western flower thrips pupation behaviour on greenhouse chrysanthemums and implications for integrated control

JA Bennison, AB Broadbent, WDJ Kirk, KA Maulden JL Shipp
ADAS Boxworth, Boxworth, Cambridge, CB3 8NN, UK, jude.bennison@adas.co.uk

Understanding the spatial distribution of thrips life stages on the host crop is essential for developing successful control strategies. Information is lacking on the pupation sites of western flower thrips (WFT), *Frankliniella occidentalis*, on different host plants. The proportions of WFT pupating on potted chrysanthemum plants and on the substrate were determined in two experiments (one in Canada and one in the UK). The experimental methods differed, but both included destructive plant assessments and counts of thrips larvae falling to sticky cards beneath the plants. In the Canadian experiment on cv. 'Miramar', 47% of thrips dropped off the plants to pupate and 10% of were found pupating on the plants. The remaining 43% were unaccounted for and presumed to be hidden within the flowers for pupation. WFT pupae were documented for the first time inside disc florets. In the UK experiment on cv. 'Swingtime', results indicated that 93-96% of thrips dropped to the ground to pupate and only 4-7% pupated on the plants. In this experiment, the few pupae found on the plants were primarily in open flowers including inside disc florets. The differences in the experimental methods and results and the implications for integrated control strategies will be discussed.

Development of IPM for thrips in greenhouses of chive.

D Ben-Yakir, N Dudai, M Chen
P.O. Box 6, BET-DAGAN, 50250, ISRAEL, benyak@volcani.agri.gov.il

Chive *(Allium schoenopransum*; Liliaceae) is a major exporting crop for fresh herb growers in Israel. In recent years "silver spots", resulting from thrips feeding (both *Thrips tabaci* and *Frankliniella occidentalis*), significantly restricted the ability of local growers to export chive. We determined the distribution of these thrips outside and inside walk-in tunnels (10x30m) used for chive growing in Northern Israel. The study was conducted from September to July for three years. Thrips populations were highest during the Spring and Fall seasons. Outside the tunnels significantly higher numbers of thrips were trapped on the eastern side. About 75% of the thrips were caught between 7:00 to 13:00 and they were evenly dispersed in height between 0.5-2.0 meters. Inside the tunnels most thrips were caught at the south side, which is the hottest and has the most light. However, the highest numbers of thrips and damaged leaves were found on plants at the northwestern side which had the optimal climatic condition for their establishment. This information may be used to reduce the risk of thrips entry and establishment.

Genetic status of medfly in Australia as inferred from microsatellite markers

M Bonizzoni, R Guglielmino, LM Gomulski, C Smallridge, AR Malacrida, G Gasperi
"Dept. of Animal Biology, University of Pavia, Piazza Botta 9, 27100 Pavia, Italy; mariboni@unipv.it"

The Mediterranean fruit fly *Ceratitis capitata* is one of the world's most important pest species. It is native of sub-saharan Africa, is highly polyphagous and has a long history of invasion success. In Australia, it was first captured near Perth in 1895 and soon spread throughout the country. As a consequence of the expansion of the native pest species, *Bactrocera tryoni*, medfly disappeared in East Australia by the 1930s, but resisted in the Western coastal region. The presence of an inhospitable land separating West and East Australia and the limited number of roads and rail routes, concurred in protecting South Australia from medfly infestations. However, during 2000/2002 several medfly outbreaks occurred nearby Adealide. With the aim of deriving a general picture of the status of medfly in Australia and detecting the possible origin of medfly bioinfestations in South Australia, the genetic status of medflies from South and West Australia was analysed at ten SSR loci and compared to that of flies from Africa, south Europe and Hawaii. The combination of phylogeographic analysis and assignment test approaches showed that overall Australian medflies are most similar to Mediterranean medflies and that flies from South Australia are most probably derived from West Australia.

Common salt as a mirid management tool

HB Brier, RC Creagh, KM Knight and JW Wessels

Queensland Department of Primary Industries and Fisheries, PO Box 23, Kingaroy, QLD, 4610, Australia. hugh.brier@dpi.qld.gov.au

Common salt (NaCl) at 0.5% (5g/L of water) gave significant control of mirids (predominantly *Creontiades dilutus* (Stål)) in two trials in podding mungbeans (*Vigna radiata*). In the first trial at 3 day after treatment (3 DAT), salt gave 80% control of adults, but only 28% control of nymphs. In the second trail, salt gave 70% and 77% control of nymphs and adults at 1 DAT respectively, and 74% and 56% control respectively at 4 DAT. However salt had little residual activity, giving poor mirid control by 9 and 7 DAT in trials 1 and 2 respectively. The addition of salt (0.5%) significantly improved the effectiveness of low rates (£ 250 mL/ha) of dimethoate (Ȯ at 500 mL/ha) against mirids. In two trials, dimethoate plus salt treatments had on average only half as many mirids as the corresponding rates of dimethoate without salt. While dimethoate, plus salt, at rates as low as 125 mL/ha, gave excellent control of mirids present at spraying for 2-4 DAT, dimethoate plus salt at < 250 mL/ha gave poor control of nymphs hatching (from eggs) post spray. Populations of small nymphs reached pre-spray levels by 6 DAT for the lowest dimethoate rate trialed (62.5 mL/ha).

Failure of mating disruption for *Helicoverpa armigera* H. (Lepidoptera: Nocutidae) in isolated tomato and capsicum crops.

DR Britton, PC Gregg
Australian Museum, 6 College St., Sydney, NSW, Australia, 2010 daveb@austmus.gov.au

A full scale trial of mating disruption for *Helicoverpa armigera* was run in isolated tomato and capsicum crops in the Promised Land cropping region, south-eastern Queensland. The cropping area in this region consists predominantly of a mosaic of tomato, capsicum, sugarcane, citrus and avocado. The region is isolated from sources of *H. armigera* adults by at least 6km of state forest which is virtually devoid of larval host plants. We attempted to prevent *H. armigera* mating by treating all solanaceous crops within the region with mating disruption dispensers. Monitoring with pheromone traps and sentinel females indicated that complete mating disruption was achieved in the treated areas, but there was no corresponding decrease in the number of eggs laid in the treated crops, or in the proportion of mated wild females captured in light traps compared with untreated regions. Further trapping and observations indicate that mating was occurring on untreated non-host plants such as sugar cane adjacent to the treated areas. This is a novel finding and contradicts published observations and assumptions made in regard to pheromone production and mating behaviour in heliothine moths. A commercially viable mating disruption program in the Promised Land region would require treating both host and non-host plants within the cropping region. This is currently neither economically nor logistically feasible.

IPM of protected cropping in established northern greenhouse regions

HF Brodsgaard, A Enkegaard
Danish Institute of Agricultural Sciences, Research Centre Flakkebjerg, DK-4200 Slagelse, Denmark,
henrik.brodsgaard@agrsci.dk, annie.enkegaard@agrsci.dk

Biological control of pests in Northern Europe and Canada was taken up in the late 1970s in vegetable crops due to severe problems with pesticide resistance in glasshouse whiteflies and two spotted spider mites. In the Netherlands, the UK, and Scandinavia biological control of the two pests soon proved to be viable and economically feasible and the method was almost immediately implemented by the glasshouse industry. Besides growers' positive attitude, the climate and glasshouse constructions have facilitated the effect of biological control agents. A key aspect is that in the major part of the growing season, the glasshouses can be considered as closed environments with little influx of pests. Another aspect is the generally high sanitary standards of the glasshouse operations in these regions that reduce refuges of pests and thereby increase the control effect on the crop. The research community has focused on developing biological control agents for former secondary pests and the commercial producers have been very effective in utilizing the scientific results. Insectaries have, thereby, been able to provide biological control solutions to pest problems soon after they have emerged in both vegetable crops and ornamentals. Until recently, a rather liberal legislation on importation of exotic beneficial arthropods into continental Europe has facilitated the utilization of the same biological control agents across borders. This increases the market for insectaries and the availability of biological control agents to growers.

Western flower thrips: Australia's unwanted immigrant

S Broughton
Department of Agriculture Western Australia. 3 Baron-Hay Court, South Perth WA 6151
smbroughton@agric.wa.gov.au

Western Flower Thrips, *Frankliniella occidentalis*, is a recent introduction to Australia. WFT were first detected in Perth in 1993. They have since spread to all states of Australia, with the exception of the Northern Territory. WFT cause damage to crops through direct feeding, and through virus transmission. Wide ranges of crops are affected including vegetables, ornamentals and fruit crops. Insecticides are favoured by commercial growers in Australia as their main control method. However, as has occurred elsewhere, WFT are resistant to a number of insecticides. Furthermore, the current registered rate of many insecticides in Australia may be too low. This would increase selection for resistance, because pesticides are being applied at a sub-lethal dose. Resistance has already been detected against the newer chemistries such as spinosad and fipronil, albeit at a low level. In the long-term, insecticidal control of WFT is unsustainable. An integrated approach must be adopted. However, few other control methods are available to Australian growers. For example, biocontrol agents effective overseas are unlikely to be approved for release here. This is due to Australia's quarantine regulations that govern the importation, testing and release of exotics. Nevertheless, other control methods are required.

Pheromone based mating disruption strategy in agroforestry.

JJ Brown, N Kittelson, G Hannon, D Walsh
Dept. of Entomology, Washington State University, Pullman, WA 99164-6382, USA, brownjj@mail.wsu.edu

Western poplar clearwing moth (*Paranthrene robinae* Hy. Edwards) populations have reached outbreak proportions in hybrid poplars grown for pulp and saw timber in eastern Washington and Oregon. Not even recorded as a serious pest of poplar in 1999, there were only 95 *P. robinae* males captured in 2001, but the following year the same number of pheromone baited traps captured 17,000 male moths. Clearwing larvae burrow into the heartwood of these trees. Repeated applications of chlorpyrifos in 2002 had little or no effect on the number of males captured in baited traps or damage to trees. We treated 3,823 Ha with synthesized female pheromone [4:1 ratio (E,Z):(Z,Z)-3-13-octadecadienyl alcohols] beginning June 2, 2003. Formulations included membrane dispensers and aerial applied flowable microcapsules (WPCM-F Suterra®, Bend OR). After pheromone application the trap capture was reduced by a dramatic 99.75%; however, some damage was attributed to moths that had emerged and mated before the June application. Application in 2004, started in April and the entire 14,164 Ha was treated with pheromone. This is the first attempt to use a pheromone based 'mating disruption' strategy on a large scale Agroforestry system.

Disruption of moth mating with pheromones: formulation and behavior determine efficacy

RT Cardé
Department of Entomology, University of California, Riverside, CA 92521, United States of America, ring.carde@ucr.edu

Worldwide some 430,000 ha of crops and forests are protected from many moth pests by application of formulated pheromone to disrupt mating, typically as component of a management program that also includes application of conventional pesticides. The pests controlled span a spectrum of moth families, pheromone chemistries, and crops infested. The methods of dispensing pheromone varies widely, from sprayable microdispersibles, to point sources that mimic the release characteristics of an individual female, to point sources emitting pheromone at rates many thousands of times the release rates of females. The most commonly invoked explanations of mating disruption invoke adaptation of peripheral sensory receptors, CNS habituation of responsiveness, competition between pheromone sources and females, and camouflaging of the female's plume. The type of formulation, the nature of the plant canopy, wind conditions, and the sensory and orientation capabilities of the particular moth species, together dictate which mechanism predominates in achieving disruption of mate finding. But most successful cases of disruption seem to hinge on multiple, interacting mechanisms. Understanding how these can be optimized in a formulation for a given species may allow improvements in efficacy.

Development of integrated fruit production for apples in Eastern Canada: making use of pesticide risk indicators to facilitate adoption of IPM practices and to monitor changes in pesticide use over years

G Chouinard, S Bellerose, F Pelletier, D Cormier
IRDA, 3300 Sicotte, St.Hyacinthe (Qc), Canada J2S 7B8, gerald.chouinard@irda.qc.ca

In North America as in most other regions of the world, numerous policies aiming to reduce the use of pesticides were implemented in the past 20 years with variable success. Among encountered problems, the debatable choice of an indicator to measure the progress of these programs can be pointed out. We used data collected since 1977 in a series of apple orchards in Quebec, Canada as an example to demonstrate a decline of the environmental impact of spray programs used in this region against insects and mites. During this period, the average field value of the Environmental Impact Quotient (EIQ) decreased by 66%. The same decrease was not always noticed, however, when other indicators were used, such as the number of applications or the amount of active ingredient used per hectare. Since the use of precise quantitative tools can make a difference when drawing conclusions from pesticide use data, we suggest to make use of EIQ or similar risk indicators to facilitate the classification of pesticide applications according to recommendations in IFP programs currently under development for apples grown in Canada.

When can pestiferous mirid bugs be beneficial biological control agents?

M Coll, A Allouche, S Steinberg
Department of Entomology, The Hebrew University of Jerusalem, PO Box 12, Rohovot 76100, Israel, coll@agri.huji.ac.il

Insect ecologists have only recently begun to acknowledge that many species exhibit omnivorous feeding habits as they exploit both plant-based resources and arthropod prey. The prevalence of omnivores in agroecosystems calls for special attention in IPM programs. Understanding the feeding habits of omnivorous pests is particularly important for mirid bugs, as several economically important pests in this family also feed on other arthropod pests in the system. It appears that mirid populations previously suppressed by insecticides, tend to build up under IPM regime. A better knowledge of their feeding biology will thus help assess their overall economic impact and allow the development of new approaches to population management. The major challenge facing applied entomologists is to identify the conditions, including plant characteristics and availability of arthropod prey, which may influence levels of omnivore-inflicted crop damage. This is the objective of our research-in-progress on *Creontiades pallidus* in greenhouse sweet pepper. Results to date indicate that different prey species in the system, such as red spider mite, sweet potato whitefly, western flower thrips, and moth eggs, differ in their nutritional suitability for the bug. I will discuss the relationship between prey availability and *C. pallidus*-inflicted damage to sweet pepper fruits.

Attraction of male *Lygus rugulipennis* to components of the female sex pheromone

PJ Innocenzi, A Cork, DR Hall, JV Cross, H Yeo.
Natural Resources Institute, University of Greenwich, ME4 4TB, UK. a.cork@gre.ac.uk

We previously showed that three chemicals, hexyl butyrate, (*E*)-2-hexenyl butyrate and (*E*)-4-oxo-2-hexenal are present in both male and female adults of the European tarnished plant bug, *Lygus rugulipennis* (Poppius) (Heteroptera: Miridae), but that only the females produce these in detectable amounts when undisturbed. They were suspected to be components of the female sex pheromone, but field trapping experiments using polyethylene vials and sachets as dispensers were unsuccessful. Here we report more recent field experiments during which the chemical components were released from microcapillary tubes. The mixture of hexyl butyrate and (*E*)-4-oxo-2-hexenal was significantly attractive to male *L. rugulipennis,* and a blend of all three components attracted significant numbers of males of the congeneric species *L. pratensis*. The possible reasons for the success of the microcapillaries compared to other dispensers are discussed in terms of the release rate, the release ratio and the importance of a point source dispenser.

Pushing insects around: the use of 'push-pull' strategies in integrated pest management

SM Cook, W Powell, LE Smart, NP Watts, IH Williams
Plant & Invertebrate Ecology Division, Rothamsted Research, Harpenden, Hertfordshire, Al5 2jq, UK. sam.cook@bbsrc.ac.uk

'Push-Pull' strategies could further decrease pesticide usage in IPM systems by reducing insect pest infestations through the use of repellents / deterrents to 'push' pests from the main crop while simultaneously attracting or 'pulling' them onto neighbouring, more preferred host plants (trap crops), where they can be more efficiently controlled. We explain the principles of push-pull strategies and demonstrate their potential using a model system. Oilseed rape (*Brassica napus*) can be protected from damage by the pollen beetle (*Meligethes aeneus*) through use of Lavender essential oil and turnip rape (*Brassica rapa*). Lavender oil shows potential as an effective repellent; it deters pollen beetles from colonising treated oilseed rape plants. Turnip rape acts as an efficient trap crop; pollen beetles prefer turnip rape to oilseed rape. The mechanisms of attraction were investigated to maximise the efficiency of this component of the strategy. In the field, a border of turnip rape surrounding oilseed rape plots reduced infestation of the oilseed rape to below spray-threshold levels, and damage was significantly lower than in control plots. Turnip rape can also augment biological control of the pollen beetles by positively influencing the distribution of their parasitiods.

Grape IPM and biological control in California organic vineyards

KM Daane
Center for Biological Control, Division of Insect Biology, University of California, Berkeley, CA , 94720, USA, daane@uckac.edu

Development of novel approaches for Integrated Pest Management (IPM) systems has often relied upon research in organic or sustainable crops systems. California vineyards were at the forefront of many novel approaches developed in the 1950-70s, with vineyard insect pests the target of classical, augmentation, and conservation biological control, as well as many cultural control practices. Today, the practice of organic vineyard farming in California is jeopardized by a series of newly invasive pests, such as the glassy-winged sharpshooter and the vine mealybug. New control options currently developed for these pests include biological control, the use of area-wide management (glassy-winged sharpshooter) and mating disruption (vine mealybug). Nevertheless, these approaches have yet to be proven effective for organic producers that have infestations of these newly invasive insect pests. As a result, successful organic farming may rely more on pest species present, vineyard location and commodity (wine, raisin or table grape) than on implementation of sustainable insect management practices. I discuss both past and current insect pest management programs, as well as the outlook for organic farming in California vineyards.

Plant extracts as source of semiochemicals and fumigants for thrips control

WJ de Kogel, BC Boertjes, CGM Conijn
Plant Research International, PO Box 16, 6700 AA Wageningen, The Netherlands, willemjan.dekogel@wur.nl

Many plant species have insect repellent or pesticidal properties. Extracts from these plants can be used to develop pesticides or repellents to be used in pest control strategies. We have selected several (compounds from) plant extracts that show in laboratory assays repellent and/or toxic effects on several species of thrips: *Frankliniella occidentalis* (western flower thrips), *Thips tabaci* (onion thrips) and *Thrips simplex* (gladiolus thrips). Current research focuses on the development of control strategies for thrips species based on these compounds. These strategies include: 1) repellents as synergist of pesticides, 2) plant extracts as fumigants for disinfection, 3) formulated extracts as toxic and/or repellent crop spray to keep thrips away. We will present examples from these strategies that show that plant extracts have potential for control of thrips.

Effective emulsified wax dispensers for pheromone-based pest control

FM de Lame, JR Miller, LJ Gut, CA Atterholt, TP Reed, R Borges, LEJ Mafra, R Coler, A Mafra-Neto
The Pennsylvania State University, 6A Pesticide Research Lab, University Park, PA 16803, USA, fmd114@psu.edu

Atterholt (1996) demonstrated the potential of using emulsified paraffin wax to release insect sex pheromones, creating biodegradable Emulsified Wax Dispensers (EWDs) which are more economical, adaptable, and easier to apply than other available pheromone dispensers. Optimization of EWDs at Michigan State University, U.S.A., for mating disruption of *Grapholita molesta* resulted in the development and field-testing of a dollop formulation that was as effective as the commercial standard (Isomate M-100 ropes, Shin-Etsu Chemical Co., Ltd.) season-long in peaches (*ca.* 15 wk) and could be applied almost twice as fast. In subsequent studies, substituting microcrystalline wax for paraffin improved the formulation by reducing the emission rate of *G. molesta* pheromone by half and increasing dollop adherence to tree bark. ISCA Technologies, Inc. (Riverside CA, U.S.A.) scaled-up production of the microcrystalline formulation. This commercially-available Semiochemical and Pheromone Lure Application Technology (SPLAT) is providing excellent protection against *G. molesta* through mating disruption and attract & kill in large-scale commercial enterprises. By reducing the cost of pheromone-based pest control, SPLAT should encourage wider adoption of this technique in organic and IPM programs worldwide. Atterholt, C.A. 1996. Controlled release of insect sex pheromones from sprayable, biodegradable materials for mating disruption. Ph.D. dissertation. University of California, Davis, CA.

Organic pest management in the U.S. grain belt: challenges and perspectives of an increasing trend

K Delate, J DeWitt, J Kennicker, and B Lang
Iowa State University, Ames, Iowa U.S.A. 50011 kdelate@iastate.edu

Organic soybean [*Glycine max* (L.)] production in the U.S. has risen to more than 60,000 ha in less than 10 yr. and other organic grain crops have also experienced tremendous growth. This presentation reviews current organic pest management research and producer findings across the Grain Belt. Critical challenges associated with organic soybean production include soybean aphid (*Aphis glycines*), other seed-staining fungi such as *Cercospora kikuchii* and *Fusarium*, and bean leaf beetle (*Ceratoma trifurcata*) as a vector for bean pod mottle virus. Despite challenges facing producers from these insect pests, an economic evaluation based on three years of research at the Neely-Kinyon Long-Term Agroecological Research site near Greenfield, IA revealed that food-grade organic soybean could return \$1160 to 1250 ha^{-1} compared to \$235 for conventional soybean grown in a 2-yr rotation with corn (*Zea mays* L.). At the Neely-Kinyon site, staining ranged from 7.5 to 22% while yields ranged from 3.5 to 3.8 Mg ha^{-1} in 2002. Other IPM successes include cucumber beetle and squash bug in organic squash, and codling moth management with mating disruption and approved organic treatments. Despite the many challenges, increasing consumer demand for certified organic crops warrants more aggressive and participatory IPM research around the world.

Developments in organic IPM research and priorities for the future

JR DeWitt
2104 Agronomy, Ames, IA 50011, USA, jdewitt@iastate.edu

Organic agricultural research in the United States is undergoing a rebirth of interest, focus, and scope involving federal, state, university, and private sector partnerships. Still, less than 0.2% of the available research acres at academic institutions (US Land Grants) are devoted to organic research. Increased numbers of competitive funding opportunities exist from federal (USDA), state universities, state departments of agriculture, and the non-profit sector. The USDA-CSREES-SARE program, the USDA Organic Transitions Program, and The Organic Farming Research Foundation provide visible and targeted funding for organic agriculture research. Consumers, farmer groups, local non-profit organizations, and selected academic institutions are providing increased visibility, accountability, and prioritization to needed organic research and policy. A unique partnership of farmers and scientists (SCOAR) has been organized to develop a prioritized research agenda for pursuit of multi-disciplinary research and extension on working farms. US Midwestern farmers rated weed management, crop rotations for pest management, cover cropping, and the relationship of organic systems to product nutritional value as high research priorities.

Host plant-derived volatiles attract female oriental fruit moth *Cydia (Grapholita) molesta* in the laboratory

S Dorn, D Natale, L Mattiacci
Institute Of Plant Sciences, Applied Entomology, Swiss Federal Institute Of Technology (ETH), CH - 8092 Zurich, Switzerland, silvia.dorn@ipw.agrl.ethz.ch

The oriental fruit moth, a key pest of peach, also caused considerable damage to apple in recent years, particularly in the later part of the growing season. A small proportion of the population has the capacity for long distance flight and gravid females appear to be the main dispersers. With the ultimate goal of developing a monitoring system for females, peach shoot volatiles were analysed and tested for behavioural response of female moths. The following results and conclusions were made: (1) Mated female moths were attracted to volatiles from peach shoots, even when visual contact was completely prevented. (2) 22 compounds were identified and quantified from peach shoot, using direct thermodesorption followed by coupled gaschromatography-mass spectrometry. (3) The bioactive constituents were the short-chain compounds as found by bioassay-assisted fractionation based on selective sorbent polymers ("subtraction approach"). (4) A three-component mixture originating from two different metabolic pathways showed significant bioactivity. This synthetic mixture elicited a similar attractant effect for female oriental fruit moths as the full natural blend from peach shoots and the bioactive fraction. Further work is in progress to develop a surveillance system for use under field conditions.

Host switching during the season: sex-dependent flight behaviour and monitoring in a lepidopteran pest, *Cydia (Grapholita) molesta*

S Dorn, J Hughes, D Natale

Institute Of Plant Sciences, Applied Entomology, Swiss Federal Institute Of Technology (ETH), CH - 8092 Zurich, Switzerland, silvia.dorn@ipw.agrl.ethz.ch

Inter-orchard flight of moths may have important consequences for pest management in orchards, as exemplified by *Cydia (Grapholita) molesta*. Originally known as a key pest of peach, it has been found recently in several countries to cause significant damage to pome fruit orchards in the later part of the season. Mechanisms underlying this late-season host shift have been investigated using behavioural assays in a dual choice odour arena as well as using comparative assessments on a computer-linked flight mill, with the following results and conclusions: (1) There is no indication that olfactory cues emanating from pome compared to peach fruit trees elicit any preference in the moths that could promote a host shift. (2) A proportion of the moth population is capable of undertaking long flights, with gravid females being the main dispersers. (3) Changing abiotic but not changing biotic conditions during the insect's development were found to correlate with markedly increased flight in the adult stage. The most powerful influence was noted for decreasing photoperiod at constantly high temperature during the preimaginal phase. It is postulated that decreasing photoperiod during the insect's development is the main factor eliciting the late summer host shift observed in this lepidopteran pest.

Areawide organic IPM in pear: a 3-year study

JE Dunley, TM Madsen
Washington State Univ., Tree Fruit Research Center, Wenatchee, WA, 98801 USA, dunleyj@wsu.edu

Areawide management programs for insect pests of apple and pear in the Western US have been successful since their inception a decade ago, targeting codling moth through mating disruption to replace organophosphate insecticides. Pear psylla, another important pear pest, is also appropriate for areawide management, being highly dispersive with potential natural enemies in surrounding habitat. Establishing organic orchards among conventional orchards has been difficult: pests readily migrate from adjacent conventional orchards, yet natural enemy movement is limited by the pesticide barriers. Organic IPM on an areawide basis provides opportunities for immigration of biocontrol agents. In 2002, an Areawide Organic Management Program was established on 310 ac of contiguous pear, surrounded by native vegetation. Organic IPM practices were implemented for insect control throughout the project. However, other organic practices were not required (e.g., nutrient, rodent, and weed management), and approximately 50% of the acreage was Certified Organic. Over three years, there was a reduction in pesticide use and insecticide costs, with no differences in pest densities. However, there have been no correlated increases in natural enemy densities. Fruit yield and quality have been maintained, and alternative marketing programs have been attempted.

Habitat manipulation – half a century in waiting

H van Emden
Department of Agriculture, The University of Reading, Earley Gate, READING, RG6 6AR, U. K., h.f.vanemden@reading.ac.uk

By the 1950s, the components of habitat manipulation that we use today to favour natural enemies were already established - nectar feeding, alternative and alternate hosts and microclimate. However, neither farmers, politicians nor the public were interested. The newly-arrived organochlorine insecticides were cheap, efficicnt and as yet irreproachable, biocontrol was only about importation, no one wanted weeds on a farm and diversity was an arcane and complex concept. What a 'sea-change' there has been! Environmentalists have fuelled an unreasonable public distaste of insecticides, that same public now demands cheap food from a beautiful and diverse agricultural landscape, and we in Europe have realised that our despised indigenous natural enemies have, already for a long time, been seen in the New World as valuable imports for biocontrol.. The principles of the 50s have now become farmer practice in Europe. Much of the purposeful introduction of 'biodiversity', however, is not designed for the improved biocontrol it achieves as much as for survival of 'our feathered friends'. Economically viable options for habitat manipulation will be described.

Plant bug (*Lygus lineolaris*, *Lygocoris inconspicuous*, and *Taedia scrupeus*) biology on strawberries and grapes

G English-Loeb, M Rhainds

"Department of Entomology, Cornell University, New York State Agricultural Experiment Station, Geneva. NY 14456, USA, gme1@cornell.edu"

Plant bugs are a common constituent of the arthropod communities of cultivated grapes and strawberries in the Northeastern USA. *Lygus lineolaris* (Tarnished Plant Bug or TPB) is a well-recognized direct pest of strawberries while *Taedia scrupeus* (Banded Grape Bug or BGB) and *Lygocoris inconspicuous* were thought to have little impact on grapes. We initiated research on ecology of all three species with different goals in mind. For TPB, we examined use of reflective mulch, variation in host plant resistance/tolerance, and influence of host plant density/patch size on abundance and damage to develop insights into non pesticidal approaches for control. Reflective mulch surrounding strawberry plants resulted in increased plant productivity, reduced nymphal densities, and reduced damage. We found evidence of cultivar differences in TPB damage mediated through multiple mechanisms but predominantly from increased productivity. Higher density of fruit was associated with less injury per fruit after controlling for TPB density indicating a saturation functional response. In grapes, we found that nymphs of BGB and *L. inconspicuous* are capable of causing significant reduction in yield at low densities (1 nymph per 10 shoots) mainly through reduction in number of clusters. Monitoring guidelines and control recommendations are in development.

Suppression of caterpillar pests in cole crops using pheromone-based attracticides

HY Fadamiro, E Maxwell, and J McLaughlin

Department of Entomology and Plant Pathology, Auburn University, 301 Funchess Hall, Auburn, AL 36849, USA, Email: fadamhy@acesag.auburn.edu

Cabbage looper (*Trichopulsia ni*), diamondback moth (*Plutella xylostella*), and imported cabbageworm (*Pieris rapae*) are among the most serious pests of cole crops in the United States. The objective of this research is to determine the feasibility of using sex pheromone-based attracticide formulations to control these lepidopteran pests in cole crops. We evaluated two sex pheromone-based *LastCall*™ (attracticide) formulations (IPM Tech. Inc., Portland, Oregon, USA): one for *P. xylostella* and one for *T. ni.* Laboratory tests showed that male moths of each species were able to locate and make contact with conspecific *LastCall*™ droplets, and that minimal contact with *LastCall*™ resulted in significant moth mortality. In field evaluations, we recorded suppression of trap catch, and significant reductions in larval infestations and crop damage in *LastCall*™-treated plots, compared to untreated plots. Damage ratings for cabbage heads and collards in *LastCall*™-treated plots were similar to ratings in *Bt* plots, and both were significantly lower than in control plots. These results suggest that applications of sex pheromone-based *LastCall*™ formulations for *P. xylostella* and *T. ni* can provide control levels comparable to *Bt*.

Evaluation of conservation strips as a conservation biological control technique on golf courses

S Frank, P Shrewsbury
"4112 Plant Science Building, University of Maryland Department of Entomology, College Park, MD 20742, sfrank@wam.umd.edu"

Conservation strips combine the conservation biological control tactics of beetle banks and flowering insectary strips to create aesthetically pleasing refuges for predatory arthropods. The conservation strips contained two flowering plants, alyssum and coreopsis, and ornamental switchgrass. Conservation strips were established next to golf course fairways to evaluate their effect on arthropod abundance and distribution. Spiders, carabid beetles, and staphylinid beetles were of particular interest. They are the most common predators on golf courses and have been shown to inhabit beetle banks. Conservation strips supported a greater abundance of predators, parasitoids, and alternative prey than turf in the fairways or roughs. In addition, fairways and roughs adjacent to conservation strips had a greater abundance of predators and alternative prey than fairways and roughs without conservation strips. Black cutworm, *Agrotis ipsilon* (Lepidoptera: Noctuidae), is a common pest of golf course fairways. Predation of black cutworm larvae was significantly more frequent in fairways when conservation strips were present. For these reasons conservation strips show potential as a conservation biological control tactic on golf courses and agricultural systems. Manipulation of golf course habitat, by installing conservation strips, could reduce pest pressure and the need for insecticide applications.

Pest management in Australian sorghum – a success story

BA Franzmann, DAH Murray, AT Hardy and MP Zalucki
Department of Primary Industries & Fisheries, PO Box 102, Toowoomba, Qld. 4350. Bernie.Franzmann@dpi.qld.gov.au

During the past decade there have been dramatic changes in the management of the two main pests of Australian sorghum, the sorghum midge, *Stenodiplosis sorghicola,* and the corn earworm, *Helicoverpa armigera.* More than 95% of sorghum crops now have resistance to sorghum midge. Levels of resistance range from x2 to x12. Insecticide sprays to control midge have reduced from about 20-30% of crops being sprayed to less than 1%. The corn earworm has developed resistance to most of the synthetic insecticides previously used. A *Helicoverpa* specific nucleopolyhedrovirus (NPV), is now widely used with a concurrent marked decline in the use of broad-spectrum chemical insecticides. Currently, more than 95% of the treated crop is sprayed with NPV. Minimal spraying of sorghum crops with hard insecticides has increased survival of natural enemies and changed sorghum from a 'source' to a 'sink' for corn earworm, and a nursery for beneficial insects, including *Trichogramma, Microplitis,* Coccinellidae and Syrphidae. Sorghum's new attributes are being exploited in area-wide management strategies for corn earworm. A combination of plant resistance for midge and NPV/natural enemies for corn earworm has revolutionised sorghum pest management in Australia.

Citrus leafhopper IPM in Queensland, Australia

CG Freebairn, D Smith
Queensland Department of Primary Industries & Fisheries, Maroochy Research Station, PO Box 5083, SCMC, Nambour, 4560; chris.Freebairn@dpi.qld.gov.au

Empoasca smithi, is a serious pest of the valuable early varieties Imperial mandarin and Navel orange, and in bad years also of mid- and late-season varieties in Queensland's Central Burnett area. Adults, which breed and feed on flush growth through spring and summer, switch in autumn and winter to green mature and colouring fruit where they cause skin blemishes, downgrading of up to 80% of fruit. Two mymarid wasp parasitoids, *Stethynium empoascae* and *Anagrus baeri*, kill up to 100% of eggs, but need insecticide assistance in most years. Endosulfan at 30 ml/100 L is cheap and effective, killing both nymphs and adults, but must be re-applied to kill hatching nymphs. The insect growth regulator buprofezin kills only nymphs, but also is very effective, though expensive - but contributes significantly to red scale and mealybug control. An orchard-wide strategy and good scouting and decision making is required to prevent re-infestation of treated trees by adults dispersing from hardening flush in untreated trees, especially in late autumn from mid-season varieties with non-susceptible fruit to early season varieties with maturing fruit, and from the common exotic weed tree species *Celtis sinesis*. The benefit to growers of this research is estimated at $11,250-$38,500/ha.

Greenhouse IPM - a part of a holistic integrated crop management approach

K Fry

Alberta Research Council, PO Bag 4000, Vegreville, AB, T9C 1T4, Canada, ken.fry@arc.ab.ca

Greenhouse production is a complex undertaking, comprised of several disciplines, among them entomology, agronomy, pathology, engineering, marketing and economics. Greenhouses are controlled environment structures considered to alleviate or eliminate uncertainty due to fluctuation and extremes in weather characteristic of field production. However, having this added control over plant production growers face the challenge of setting priorities regarding crop production components given that practices in one system can affect the outcome of management practices in another area of crop management. In addition to plant and pest management, a grower must make decisions regarding structures, staffing, scheduling, markets, and depending on locality or size of operation, export restrictions and international treaties. Integrating all these aspects of crop management to obtain optimum yields and profitability is a difficult task. A description of how integrated pest management practices impact and are impacted by crop production systems and how best to integrate these disciplines will be provided.

IPM in field crops

Joe Funderburk
University of Florida, 155 Research Road, Quincy, FL 32351, USA, jefunderburk@mail.ifas.ufl.edu

Four species of thrips are common in northern Florida. Three are vectors of tomato spotted wilt virus. The population dynamics of individual species varies in different crops. Tomato is a poor reproductive host for each species. Pepper is a food and reproductive host for *Frankliniella occidentalis*, *Frankliniella tritici*, and *Frankliniella bispinosa*. Peanut is a food and reproductive host for *Frankliniella fusca*. This talk will present IPM programs for thrips and tomato spotted wilt in these crops. The IPM programs were developed from knowledge of the population dynamics of thrips and their role in the spread of tomato spotted wilt virus. The predator *Orius insidiosus* is an effective natural enemy in pepper resulting in suppression of thrips populations. Other tactics provide additional control including reduced-risk insecticides that conserve populations of the predator. An integration of UV reflective mulch, reduced-risk insecticides, and an acquired systemic resistance inducer provide control of thrips in tomato, and they reduce primary and secondary spread of tomato spotted wilt virus. A natural enemy *Thripinema fuscum* suppresses populations of *Frankliniella fusca* in peanuts and it is effective in preventing cycles of secondary spread. This natural enemy is compatible with the use of cultural and insecticidal tactics.

Disruptive factors hindering IPM implementation in protected cropping

S Goodwin, M Steiner
National Centre for Greenhouse Horticulture, NSW Agriculture, Locked Bag 26, GOSFORD NSW 2250, Australia, stephen.goodwin@agric.nsw.gov.au

In Europe and Canada, IPM in the protected cropping industry, particularly in greenhouse vegetable crops, has achieved success and is now regarded as standard practice. Despite this situation, IPM programs continue to evolve with the development of new biocontrol agents in established greenhouse regions and the introduction of IPM programs in developing greenhouse regions. Additional external factors have the potential to disrupt these efforts. Factors such as pesticide toxicity, lack of IPM-compatible chemicals, new invasive pest species, regulations for registration of biocontrol agents (national and global), export rules (zero tolerance), consumer perceptions/expectations and lack of education, and technology transfer are discussed.

Commercial-scale field trials of attractants for *Helicoverpa* moths based on plant volatiles

PC Gregg, AP Del Socorro, A Hawes
Australian Cotton CRC, School of Rural Science and Agriculture, University of New England, Armidale NSW 2351, Australia. pgregg@metz.une.edu.au

Plants emit volatile compounds that attract insects for foraging and oviposition. We have developed plant volatile-based attractants for *Helicoverpa* moths that can be used for attract-and-kill in cotton and other crops like corn and legumes. These formulations are mixed with an insecticide, methomyl, and sprayed on crops. Typically one row in every 72 is treated. In the 2002/03 season, two fields of cotton, approximately 40 ha each, were treated three times. The impact on treated and surrounding untreated fields was monitored by counting and dissecting dead moths to estimate the number of eggs which were not laid as a result of the treatment, and by regular scouting for a range of pest and beneficial insects. In the 2003/04 season, approximately 13,000 ha of cotton were treated under a product evaluation permit from the Australian Pesticides and Veterinary Medicines Authority. Results from both seasons indicate that attract-and-kill for female *Helicoverpa* spp. using plant volatiles could make a significant contribution to IPM on an area-wide basis.

Efficiency of parasitoids from a behavioural perspective

H Gu, Q Wang, S Dorn
Institute of Plant Sciences/Applied Entomology, Swiss Federal Institute of Technology (ETH), Zurich, CH-8092, Switzerland, hainan.gu@ipw.agrl.ethz.ch

Whilst parasitoids benefit from host herbivore-induced plant volatiles, their behavioural response to these olfactory cues is variable. This variability can cause the inconsistent performance of parasitoids as natural antagonists, but it may also facilitate improvement of their efficiency in biological control through genetic manipulation. Using a model system consisting of cabbage plant *Brassica oleracea*, herbivorous insect *Pieris brassicae*, and parasitic wasp *Cotesia glomerata*, we address how genotypic differences in olfactory response influence host parasitism, and how genetic manipulation of the odour-guided behaviour can enhance the efficiency of parasitoids. Bidirectional selection resulted in two genetically diverged strains of *C. glomerata* in behavioural response to the host-induced plant volatile. Simulation experiments demonstrated that the capacity of both habitat colonization and parasitism significantly increased in the high olfactory response strain, as compared to the low olfactory response strain. Thus, the efficiency of parasitoids can be improved by genetic manipulation of relevant traits. A newly developed technique to mark parasitoids with a stable isotope makes it feasible to test this postulate in the field. The novelty of this technique allows the movement of parasitoids and the resultant parasitism to be tracked at a spatial scale.

New frontiers in habitat manipulation: a 'reductionist' versus 'biodiversity' schism?

GM Gurr
Faculty of Rural Management, The University of Sydney, PO Box 883, Orange, NSW 2800, Australia.
ggurr@orange.usyd.edu.au

This paper will explore an emerging tension between a 'reductionist-paradigm' and a 'biodiversity-paradigm'. In the former, pest management scientists typically apply quantitative criteria to the selection of habitat manipulation strategies. Examples from Australian work will illustrate the utility of this approach for the enhancement of parasitoids such as *Trissolcus basalis*, an important stinkbug natural enemy. 'Reductionist-paradigm' strategies offer scope for incorporation into high-input, arable crop production systems with low risk of adverse consequences and high likelihood of acceptance by farmers. The 'biodiversity-paradigm' for habitat manipulation is less concerned with the integration of carefully selected species into crop systems but focuses on the net benefit of the ecosystem services that are provided by species-rich communities such as weed strips or patches regenerated woodland. Such approaches to habitat manipulation may more risky in terms of pest management and less likely to be accepted by many types of farmer but potentially offer scope for a wider range of ecosystem services. Accordingly, they are increasingly promoted for reasons such as wildlife conservation and hydrology. Pest managers are developing an understanding of the benefits to them of farmland biodiversity, as will be illustrated by current Australian work on floristically diverse shelterbelts.

Feeding behavior of *Lygus hesperus* and *Lygus lineolaris* on whitefly life stages

JR Hagler and CG Jackson
USDA-ARS, 4135 E. Broadway Road, Phoenix, Arizona, USA, jhagler@wcrl.ars.usda.gov

Although omnivorous *Lygus* spp. feed on and cause economic damage to a wide variety of important crops, the degree of their predatory activity is unknown. A study was conducted to compare the degree of herbivory and carnivory between *Lygus hesperus* and *L. lineolaris*. The feeding behavior of the 3rd, 4th and 5th instar and adult *L. hesperus* and *L. lineolaris* was quantified in feeding arenas containing a surfeit of *Bemisia tabaci* eggs, nymphs and adults on a cotton leaf. *Lygus lineolaris* generally fed more frequently and for longer periods of time on the cotton leaf than *L. hesperus*. Both *Lygus* spp. exhibited similar patterns of prey choice with a preference for whitefly nymphs > adults > eggs. *Lygus hesperus* consistently consumed more of each whitefly lifestage than *L. lineolaris*. Moreover, the amount of time spent feeding on whitefly nymphs was significantly less for *L. hesperus* than for *L. lineolaris*. The data obtained from this study suggest that *L. hesperus* is a slightly better adapted predator than *L. lineoloris*.

Evaluation of mating disruption for the control of the jasmine moth, *Palpita unionalis* (Lepidoptera: Pyralidae) in Egypt

EM Hegazi, BE Mazomenos, P Milonas, WE Khafagi, A Zitoun, S Showel, L Abo-Abdalla, A El-Shazly, A El-Minshawy M Hafez, S El-Kemny, N Khamis
Faculty of Agriculture, Alexandria University, Alexandria, Egypt. eshegazi@hotmail.com

In olive groves the jasmine moth, *Palpita unionalis* (Hübner), maintain low to moderate population densities, however periodically outbreaks occur causing severe damage to olive trees. Control measures are based on conventional pesticides. The use of pesticides has caused serious problems: environmental pollution, development of insecticide resistance. This has caused concern and has led to a concerted effort for the development of Integrated Pest Management (IPM) systems. Mating disruption with synthetic sex pheromones is a promising method to be used in IPM. The effect of mating disruption on the population of *P. unionalis* was evaluated for two successive years of 2002 & 2003 in Egypt A formulation of the two female pheromone components, E11-hexadecenyl acetate and E11-hexadecenal (E11-16:AC/E11-16:Ald), at a ratio of 7:3 in Montmorillonite K-10 was prepared. Measurements of the pheromone release rate indicated high emission of E11-16:Ald, 80% percent of the aldehyde was released within two weeks following installation. The emission rate of E11-16:AC was lower, more than 50% of the initial dose used was present 6 weeks after exposure to the field. Results of large-scale field trials in a highly infested olive grove near Cairo/Egypt revealed male disorientation around 90-95%. Female egg laying and tree infestation levels were reduced on the treated site in comparison to the control.

Mass trapping of the olive moths

EM Hegazi, WE Khafagi
Faculty of Agriculture, Alexandria University, Alexandria, Egypt, eshegazi@hotmail.com

A simple and inexpensive UV-trap was developed by the first author from materials generally available around the olive farm, to capture the main lepidopterous pests of olive trees. The trap consisted of a sticky-collecting device, two ultraviolet fluorescent tubes and tilted mirrors to increase light intensity by interference of reflected rays and spreading light reflection over a wider area. The trap was compared with delta-traps (baited with (Z)-Z-tetradecenol) and funnel traps (baited with (E)-11-hexadecenol and (E)-11-hexadecenyl-acetate) for monitoring the olive moth, *Prays oleae* and jasmine moth, *Palpita unionalis*, respectively. Sex pheromone catches (only males) were persistently lower in all collections of 2 successive olive seasons of 2002 & 2003 than those of UV-traps. *P. oleae* catches (males & females) in the UV-trap significantly ($P<0.01$) exceeded *P. unionalis* moths. The obtained results indicated that the UV-trap may represent an effective tool for mass-trapping of *P. oleae* and monitoring tool for *P. unionalis* and other species of moths in the area. The trap was so effective in trapping *P. oleae* even when adult population was low compared with sex pheromone trap. Some of non-target species may be protected from damage by placing a screen of proper sized mesh over the entrance of the trap. The UV-trap saved the fruit yield of a large olive farm without using any insecticides throughout the study period.

Classification of the Miridae (Hemiptera: Heteroptera): current status and need for future study

TJ Henry
Systematic Entomology Laboratory, Agricultural Research Service, United States Department of Agriculture, c/o National Museum of Natural History, Smithsonian Institution, Washington, DC, USA, thenry@sel.barc.usda.gov

The Miridae represent the largest family of Heteroptera, with more than 10,000 species. Despite their importance and the availability of a world catalog, the classification of this diverse family is far from stable. Currently, eight subfamilies are recognized: Bryocorinae, Cylapinae, Deraeocorinae, Isometopinae, Mirinae, Orthotylinae, Phylinae, and Psallopinae. The relationships among them, however, are uncertain and at least one of the larger subfamilies probably is not monophyletic. Phylogenetic relationships of the subfamilies and their tribes based on morphological attributes and trophic habits are discussed, and recommendations for further study are offered.

Adult development and behavior of Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann) (Diptera: Tephritidae) recorded using digital photography at different constant temperatures.

JM Heunis, KL Pringle
Department of Entomology and Nematology, University of Stellenbosch, Private Bag X1, Matieland, 7602, South Africa; jmhe@sun.ac.za

The development and behavior of adult Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann) were examined using digital photography taken in growth chambers maintained at constant temperatures of 18, 22, 24, 26, 28, 30, 32 and 34 ±1°C. Fly maturity (days until calling, mating and ovipositing) was slightly shorter at higher temperatures (24 - 34°C) than at 22°C. However, the time to maturity was more than twice as long at 18°C than at 22°C. Calling by male flies occurred during the morning and early afternoon. Males stopped calling before 13h00 at temperatures below 24°C but the calling period was extended until after 14h00 as temperatures increased. These findings imply that temperatures below about 18°C are unsuitable for mass releases of sterile flies in SIT programmes. The frequency of mating and ovipositing increased during early morning and decreased again from mid-afternoon at most temperatures. Feeding on both protein and sugar took place throughout the day. Fecundity was highest at temperatures between 22 and 30°C. The number of days until 50% of the total number of eggs laid decreased from 34 days at 18°C to 8 days at 34°C. The minimum threshold temperature for oviposition was estimated at 12.22°C.

Biological control of pest thrips in perennial tree crops

MS Hoddle

Department of Entomology, University of California, Riverside, CA 92521, U.S.A. mark.hoddle@ucr.edu

Pest thrips attack a variety of economically important tree crops in tropical, subtropical, and temperate climes. Typically thrips pest populations build rapidly, and larval and adult feeding damage to immature leaves and fruit and can be very serious resulting in significant economic losses. Many attempts have been to control exotic and native thrips pests with natural enemies. Control programs have included classical biological control programs against exotic thrips neoclassical programs against native pest thrips, and augmentative or inundative programs against native and exotic pest thrips with mass-reared natural enemies. To date there have been no successful or economically feasible control programs for thrips pests of outdoor tree crops. This presentation will examine the question "Why?" this lack of control is so consistent and prevalent. The avocado thrips, *Scirtothrips perseae*, avocado, *Franklinothrips orizabensis*, *Chrysoperla carnea* system in California will be critically examined to determine why biological control of this pest has consistently failed.

Attract and kill strategy to control *Carpophilus* spp. (Coleoptera: Nitidulidae): where are we now?

MS Hossain, RJ Bartelt, DG Williams

Primary Industries Research Victoria, Department of Primary Industries – Tatura Centre, Private Bag 1, Tatura 3616, Victoria, Australia. mofakhar.hossain@dpi.vic.gov.au.

We previously demonstrated that aggregation pheromone and co-attractant (fruit and fermented fruit juice) had considerable promise to control *Carpophilus* spp. by using attract and kill techniques. The trapping system used from 1999 to 2002 was messy and time consuming. To make the system more practical we identified the active components of the co-attractant and produced a synthetic version. Chemical analysis was conducted in the USDA – Peoria, IL laboratory and identified a series of aldehydes, alcohols and esters as potential attractant. We tested this with mainly *C. davidsoni* in the wind tunnel to understand how they respond to the smell from fresh and fermented fruit juice, and various blends of synthetic attractant. The best-performed blend of synthetic co-attractant was field tested to evaluate its performance. Synthetic co-attractant performed very well in the field and proved to be very species specific to *Carpophilus* spp. This facilitated easier and faster segregation and counting. Trapping efficacy usually depends on trap design as well as the chemical components (co-attractant). The results of an experiment to determine the best trap design to use for mass trapping of *Carpophilus* spp. will be discussed.

Understanding host-associated effects on oriental fruit moth, *Grapholita molesta* busck, biology: optimizing tree fruit IPM programs in the eastern united states.

L Hull, C Myers, G Krawczyk
Penn State University , P.O. Box 330, Biglerville, PA 17307-0330 USA, lah4@psu.edu

The Oriental fruit moth (OFM), *Grapholita molesta* Busck, has recently emerged as a major direct pest of apples in the eastern United States. OFM has traditionally been a pest of stone fruits, but since 1998, OFM infestations have resulted in over a thousand rejections of truckloads of apples from processing companies in the mid-Atlantic region. In order to better understand the reasons for these recent OFM outbreaks, a multi-faceted research program was conducted to explore the effects of host plants (apple and peach) on OFM survival, development, and behavior. Larval survival and development varied significantly between apple and peach. Additionally, host plants affected OFM oviposition behavior and possibly adult dispersal patterns between hosts in ways that could affect population dynamics at the orchard level. Also, degree-day based egg hatch models for both apple and peach were developed and validated based on daily egg hatch data collected in orchards. The results of our studies have allowed us to develop more host-specific models for OFM population dynamics and phenology and to tailor specific recommendations for OFM management on each host. This new information will allow growers to more effectively implement control tactics for the management of this pest on both hosts.

Integrated pest management in macadamias – opportunities and challenges

RK Huwer, CDA Maddox
PO Box 72, Alstonville, NSW 2477, Australia, ruth.huwer@agric.nsw.gov.au

IPM is a new approach working towards control of major pests in macadamia orchards in Australia. The two key insect pest of major concern for macadamia growers are currently the macadamia nutborer (*Cryptophlebia ombrodelta*) and fruitspotting bugs (*Amblypelta* spp.). Due to the problematic sustainability of repeated pesticide use in orchards, a pest management strategy with minimal input of chemicals is required. The proposed IPM strategy includes biological control, improved monitoring and IPM compatible pesticides. A current challenge is the integration of an egg parasitoid for control of *C. ombrodelta* into an overall IPM program. Improvements on monitoring tools for better indications on activity of fruitspotting bugs (*Amblypelta* spp.) female and *Amblypelta* spp. are required in the future for a successful IPM program. New developed insecticides for major pests in the orchard are being screened for their impact on beneficials to determine their compatibility with IPM. To ensure the practicality and adoptability of a new IPM program, involvement of crop consultants and growers is essential. Once the current key pests are being managed, adaptation to new emerging pests will have to be considered in the future. IPM needs to be regarded as a continuously adjusting process.

Integrated management of aphid on chilli (*Capsicum Annuum* L.) in Malaysia

AB Idris, MN Mohamad Roff,
Faculty of Science & Technology, National University Malaysia, 43600 Bangi, Selangor, Malaysia.
idrisgh@ukm.my

Chilli (*Capsicum annuum* L.) cultivation is a viable venture in Malaysia provided that the major pests and diseases on chilli can be successfully managed. The aphid, *Aphis gossypii* Glover has been reported as one of the major insect pests of chilli in Malaysia because it is a vector for CMV and chilli CVMV diseases. Majority of growers resort to use insecticide to control it that led to resistance problem. In Malaysia, studies on effect of crop variety and diversity, plant densities, mixed and inter-cropping, optimum chilli density, crop rotation and monitoring and use of reflective much on population dynamic of *A. gossypii*, its predators and virus diseases incidence have been conducted for years. Results were convincing and many of these IPM approach have been put into practiced by the growers and that incidence of virus diseases have been reduced. Interestingly, with the implementation of IPM in chilli cultivation, the cost of production was 11.8% lower than before IPM; with an annual chilli production about 4 000 ha, savings in the cost of production over US$ 2 million annually. Additionally, 13% increase in yield in chilli with IPM was reported that worth of US $ 1 – 2.5 million.

Development of sustainable area-wide mating disruption IPM in Victorian orchards, Australia.

AL IL'Ichev
Primary Industries Research Victoria, Tatura, DPI, Victoria 3616, Australia. Alex.Il'Ichev@dpi.vic.gov.au

Mating disruption (MD) is a major tool of Integrated Pest Management (IPM) in Australian orchards. The successful use of MD to control oriental fruit moth (OFM) in Australian orchards started about 20 years ago and the approach was to treat with MD only individual orchard blocks and only known hosts. After that, some OFM damage at the edges of MD treated blocks stimulated the establishment of an area-wide MD approach. Such an area-wide MD program improved the protection of 40 contiguous orchards (1,100 ha) during two consecutive seasons in 1997-99. This program substantially reduced OFM numbers, prevented edge damage and helped many growers to reduce or eliminate insecticide sprays against OFM. Despite this success some growers did not continue MD applications after the project finished. OFM began to increase and this encouraged local growers to continue area-wide MD program as a self-sufficient community approach. They achieved re-establishment of MD across the whole region in 2002. To reduce the cost of the area-wide MD program, trials were conducted on the use of reduced rate of MD on pome fruit, barrier MD treatments, new MD products including sprayable microencapsulated and multi-species MD dispensers. Pheromone and semiochemical based IPM and selective area-wide MD programs are the key elements in development of sustainable strategies for multi-species pest control while protecting the environment by reducing pesticide pressure in orchards.

The importance of considering the impact of providing nectar sources on pests as well as natural enemies.

LE Jamieson, PS Stevens, G Burnip, DM Suckling
HortResearch, PO Box 92 169 Mt Albert, Auckland, New Zealand, ljamieson@hortresearch.co.nz

The provision of nectar sources in the form of flowering plants has the potential to increase the level of biological control in orchards. Laboratory experiments concluded that the provision of flowers of buttercup, dandelion or honey solution increased the net reproductive rate of the leafroller egg parasitoid *Trichogrammatoidea bactrae fumata* when compared to provision of clover or water. In addition, the provision of honey solution increased the longevity and fecundity of a larval parasitoid, *Trigonospila brevifacies,* attacking leafrollers. Although field trials in an apple orchard revealed that the provision of *Alyssum* resulted in an increase in sticky trap catches of the leafroller larval parasitoid *Dolichogenidea tasmanica*, no corresponding increase in leafroller parasitism on the crop could be detected. The benefits of nectar sources increasing the reproductive rate of a parasitoid would be negated if the reproductive rate of the pest also increased. Subsequent trials showed that although the provision of honey solution increased longevity of the adult leafroller *Ctenopseustis obliquana*, it did not increase the pest's fecundity. We highlight the importance of the provision of plants that provide benefits to natural enemies but do not confer any benefits to the pest. We also emphasis the need to make the link to the desired end result - a reduction in pest damage.

Environmental friendly methods for controlling *Oryctes rhinoceros* **(Coleoptera: Scarabaeidae) in oil palm**

NH Kamarudin, M Basri Wahid, R Moslim

Malaysian Palm Oil Board, Po Box 10720, 50420 Kuala Lumpur , Malaysia. norman@mpob.gov.my

The zero-burning replanting method is recommended for the oil palm industry in Malaysia. A slight drawback is that it provides an abundance of decomposing oil palm trunks which are very attractive for the breeding of rhinoceros beetles (Oryctes rhinoceros). To reduce this problem, monitoring and mass trapping should start a few months before replanting, in order to reduce the resident population and the immigration rate of the pest into the replanting area. The correct choice of replanting technique is very important. Underplanting is not recommended, as the standing dead trunks are most attractive to the beetles. The decomposing materials should be made less conducive for breeding, by spreading them in a single layer as mulch. In this manner, the decomposing material dries out quicker, rendering it unsuitable for breeding. Biological control agents in the form of Metarhizium wettable powder formulation have been developed for drenching in the trunk chips, giving effective control of the population up to eight months. A local virus strain which is most effective for O. rhinoceros can be released into the infested area by inoculation onto live adult beetles and re-releasing them. These biological control agents offer good alternatives to minimize use of chemicals.

Integrated pest management of western corn rootworm (*Diabrotica Virgifera Virgifera* Le Conte) in Bosnia And Herzegovina

Nedzad Karic
Zmaja od Bosne 8, BA-71000 Sarajevo, nkaric@bih.net.ba

Western Corn Rootworm(WCR) is noted for first time in Europe 1992 and in B&H 1997. We start intensive farmer's education about WCR at the same time when WCR is noted in B&H for first time. In the beginning we mostly did lectures and last year we organised Farmer Field School (FFS) on cornfields already infected by WCR. All our activities made until 2002 were good base for FAO Project Integrated Pest Management (IPM) of Western Corn Rootworm in Central and Eastern Europe. B&H are also part of this Project as well as Hungary, Serbia and Montenegro, Romania, Bulgaria, Croatia and Slovakia. Project started officially 2003. We worked with 4 farmers groups. We educated them about WCR and ways how protect corn fields without pesticide use. Farmers came ordinary on the monitoring field, checked it, noted weather and soil conditions, WCR and other pests showing, damages on corn caused by different pests and at the end farmers discussed about results, made conclusions and decided on next meeting. Results, which we got during one year, showed farmers great interest for FFS education model and for IPM of WCR. These facts are very important for us in B&H where WCR is noted 1997 but there are not damages on corn caused by this pest.

Utilizing native biodiversity to enhance biological control

DA Landis, AK Fiedler
Department of Entomology, 204 Center for Integrated Plant Systems, Michigan State University, East Lansing , Michigan, USA landisd@msu.edu

Habitat management to enhance natural enemy efficacy has emerged as a central component of conservation biological control research and implementation. A survey of the recent literature on habitat management reveals a surprising reliance on plants not native to the region of study. This reliance on non-natives may be influenced by several factors including; availability, low cost, ease of establishment, and research indicating prior success in other environments. However, there is little ecological rationale to suggest that plants native to the region of interest cannot provide similar benefits. In addition, native plants may have unique ecological, economic and cultural values that favor their use. As science and societies move towards large-scale implementation of landscape management plans, the use of native plants in habitat management schemes takes on added significance. We describe research aimed at identifying native plants to provide pollen and nectar resources to insect predators and parasitoids and the development of strategic partnerships to facilitate their incorporation into agricultural landscapes.

Assessing insect dispersal with stable isotope techniques as a basis for accurate IPM decisions

GA Langellotto, JA Rosenheim
Louis Calder Center, Biological Field Station, Fordham University, 53 Whippoorwill Road Box 887, Armonk, New York 10504. langellotto@fordham.edu.

"Whether an IPM program should be implemented on a local (e.g. individual field) or regional basis (e.g. through the cooperative effort of several farm managers) depends in large part on the dispersal capabilities and behaviour of a focal pest and its key natural enemies. Because there is a relationship between the nitrogen stable isotope signature of a consumer and its diet, it is possible to infer whether a population has developed locally versus regionally by assessing the correlation between the nitrogen isotope signal of a field versus the nitrogen isotope signal of an insect population collected within that field. However, this analysis is complicated by the fact that immigrants quickly diverge from the signature of their natal field once they arrive and begin to feed in a novel field. Working in California cotton, we circumvent this issue by analyzing the wings and bodies of adult insects separately. Because the wings of adult insects are relatively inert, metabolically, contemporary feeding does not change the nitrogen isotope signature of the wings and they thus reflect natal feeding. Stable isotope analysis revealed that the herbivorous pest, *Lygus hesperus* (Miridae), exhibited local dynamics, as did predatory lacewings (Chrysopidae). Predatory damselbugs (Nabidae) exhibited regional dynamics, while big-eyed bugs (Miridae) and assassin bugs (Reduviidae) exhibited a mix of regional and local dynamics. These data suggest that *Lygus hesperus* should be managed on a local basis (e.g. field by field) and that three of its four key predators had foraged extensively within cotton fields where they were collected.
"

Maternal spread of *Enterobacter agglomerans* and *Klebsiella pneumoniae* through populations of the Mediterranean fruit fly, *Ceratitis capitata* (Weidemann): another piece of the symbiotic puzzle

C Lauzon, S Potter, S McCombs, N. Niyazi, T Shelly
"California State University, Department of Biological Sciences, 25800 Carlos Bee Boulevard, Hayward, CA , 94542-3090, USA, clauzon@csuhayward.edu"

Enterobacter agglomerans and *Klebsiella pneumoniae* have been associated with fruit fly pests within four genera of Tephritidae. The associations include aspects of fruit fly nutritional, chemical, and behavioral ecology. The role these bacteria play in the life history of pest tephritids is not fully understood, however recent findings suggest that these bacteria are important in maintaining a healthy and functional gut. Probiotic diet formulations containing *E. agglomerans* and *K. pneumoniae* have been shown to improve the gut of irradiated male *C. capitata* and *A. ludens* used for SIT. In addition, sterile *C. capitata* have demonstrated improved mating efficiency after feeding on particular probiotic formulations. Reports of horizontal and now vertical transmission of *E. agglomerans* and *K. pneumoniae* strongly link these two bacteria to tephritid fitness.

Resource subsidies for enhancing the effectiveness of *Diadegma semiclausum* Helen, a parasitoid of the diamondback moth (*Plutella xylostella* (L.))

BI Lavandero, SD Wratten, GM Gurr, S Worner, R Didham.
National Centre for Advanced Bio-Protection Technologies, PO Box 84, Lincoln University, Canterbury, New Zealand. lavandbl@lincoln.ac.nz

When biodiversity is increased in agro-ecosystems, a range of benefits may follow. However, researching and selecting the most appropriate type of biodiversity is important. 'Resource subsidies' for predators and parasitoids can, for example, be valuable for the enhancement of natural enemy fitness, through aggregation on or near the added resource, changes in longevity, fecundity, parasitism rates and sex ratio and, ultimately and desirably, reduced pest populations. Many flower species have proven appropriate for this, with the ideal species depending on the agro-ecosystems. Selectivity of these can be achieved by using plant species that enhance a particular parasitoid's activity without enhancing the pest's fitness. The fact that many habitat manipulation studies have been done without considering possible positive effects on the pest population, and that plant selection has not often been rigorously tested, is an obvious limitation. In the current work, the effect of floral resource subsidies on the fitness of *D. semiclausum* and its host, the diamondback moth, was studied in the laboratory and field. Dispersal of the parasitoid from flower patches in the field was quantified, as was the parasitoid's effect on its host at a range of distances from the flower patches. The value of the appropriate selection of floral resource subsidies for pests' natural enemies and its relevance in IPM are discussed.

Successful IPM in protected cropping: cooperation between research and application

JC van Lenteren
Laboratory of Entomology, Wageningen University, PO Box 8031, 6700 EH Wageningen, The Netherlands, Joop.vanLenteren@wur.nl

Development of resistance shortly after pesticide use in greenhouses in the 1950s initiated research in Integrated Pest Management. The first natural enemies became available in the 1960s. A change from pure chemical control to very advanced IPM programmes could took place in the short time span of only 20 years, because of thorough basic and applied research, and intensive international collaboration. These IPM programmes were developed in close collaboration with all stakeholders, e.g. growers, biocontrol/IPM industry, extension service, plant breeders, entomologists, phytopathologists, micrometeorologists, simulation modelers and agronomists. The change to IPM was not based on idealism (cleaner or healthier environment), but was rooted on clear advantages for the grower. Nowadays, most if not all insect problems can be solved without use of insecticides in the main vegetable crops in northern Europe. Climate management, use of tolerant/resistant cultivars and recently biocontrol prevent/reduce disease problems. New activities in plant breeding aim at selecting plant cultivars that are able to attract natural enemies stronger after pest attack. Integrated management of pests and diseases without conventional chemical pesticides is a goal that will be realized in Europe within a decade (van Lenteren 2000 A greenhouse without pesticides. Crop Protection 19:375-384).

Key components involved in behaviorally based monitoring and management of flying and walking pests of tree fruit

TC Leskey
USDA-ARS, Appalachian Fruit Research Station, 2217 Wiltshire Road, Kearneysville WV 25430

Integrated pest management approaches are becoming more prevalent in tree fruit production systems. These strategies include behaviorally based monitoring and control methods which rely on manipulation of a specific behavior of an insect pest in order to protect a valued resource. Identification of specific stimuli which result particular behaviors are the focal point for development of these strategies. A stimulus must be one that can be presented to the insect pest in a specific, perceivable, reliable, and practical form. In general, key components of behaviorally based monitoring and control methods include: (1) olfactory stimuli; (2) visual stimuli; (3) an effective capture mechanism; and (4) a decisive deployment strategy. However, these components differ widely among pests and particularly among pests which move differently toward host fruit trees, i.e., by walking or by flying. Comparisons of tree fruit pests belonging to Tephritidae and Curculionidae families will be used to highlight these fundamental differences.

The parasitism rate of leafrollers is influenced by the regional, rather than local, distribution of resources in New Zealand apple orchards.

VA Bell, PJ Lester
Victoria University of Wellington, PO Box 600, Wellington, New Zealand, Phil.Lester@vuw.ac.nz

The availability of resources such as nectar or pollen can extend the longevity of parasitoids and increase the parasitism rate of prey populations. We provided the braconid parasitoid *Dolichogenidea tasmanica* with such resources in an attempt to increase the parasitism rate of the lightbrown apple moth larvae (*Epiphyas postvittana*) in apple orchards. Five replicated treatments of plots with different flowering plants were established within orchards. Parasitism rates of natural moth infestations and of those on sentinel plants were not significantly different from controls. However, parasitism rates were high, ranging between 51-94%. One hypothesis that may explain this result was that parasitoids freely dispersed between treatments within orchards. Further experiments examined how parasitism changes with distance from a large refuge population of parasitoids, and with a varying amount of local floral resources. Logistic regression analysis showed no significant effect of the availability of nectar, but a highly significant effect of distance from the refuge. Parasitism rates were on average 68% at 30m from the refuge, but declined linearly with distance to 21% at 300m. For this parasitoid-host relationship, effects of resources at the patch level appeared to be overwhelmed by a high regional dispersal ability of the parasitoid.

Management of oriental fruit moth with SPLAT-OFM A&K by ISCA technologies

R. Borges, L.E.J. Mafra, F.M. de Lame, J.R. Miller, L.J. Gut, C.A. Atterholt, T.P. Reed, R. Coler, A Mafra-Neto
ISCA Technologies, Inc. 2060 Chicago Ave Suite C2, Riverside CA 92507 USA, president@iscatech.com

SPLAT-OFM A&K (ISCA Technologies, Inc. Riverside CA, U.S.A.), a proprietary biodegradable emulsified semiochemical dispenser containing *Grapholita molesta* (OFM) sex pheromone and small amounts of insecticide, proved to be economical, adaptable, easy to apply, and highly effective in controlling high OFM populations densities in commercial apple orchards. A single application of SPLAT-OFM A&K promoted continued trap shutdown, substantially decreased numbers of immature OFM findings, and improved the quality of fruit at harvest. Check plots under traditional management relying on insecticide applications sustained large populations of OFM, as reflected by large numbers of males captured in monitoring pheromone traps and larval damage.

Management of codling moth with ISCA Protec-Cydia by ISCA technologies

LEJ Mafra, BH Mafra, JT Abreu, R Borges, R Coler, A Mafra-Neto

ISCA Technologies, Inc. 2060 Chicago Ave Suite C2, Riverside CA 92507 USA, president@iscatech.com

ISCA Protec-Cydia (ISCA Technologies, Inc. Riverside CA, U.S.A.) is a low cost, low density, mating disruption formulation designed to effectively combat the quarantined pest *Cydia pomonella*, the Codling moth, present at medium and low densities in urban settings in Brazil. The proprietary formulation ISCA Protec-Cydia, consists of two components, a killing board and a sex pheromone based lure, to attract and kill males of *C. pomonella*. ISCA Protec-Cydia was applied on host trees of the quarantined urban zones at densities that varied between 12 and 60 units per hectare. Population data from pheromone-baited monitoring traps installed in the more than 7000 hectares under the mating disruption program indicate that the formulation ISCA Protec-Cydia effectively suppressed urban *C. pomonella* populations every time it was applied in the field, independent of the density of units per area. ISCA Protec-Cydia is an efficacious, safe and economical form of control of *C. pomonella* populations in urban settings.

"Montor system, an automated data collection and management system to effective support pest management decision making. "

G Ngo, A Yap, V Tran, JT Abreu, R Borges, LEJ Mafra, T Carrillo, M Dunham, R Coler and A Mafra-Neto
ISCA Technologies, Inc. 2060 Chicago Ave Suite C2, Riverside CA 92507 USA, president@iscatech.com

"The Moritor System (www.moritor.com, ISCA Technologies, Inc.) incorporates the latest innovations in information technology and engineering to give growers timely and accurate information about pests in their fields to support rapid, collaborative, pest management decision making. With ISCA's Moritor System, field data is collected with handheld or automated devices, sent to an internet accessible centralized database, where they are parsed, stored and analysed to generate reports which identify alarm situations and predict pest population densities, thereby facilitating decision making and the deployment of pest control measures in the field. Developed in part with funding from the National Science Foundation and National Institute of Standards and Technology, the Moritor System enables targeted, environmentally friendly pest management practices - the right pesticides at the right quantity, at the exact location, at the right time - specifically tailored to the user's needs. We will discuss the effect of Moritor's nearly real time field information on the increasing of precision in decision making and how it can foster interdisciplinary collaboration to micromanage insect populations on order to achieve effective low impact pest control.
"

SPLAT-OFM MD by ISCA technologies promotes long term mating disruption of *Grapholita molesta*, the oriental fruit moth (OFM)

R Borges, LEJ Mafra, FM de Lame, JR Miller, LJ Gut, CA Atterholt, TP Reed, R Coler, A Mafra-Neto
ISCA Technologies, Inc. 2060 Chicago Ave Suite C2, Riverside CA 92507 USA, president@iscatech.com

Although pheromone mating disruption offers notable advantages such as human and environmental safety, this tactic for managing moth pests in tree fruit crops has sometimes proven less effective than desired, precluding its use even under the current regulatory climate of shrinking insecticide availability. SPLAT (ISCA Technologies, Inc. Riverside CA, U.S.A.) brings a new brilliant solution to the pheromone mating disruption field, opening new perspectives to the formulation of economical and environmentally friendly, yet effective pest control solutions. SPLAT-OFM MD, a proprietary biodegradable emulsified semiochemical dispenser containing *Grapholita molesta* (OFM), proved to be economical, adaptable, easy to apply, and highly effective in controlling OFM populations in commercial apple orchards. A single application of SPLAT-OFM promoted over four months of nearly complete trap shutdown, virtualy eliminated OFM larval findings, and substantially improved the quality of fruit at harvest in the treated orchards. SPLAT-OFM is a good candidate to substitute traditional insecticides for the protection of orchards in more sustainable fruit production enterprises.

SPLAT-PNC MD, a paint ball formulation by ISCA technologies promotes effective mating disruption of *Acrobasis nuxvorella* (Lepidoptera Pyralidae) the pecan nut casebearer (PNC)

T Carrillo, J Ellington, G Ngo, A Yap, V Tran, R Coler, A Mafra-Neto

ISCA Technologies, Inc. 2060 Chicago Ave Suite C2, Riverside CA 92507 USA, president@iscatech.com

"SPLAT-PNC MD (ISCA Technologies, Inc. Riverside CA, U.S.A.), a slow release matrix containing the sex pheromone of *Acrobasis nuxvorella*, the pecan nut casebearer (PNC) encapsulated in paint ball shells was applied to commercial pecan orchards to disrupt mating finding of this key pest. The use of CO_2-propelled paint ball guns to apply SPLAT-PNC MD allowed for the easy, fast and precise delivery of the mating disruption product to otherwise inaccessible points in the canopy of these often very tall pecan trees. Use of the Moritor Data Management System (www.moritor.com) allowed for fast field monitoring data collection and instantaneous automated internet reporting and distribution, thus allowing for efficient remote collaboration, project management and rapid, well-informed pest management decision making. The mating disruption treatment resulted in a substantial reduction in monitoring trap catch, and nearly eliminated PNC larval findings in the area, with no detectable damage to nuts at harvest. SPLAT-PNC MD is a prime candidate to replace the currently used chemical and biological insecticides in the management of PNC in commercial pecan orchards.
"

Mango flower thrips abundance and development and their impact on fruit set in the soconusco region of chiapas, Mexico

R Magallanes-Cedeño, R Johansen-Naime, LO Tejada-Molina, I Blanco-de la Cruz, MG Nieto-López
E. Marcelin Lotes 5 y 7, Magisterial. Tapachula, Chiapas. México, C.P. 30770. ricardomagallanes@doctor.com

The relationship between mango flower thrips and fruit set was assessed under three different environments in the Soconusco region of Chiapas, Mexico from November 1998 to May, 2000. Samples of mango panicles were taken weekly to identify as well as to assess abundance and development of thrips; number of thrips per date was transformed to thrips-days, an expression that involves both abundance and permanence of thrips on mango panicles. Fruit set was measured from the end of anthesis until harvest, and wild plants in orchards were sampled to determine presence of thrips. Mouthparts of immature thrips were observed by electron microscopy. Four *Frankliniella* species were found on both mango panicles (only while flowers were open) and wild plants; most of the thrips on mango panicles were immature individuals. No correlation was found between thrips-days and fruit set, therefore it was assumed that thrips do not influence yield. A round structure was observed at the tip of the mouthparts in immature thrips, which suggests they mostly feed on nectar. Because thrips were present on wild plants all year round, it was assumed that mango panicles function as a secondary host, providing a source of nectar and assuring survival of young individuals.

Control of pest thrips on economic importance crops and influence of wild plants for infesting and preserving natural enemies.

R Marullo
Dipartimento di Agrochimica ed Agrobiologia, Università degli Studi Mediterranea di Reggio Calabria, Piazza S. Francesco di Sales n.4 I-89061 Gallina (Reggio Calabria), Italy E-Mail: rmarullo@unirc.it

Polyannual field trials and surveys have been carried on two economic importance crops, peach (in open field) and strawberry (as protected crop in tunnels), in two Southern Italian Regions (Basilicata and Calabria) to draft protocols of integrated control strategies for pest thrips. Three species of thripids have been studied: *Frankliniella occidentalis*, the most harmful on both crops, *Thrips meridionalis* and *Thrips major* only for peach orchards. Here, data referred to chemical action thresholds and the influence of wild host plants on infesting crops are reported and discussed. On peach, the relationships between the presence of larvae and adults of thrips in flowers and symptoms on fruits provide a mean threshold at 5% of infested flowers (1/2 thrips per flower corresponding to 25-30% of damaged fruits). Wild plants contribute to increase slightly the thrips populations on flowers and little fruits in spring but constitute important hosts of natural enemies (predators). On strawberry, 3-5 larvae or adults of WFT per flower can be considered as threshold value. Infestations of wild plants by thrips contribute to increase the WFT populations and do not provide any support for preserving natural enemies.

Lettuce IPM in Australia

S McDougall, J Mo, A Creek
YAI PMB, Yanco, NSW, 2703, Australia, Sandra.McDougall@agric.nsw.gov.au

Integrated Pest Management is an approach that encourages continual improvement in pest management techniques. Although the concept has been in circulation for half a century, strong IPM systems have been developed in few vegetable commodities in Australia. This paper will discuss the approach taken in the past five years to develop lettuce IPM in Australia, with a primarily focus on management of insect pests. The range of tools and techniques will be discussed for the development of the IPM strategy and for adoption. Regional variation in approaches and uptake will be discussed. When the project begun the key pest in lettuce in Australia and the primary motivation for the project was *Helicoverpa armigera* but the introduction and spread of *Frankinella occidentalis* and *Bemisia tobcci* Biotype B, and the potential threat of *Nasonovia ribis-nigri* have become important drivers for lettuce IPM.

Development and field evaluation of a pupal-color based genetic sexing strain of the melon fly, *Bactrocera cucurbitae*

D McInnis, R Mau, S Tam, R Lim, J Komatsu, L Leblanc, D Muromoto, R Kurashima, C Albrecht
USDA/ARS/PBARC, 2727 Woodlawn Dr., Honolulu, HI, USA 96822 dmcinnis@pbarc.ars.usda.gov

The first genetic sexing system for the melon fly, *Bactrocera cucurbitae* (Coquillett), based on pupal color was developed. This system permits the separation of males (wild-type brown pupae) from females (mutant white pupae). Egg hatch averaged 42% for flies 2-5 weeks old, with higher rates (ca. 50%) for younger flies. Adult emergence rate was normal, averaging ca. 92%. Adult egg fecundity and fertility (both sexes) were very low (< 1% of normal) after irradiation at 100 Gy 1, 2, or 3 days before emergence. Adult flight ability from standard 20-cm tubes averaged ca. 65%. Irradiated females landed on, and oviposited into, zucchini fruit significantly less than non-irradiated females. Field cage survival tests indicated that the new strain survived as well (over 80%) as wild males over a 7-da period when provided with food and water. Mating tests indicated that males-only sterile flies mated significantly better than sterile males from bisexual (male and female) sterile populations. Males fed only sugar failed to mate at all with wild females, while males fed a low protein diet (6:1 sugar:protein), or fed the standard 3:1 diet, mated as well as wild males. Results of several successful SIT field evaluations in Hawaii in which induced egg sterility was monitored along with fly populations in traps, will be presented and discussed.

Options for managing thrips and tomato spotted wilt on flue-cured tobacco

RM McPherson
University of Georgia, Department of Entomology, Coastal Plain Experiment Station, P.O. Box 748, Tifton, GA 31793-0748, USA, pherson@tifton.uga.edu

Several thrips management options were examined in replicated field trials to assess their impacts on the incidence of tomato spotted wilt virus (TSWV) symptomatic plants in flue-cured tobacco. Transplanting date influenced the incidence of TSWV, with a higher rate of infection in the earliest transplanted tobacco in most years. The insecticide Admire 2F and the plant activator Actigard 50WG applied as tray drench treatments to greenhouse produced transplants both reduced the incidence of TSWV. The combination of these two materials was more effective than either product alone. Foliar Actigard and Acephate treatments (at transplanting plus 3 or 4 applications soon after transplant) also reduced TSWV incidence. Thus, management options are available to suppress TSWV losses in flue-cured tobacco. Transplanting date (planting 2-3 weeks after the first tobacco is transplanted) plus tray drench treatments of selected materials are most effective in reducing TSWV; however, some early-season foliar sprays also can be effective in suppressing TSWV.

Evaluation of mating disruption in reducing the infestation of light brown apple moth, *Epiphyas postvittana* (Lepidoptera: Tortricidae), in citrus

J Mo
Yanco Agricultural Institute, PMB Yanco, NSW 2703, jianhua.mo@agric.nsw.gov.au

Light brown apple moth (LBAM), *Epiphyas postvittana* (Lepidoptera: Tortricidae), is a pest of economic importance of many fruit crops including apple, grape, and citrus in Australia. In citrus LBAM causes fruit drop and scarring and affects orange export to the US. Mating disruption is a proven technique in LBAM management in apple and grape. To assess the effectiveness of the technique in citrus, two field trials have been conducted during 2001-2003 in a 4-ha block of mixed Navel/Valencia oranges on an organic citrus farm in the Riverina, New South Wales, using the commercial mating disruption dispenser ISOMATE LBAM PLUS. A third repeat of the trial is in progress and will be finished by June 2004. In addition, mating disruption demonstration trials are being conducted concurrently on six citrus farms in the Riverina. Trials conducted at the organic site were monitored intensively with pheromone traps, sentinel females and infestation surveys. The results showed that, at the application rate of 364-728/ha, the mating disruption dispensers reduced pheromone trapping to almost undetectable levels for 4-6 months in the treated area. During this period, most sentinel females in the treated area failed to mate. More importantly, infestation by LBAM in the treated area was reduced by at least 50%. Similar results have been obtained from the demonstration trials.

Origins and recognition of pest thrips

LA Mound
CSIRO Entomology, GPO Box 1700, Canberra, Australia laurence.mound@csiro.au

Pest control strategies presuppose that a particular pest can be recognised, and thus its migration into and population dynamics within a crop can be monitored. Bio-control strategies presuppose that the systematic relationships of a pest are clear, such that natural enemies of related species can be sought. With pest thrips these suppositions are often not valid. Many workers have difficulties in recognising thrips species, particularly when two or more are associated with a crop. Evaluating the contribution of different plant species to the maintenance of thrips populations is thus difficult. In a multi-species thrips assemblage host associations may differ between thrips species, also between years and seasons. Distinguishing between within-crop breeding and thrips immigration from outside a crop adds is another problem. Biological control programmes must consider, in addition to the population dynamics of these vagile pests, the multi-trophic problems involved between tospoviruses, plants, thrips and natural enemies. This talk will examine how our inadequate information on variation in biology and behaviour within and between species impacts on control systems, particularly those based on biological methods, and introduce a new recognition system for pest thrips species, based on a simple molecular method.

Sustainable integrated system for pecan and beef cattle and their effects on arthropod populations in flood-prone and non-flooded areas

PG Mulder, BD McCraw, KS Seuhs, A Sheridan
Department of Entomology and Plant Pathology, Oklahoma State University, 127 Noble Research Center, Stillwater, Oklahoma, USA, philmul@okstate.edu

A three year study conducted in Oklahoma, USA assessed the effect of grazing legume or native companion crops on native pecan orchard floors in flood-prone and non-flooded areas of the state. Emphasis was on total system management of pecan, livestock and forage. The presence of legumes increased pecan and beef cattle gains; however, non-flood areas produced more pecan and more beef than flood-prone environments. During flood events, aphid populations were greater and beneficial organisms slightly lower in areas with native grasses compared to sites with legumes. Pecan weevil populations were higher in non-flood areas than in the flood plane. Numbers of weevils recovered in locations grazed by cattle were greater then in ungrazed sites. Adult populations of pecan nut casebearer were similar in flooded and non-flooded areas; however, these same populations were greater in grazed versus ungrazed sites. No differences were observed on larval populations of pecan nut casebearer across any treatments. The affects of companion crops on forage production and beef gain resulted in no supplemental nitrogen needs, particularly in flood-prone areas. Grazing, however, reduced nitrogen content for pecan production by 6-8%. These studies reinforce the benefits gained from growing a legume-based companion crop in pecan orchard systems.

Vain hopes and last resorts in field and forest pest suppression

TD Paine
Department of Entomology, University of California, Riverside, California 92521. USA.
timothy.paine@ucr.edu

It is tempting to look back at the techniques that have been implemented for the suppression of pests of field crops and forest systems and wonder what practitioners were thinking about. Ancient approaches relied on superstitions and divine intervention. Approaches that rely on trapping, herding, burning, barriers, or nasty combinations of highly toxic materials have been used, rejected, and resurrected. Some of these ideas worked when there were no other alternatives. Others never worked at all, but memories are short and wishful thinking or desperation can be powerful forces when the sales pitch is promising. More recently, in part because of dissatisfaction with mixed results or negative impacts of high technology, there has been a return to the spiritual approach to pest suppression and we are left wondering how far we have really come.

IPM program development: role of the stakeholders

MP Parrella and GH Whitfield
"Department Of Entomology, One Shields Ave., University Of California, Davis, USA, mpparrella@ucdavis.edu"

The development and implementation of IPM programs in protected cropping is complex with a multiple of factors involved. It is no longer acceptable to operate in a vacuum, where research/extension personnel focus only on the management of one pest (e.g., western flower thrips). In addition, for an IPM program to have broad applicability across the various regions where a crop is grown, it should be evaluated in those regions. This suggests broad and comprehensive participation by growers in the validation and adoption of IPM programs. A new model for IPM development and implementation has been evolving over the past few years and focuses on the formation of teams of individuals who bring their own expertise to bear on the diversity that is IPM. In Canada for example, the Federal Government has recently organized their IPM research under a new national program team and provided new funding for development of reduced-risk pest control technologies and strategies. This has allowed for better partnering with the sector and linkage to other government and non-government organizations. IPM has also been identified as a Best Management Practice under the new National Environmental Farm Plan initiative, which is expected to increase support and adoption of IPM by producers.

Can Thrips be controlled with insecticides?

M Parrella
Department Of Entomology,One Shields Ave., University Of California, Davis, Usa,
mpparrella@ucdavis.edu

Thrips continue to be major pests of numerous ornamental crops in the greenhouse and landscape as well as horticultural crops grown in the field. The impact of thrips has been exacerbated by 1) continued transmission of the tospoviruses by many species, and 2) increasing concern over the movement of 'new' pest thrips species around the world. The utility of traditional insecticides to effect thrips control in both the greenhouse and field will be reviewed. The development of insecticide resistance, compatibility of pesticides with IPM programs, and the influence of insecticides on virus control/spread will be discussed. With the world-wide amalgamation of agrochemical companies, registration of new pesticides has slowed dramatically. However, there has been renewed interest in the development/registration of 'biorational' products including pathogens and botanicals for thrips control and repellency. A roundup of these latest products, in addition to an objective evaluation of their potential for thrips control, will be presented. Finally, the potential role of utilizing materials that 'induce' plant resistance for control of thrips' damage and virus transmission will be discussed.

Management of cotton pink bollworm by mating disruption using Pb Rope®L

BV Patil, M Bheemanna, V Anand Kumar, SG Hanchinal, T Kobayashi
Regional Agricultural Research Station and College of Agriculture, Raichur-584 101, Karnataka, India, bvp2001@rediffmail.com

IPM through mating disruption using sex pheromones offers a practical and ideal approach to combat cotton Pink bollworm, *Pectnophora gossypiella* (Saunders). Large scale field trials were conducted in India during 2001-02 and 2002-03 at farmers level to evaluate the suitability and efficacy of Pb RopeL (sex pheromone formulation of Pink bollworm manufactured by Shin-Etsu Chemical Co. Ltd., Japan). Single application at pinsquare stage of the cotton crop with 200 and 300 dispensers/ha of Pb-RopeL were compared with control plot . Pink bollworm moth catches, average rosette flowers (2-4%), Pink bollworm damage (10-13%), bad opened bolls (7-9%) were significantly less in Pb RopeL treated plots compared to those in the control plot. Seed cotton yield was higher in Pb RopeL treated plots (21 qt/ha) as compared to control plot (18 qt/ha). Pb RopeL plots recorded 35-40% higher net profit compared to control plot. Based on two season study, it can be concluded that Pb RopeL at 200 dispensers/ha applied once during pinsquare stage effectively checks Pink bollworm damage and increases quality seed cotton with higher net profit.

Integrated pest management in mango orchards using the green ant, *Oecophylla smaragdina*, (Hymenoptera: Formicidae) as a key element in the Northern Territory of Australia

R Peng, K Christian

School of Science, Charles Darwin University, Darwin NT 0909, Australia, renkang.peng@cdu.edu.au

Mango is one of the most important commercial crops in northern Australia. Growers currently rely on toxic insecticides to control the insect pests, resulting in environmental and social problems. To reduce farmers' dependency on insecticides, a suitable IPM program is needed. Previous work showed that green ants can efficiently control the major mango insect pests, but they protect soft scales, damage fruits by their formic acid and disturb people picking fruits. Further research addressing these constraints showed that soft chemicals can reduce soft scale numbers without devastating green ants, the ant colony isolation reduces fruit damage by formic acid and water spray reduces the ant activity when picking fruit. A field experiment with two treatments (green ants plus soft chemicals (GS) and chemical insecticides (CI), each having three replicates) was conducted from 2001 to 2003 at Howard Springs in the Northern Territory. In two out of the three years, fruit quality was 20% higher in GS than in CI. Number of fruits or management costs /tree were statistically similar between GS and CI. During harvest, farmers had only minor problems with ant disturbance. An IPM model using green ants as a key element is discussed against 'organic' production.

Why and how to use weaver ants, *Oecophylla smaragdina*, (Hymenoptera: Formicidae) as a major component to manage insect pests in mango orchards in Northern Australia

R Peng, K Christian
School of Science, Charles Darwin University, Darwin NT 0909, Australia, *renkang.peng@cdu.edu.au*

Mangoes are an important smallholder and commercial crop in Southeast Asia and northern Australia. To achieve high yield and quality, growers rely on regular use of insecticides to control the major insect pests, resulting in economical, environmental and social problems. Therefore, a better control program is needed. Weaver ants are known to control over 40 species of insect pests on many tropical tree crops, but they are not being used to combat mango insect pests, although they naturally occur abundantly in mango orchards. To determine whether these ants can be used as a major component of an IPM program in mango orchards, we have studied them in Australia, Vietnam and Thailand. Based on the results from field and laboratory experiments and long-term monitoring from 2001 to 2003 at six study sites in the Northern Territory, an IPM program of using weaver ants together with the use of soft chemicals and farming strategies has been established. This poster, together with a video display, will demonstrate which mango insect pest can or cannot be controlled by weaver ants, how to use the IPM program with the potential of producing 'organic' product, and how to stabilize weaver ant populations in mango orchards.

Habitat management for stemborer control in Africa: underpinning mechanisms and long term biotechnological opportunities

ZR Khan, A Hassanali, JA Pickett, LJ Wadhams
Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, United Kingdom; john.pickett@bbsrc.ac.uk

To understand the mechanism by which lepidopteran stemborers are controlled by a "push-pull" strategy in maize production, chemical signals (semiochemicals), released into the air by trap crops and repellent intercrops, were captured from the air above the plants using entrainment into a porous polymer and analysed by gas chromatography coupled to electrophysiological preparations from the antennae of the pests and natural enemies, followed by behavioural studies. Attractant semiochemicals were identified following chemical analytical studies from trap crops such as Napier grass, *Pennisetum purpureum*, Sudan grass, *Sorghum vulgare sudanensis*, and also maize, and confirmed as such by behavioural studies assessing oviposition preferences. For the repellent intercrop molasses grass, *Melinis minutiflora*, additional semiochemicals denoting unsuitability as a host were identified, including (*E*)-ocimene and (*E*)-4,8-dimethyl-1,3,7-nonatriene. It was further discovered that increased parasitism of stemborer larvae in maize, with *M. minutiflora* as the intercrop, was caused by the nonatriene also acting as a recruitment cue for parasitoids, e.g. *Cotesia sesamiae*. These analytical studies, and the identification of the "push" and "pull" semiochemicals, are providing an important means by which to maintain quality of planting material and seed during expansion of the programme to new sites in eastern and southern Africa.

Characterizing a farming system in the central mountain region of Puerto Rico: IPM compatible?

R Pluke, G Leibee
Urb. College Park, 1783 Calle Alcalá; SAN JUAN; 00921, Puerto Rico, rpluke@ufl.edu

Farming systems research assists the successful generation and implementation of new IPM technologies. To develop effective IPM strategies there needs to be an awareness of the agro-ecological, cultural and socio-economic reality found within the target farm systems. There also needs to be an understanding of the parameters (i.e., the resources needed, the potential outputs and the inherent limitations) of the relevant IPM techniques under consideration. One effective way of summarizing this disparate information is the use of linear programming models. A socioeconomic study was conducted in the mountainous central region of Puerto Rico and, using the data generated, a linear programming (LP) model was developed. The LP model combined this information and gave a fair representation of the farming system. Most of the farm activity occurs during the Christmas period, while the summer months are normally a time of low activity. Poor, unstable markets seemed to be the biggest constraint to this system. Insecticide use is limited in many of the crops, especially roots and tubers. Any introduced IPM technique would have to focus, primarily, on keeping labor costs down. Protecting cabbage by using an IPM technique that included *Trichogramma* releases was not considered feasible by the model.

IPM of *Tanymecus dilaticollis* on maise in Romania

C Popov, A Barbulescu, S Vasilescu, C Spiridon
915200 Fundulea-Calarasi, ICDA Fundulea, Romania, fundulea@ricic.ro

The maize, cultivated on three million ha in Romania, is one of the most important crop, and the crop technology involves complex protection measures vs. pests and pathogens. The greatest damages are produced by *Tanymecus dilaticollis* attack even from the emergence. In order to avoid the damages or total crop compromising, the adoption of a complex measures system based on seed treating is necessary, as follows:
for areas where the preceding crop was a winter spike cereal, vetch-oats mixture, bean, soybean, pea or
linseed, the chemical treatments are not indicated, because the density registers low values till 3 individuals/m^2;
if the preceding crop was maize, sunflower, sugar beet or sorghum, the maize seed treating is
recommended with the following ingredient: carbofuran (8,750 g.a.i/t seed), thiamethoxam (3,150 g.a.i/t), imidachloprid (4,800 g.a.i/t), bensultap (12,500 g.a.i/t).

- in the case in which, after plant emergence, there are favourable climatic conditions for pest appearance, the application of one correction treatment during vegetation is recommended on seed areas treated with: thiamethoxam (25,0 g.a.i/

Insect behavioural ecology and the efficacy of habitat manipulation

RPJ Potting, T Bukovinszky, JC van Lenteren
Wageningen University and Researchcenter, Laboratory of Entomology, PO Box 8031, 6700 EH, Wageningen, The Netherlands. Roel.Potting@wur.nl

Insect population responses to diversified agroecosystems are highly variable, depending on the species of herbivores, natural enemies and vegetation involved. There is an urgent need to develop a mechanistic framework to understand and predict the response of herbivores and natural enemies to spatial arrangements of vegetation in agricultural systems. In this paper we investigate the sources of variation in insect response to spatial arrangements of vegetation in agroecosystems by using a combination of experimentation (with cabbage-associated species) and modelling. We introduce an individual-based spatially explicit simulation framework as a tool to investigate and predict insect spatial dynamics in heterogeneous environments. The simulation framework has a strong emphasis on state-dependent behaviour, cognitive and sensory abilities and movement of insects. Simulation results show that it is important to have a good understanding of the behavioural ecology of the target pest before one can determine whether the addition of highly attractive or repellent plants in a particular layout and density is likely to have an important effect on population density and hence potential crop damage. The reported wide variation in population response of herbivores to diverse agroecosystems is replicated in this study using different simulation scenarios by varying the behavioural features of the herbivore and ecological characteristics of the agro-ecosystem.

Pheromone mating disruption for codling moth management in apple orchards in the Elgin area of the Western Cape Province of South Africa

KL Pringle
Department of Entomology & Nematology, University of Stellenbosch, Private Bag X1, Matieland, South Africa, 7602; klp@sun.ac.za

Pheromone based mating disruption is widely used in codling moth (*Cydia pomonella*) management programs in apple orchards in the Elgin area, South Africa. Geographical plotting was used to analyse the spatial distribution of codling moth and its damage in orchards under mating disruption. Factors such as slope, wind and open spaces reduce the effectiveness of mating disruption. In the Elgin apple growing area all these factors are present. In addition there are usually three and sometimes four generations a year. Therefore, mating disruption can not be used as a stand alone control measure. However, since the introduction of mating disruption there has been a marked reduction in the number of codling moths caught in pheromone traps and in the number of sprays used for the control of this pest, despite high levels of resistance to insecticides. Fruit damage is recorded mainly in the vicinity of open spaces in orchards (homes, water points, etc), known infestation sources such as infested orchards and bin stacks, at top of steep slopes, and along the south east margin of orchards, or the margin intercepting the prevailing winds.

Influence of mineral oil and botanical extracts on Asiatic citrus psyllid, *Diaphorina citri* Kuwayama (Hemiptera: Psyllidae) in China

DJ Rae, YJ Cen, O Nicetic
Centre for Horticulture and Plant Sciences, University of Western Sydney, Locked Bag 1797, Penrith South DC, NSW 1797, Australia. Email: d.rae@uws.edu.au

Diaphorina citri is the vector of the devastating citrus disease *huanglongbing*. Biorational approaches to *D. citri* management are required both in its current range and in the event of incursion into Australia. Increasing the concentration of oil from 0.25-1.25% v/v applied to *Murraya paniculata* flushes (0.9 mL/flush) infested with adult psyllids in small enclosures increased mortality ($r^2 = 0.489$), with significant control achieved from 0.75%. Doubling oil spray volume lowered the concentration required to significantly reduce survival. A single application of 1% v/v oil spray to mature *Murraya* shrubs with heavy *D. citri* infestations resulted in a significant decrease in adult number. However, the application of sprays did not reduce the total psyllid population, indicating that at deposits applied, oil acted as a repellent and psyllids moved from oil sprayed to water sprayed control trees. When oil (0.5% v/v) and botanical extracts (1% v/v) were applied to citrus seedlings in a screened enclosure and adult psyllids subsequently released, the number of eggs laid on oil sprayed seedlings was significantly lower than on the control. The addition of *Ipomoea cairica* and *Wedelia trilobata* extracts to oil did not improve oil performance but the extracts alone did not provide significant control.

The problem of termite infestation in oil palm plantations on peat in Peninsular Malaysia

F Rahim, AB Idris, AS Sajap, K Norman, G Singh
School of Environmental & Natural Resource Sciences, Faculty of Science & Technology, University Kebangsaan Malaysia, 43600 Bangi, Selangor and Biological Research Division, Malaysian Palm Oil Board, P.O. Box 10620, 50720 Kuala Lumpur, vert_ne@lycos.com

Conversion of marginal soils such as peat for large-scale oil palm plantations in Malaysia is to meet industrial demand. However, peat is favourable for termite colonisation, thus infestation is of concern. This ongoing study aims to find better understanding of the pest behaviour, towards effective IPM in oil palm plantations in Peninsular Malaysia. Transects sampling and census in peat areas had retrieved termite species from several genera. Monitoring by using rubber wood stakes has detected various termite activities within plots of 500m^2 where colonies characterisations were possible upon detection of their unique excavation pattern. Census on palm stands found some assemblages utilising palm, indicating *Coptotermes curvignathus* as the major pest. Attacks originated from timber debris with visible mechanism of mudwork encapsulation around trunk that reflects some tropism. Infestation period on a stand varied, but shorter in immature palms. Detection of forager movement by staining technique identified clusters of infestation within a plantation block to have originated from a single colony. Infestation in a field was found to have a tendency of spreading towards fixed cardinal angles. Without disturbance, a colony will gradually infest palms that intercept their foraging tunnels, but changes towards physical anomalies, treatments and antagonists within the fields.

The Management of the tea mosquito, *Helopeltis antonii* infesting cashew in Sri Lanka.

R Rajapakse
Department Of Agricultural Biology,University Of Ruhuna,Matara,Sri Lanka , rohanr@admin.ruh.ac.lk

Cashew (*Anacardium occidentale* L.) is a crop considerable economic importance to arid and semi arid regions of Sri Lanka.. *Helopeltis antonii* seems to be found in areas where cashew is growing under conditions optimum for cashew production including the localities where intensive cultivation and the best management practices are followed. Data on the fluctuations in population density of the pests, collected from sample trees at weekly intervals, showed that its build up commences from October onwards synchronizing with the emergence of new flushes after the cessation of monsoon rains. The pest population reaches its peak during the blossom period in January. Highly significant negative correlations were observed between meteorological factors like rainfall, relative humidity, and minimum temperature and the population abundance of the pest, and positive correlations between pest population (adults and immature stages) and percentage of infested shoots and panicles. Endosulphan 35Ec was quite effective in controlling first instar nymphs as an exposure of ¾ hr completely killed the nymphs, but when the interval was 24 hrs a complete kill was recorded after 1 ½ hrs. Therefore it was found that application of Endosulphan as a high volume spray at the time of emergence of new shoots, panicles and fruit set was effective in controlling *H. antonii.*

The management of major insect pests *Bactocera cucurbitaceae* and *Aulacaphora spp.* in cucurbits under 3 intensive systems: integrated chemical and organic agriculture in southern Sri Lanka.

R Rajapakse
Department Of Agricultural Biology,University Of Ruhuna,Matara,Sri Lanka , Rohanr@Admin.Ruh.Ac.Lk

Commercial vegetable production in Sri Lanka is intensive in forms of artificial inputs ex: high levels of fertilizer and pesticide use. However, in recent years there has been increasing emphasis on alternative methods ranging from low input systems to organic agriculture. The management of insect pests in commercial agriculture (Cucurbitaceae crops) was studied under 3 systems in Southern Sri Lanka: Integrated Pest Management, Organic and Chemical in Southern Sri Lanka in two cultivated seasons in 1998 and 1999. The use of neem-based products with predatory ants gave excellent control of fruit flies *Bactocera cucurbiteae* in organic agriculture system but it was not sufficiently active to manage *Aulacapora spp.* The effect of these 3 systems on management of the major insect pests is discussed. The incidence of major pests was significantly low in organic agriculture system in comparison to the other two systems used. The benefits and implications of the three systems on management of insect pests in commercial agriculture is discussed with emphasis on the management of insect pests in organic agriculture.

Non-target Hawaiian insects captured in Biolure® traps in native Ohea and Koa forests at different elevations.

HC Revis, RI Vargas
U.S. Pacific Basin Agricultural Research Center, P.O. Box 4459, Hilo, HI 96720, USA,
hrevis@pbarc.ars.usda.gov

Control of economically important fruit flies (Diptera: Tephritidae) has been a major obstacle to expansion of Hawaiian agriculture. Efforts for area wide suppression of pest tephritid fruit flies through integrated pest management techniques, including utilization of the Biolure® fruit fly traps, have been on going across the Hawaiian island since 2001. As this program expands from local farmers fields to homeowner's backyards, the potential attraction of non-targets has increased due to closer proximity to native forests. The attraction of non-target Hawaiian insects to Biolure® fruit fly traps was assessed in a disturbed native Ohea and Koa forest across different elevations.

Insect behaviour and Bt crops

TH Schuler, RPJ Potting, A Clark, GM Poppy, AMR Gatehouse, I Denholm
Division of Plant and Invertebrate Ecology, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, UK; tanja.schuler@bbsrc.ac.uk

Transgenic plants should not be used in isolation but as part of an IPM programme to reduce the risk of pest populations developing resistance to transgene products. Insect behaviour is a key factor to consider when integrating transgenic plants into IPM systems as it plays a crucial role in the effectiveness of natural enemies in controlling target and non-target pests in transgenic crops. Behaviour also affects which natural enemy species are likely to prosper and which may decline in abundance due to reduced host/prey availability. Resistance management strategies employed to delay the build-up of resistant pest populations not only require that the transgenic crop is highly effective in controlling the target pest but also that untransformed host plants (refuges) are planted in the vicinity to reduce the selection pressure and to allow mixing of susceptible with any surviving resistant pest genotypes. This paper will outline why behaviour of natural enemies is one of the key factors influencing if parasitoids and predators will have positive or negative effects on the evolution of pest resistance. Furthermore, results will be presented on whether mutations in pest insects that allow them to survive on transgenic plants affect their ability to escape natural enemy attack.

Fruit flies on the move: what we can learn from a landscape level perspective.

SE Senger, B Roitberg
P.O. Box 1508 Lillooet BC, Canada V0K 1V0, senger@uniserve.com

Understanding the movement of insects into and out of commercial orchards is a critical factor in developing successful IPM programs. However, studying the movement of orchard pests between patches of suitable hosts requires an examination of individual behavior at the landscape level which can be difficult to obtain. Using the western cherry fruit fly, Rhagoletis indifferens (Diptera: Tephritidae), as a test insect, we modify an existing landscape dispersal model to a larger spatial scale and investigate the movement of flies between patches of cherry trees. Model results are then compared to data collected from a case study in which the history of the fly population spread is known. By determining the maximum inter-tree distance that cherry flies are likely to move, and the landscape structures that encourage or discourage movement, we can improve the quality of IPM programs for this pest.

Commercialization of insect behaviour modifiers: two case studies.

SB Sexton

Biocontrol Ltd., 3 Acacia Crt, Mt Crosby 4306 Qld. Australia stephen@biocontrol.com.au

Mating disruption has become a central pillar of integrated pest management programs for oriental fruit moth and codling moth in Australia as it is in west coast USA, Italy and South Africa. Significant fundamental research into mating disruption of both oriental fruit moth and codling moth was conducted in Australia. Similarly, the pioneering commercial development of mating disruption for both oriental fruit moth and codling moth occurred in Australia. Development of mating disruption products to the point of widespread commercial acceptance has depended on a number of factors. These include: (1) accurate identification of the sex pheromone structure, (2) availability of affordable active ingredients, (3) effective and user friendly controlled release systems, (4) selection of suitable pest targets for disruption, (5) species present in the orchard pest complex and (6) receptive end users. Comparisons are made of the population dynamics and behaviour of oriental fruit moth and codling moth as it affects their suitability as targets for mating disruption. Data on release rates of several kinds of dispensers and a critique for methods for measurement of pheromone release is presented. Pressures driving the acceptance of mating disruption and data on commercial use of mating disruption in Australia, west coast USA, Italy and South Africa is presented.

Efficacy of mushroom casing and compost treatment against the sciarid *Bradysia tritici* (coq) (Diptera: Sciaridae)

A. Shamshad, A.D. Clift
J. R.A. McMillan Building, A05, Faculty of Agriculture, Food and Natural Resources, University of Sydney, NSW 2006, Australia

The sciarid fly, *Bradysia tritici* is a pest of cultivated mushrooms and besides having pest status these flies are also reported to be associated with the spread of fungal diseases. The present study investigated the efficacy of insecticides and fungicides applied as compost and casing treatments. The results are discussed in relation to the combined effect of insecticides and fungicides to reduce the yield loses that could likely be caused by the infestation of *Bradysia tritici.*

Reduced risk IPM of thrips on greenhouse crops

JL Shipp
Agriculture and Agri-Food Canada, Greenhouse and Processing Crops Research Centre, Harrow, Ontario, Canada N0R 1G0 shippl@agr.gc.ca

IPM of thrips on greenhouse crops (ie., vegetables and ornamentals) involves a multitude of approaches depending on the target pest, host crop, marketable product and the final targeted markets (domestic versus international). The ecology and population dynamics of thrips can vary considerably depending on the host crop, especially between ornamentals and vegetables. The complexity of plant structures and the abundance of pollen in ornamental crops often result in high pest reproductive capacity and difficulty in control measures actually contacting the different thrips stages. Some thrips species are the main vectors for plant pathogens, such as tospoviruses. In these situations, control strategies are usually either prophylactic (eg., screening) or fast acting (pesticides). Today, the emphasis in IPM of thrips on greenhouse crops is reduced risk control options. These options can be IPM-friendly pesticides, biological control agents, use of trap crops, cultural/sanitation practices, and physical exclusion/control. Monitoring programs and economic action thresholds are also becoming standard IPM practices.

Incorporating new/novel approaches into IPM in protected cropping

JL Shipp
Agriculture and Agri-Food Canada, Greenhouse and Processing Crops Research Centre, Harrow, Ontario, Canada N0R 1G0 shippl@agr.gc.ca

Pest control strategies for greenhouse IPM are a constantly evolving and dynamic approach. Due to crop production under a relatively closed system and usually very sophisticated production practices, an integrated management approach is often very successful. Initially, control strategies were based on inundative releases of a few parasitoid and predatory mite species. Now control measures include mating disruption, trap crops, entomopathogens (fungi, bacteria and viruses), nematodes, sterile insect technique, and banker plant systems. Pest management is viewed as a tritrophic system with close interrelationships among pest, control agents and the host plant. The role of biotechnology in pest management is often controversial. The potential use of biotechnology in protected crop IPM will be discussed.

Pests of woody components of arid Agri-Silvi-Horti-Pastoral Production Systems: some issues in Indian context

MP Singh, N Patel
Central Arid Zone Research Institute, Jodhpur 342 003, India. mpsingh@cazri.raj.nic.in

The production systems of the arid regions support large human and livestock populations in India. The arid agroecosystem has undergone major changes over last five decades, altering the pest spectrum of the production systems. The naturally occurring *Prosopis cineraria, Zizyphus* spp and *Tecomella undulata* have been the most common woody components of the arid production systems. Although these woody plants contribute immensely to the sustainability of the systems, there has been general ignorance about the injury inflicted by insect pests to them, the consideration for pest management being restricted to crop components alone. However, the dwindling density of some of the tree species has attracted attention of researchers and stakeholders. Insect pests and diseases have been attributed as major biotic factors responsible for the phenomenon. In recent years large-scale mortality of *Prosopis cineraria* has been witnessed in some pockets. Investigations implicated the injury of *Acanthophorus serraticornis* and related species for premature drying of trees in association with other factors. As *P. cineraria* serves as a virtual insurance for sustenance during the frequently occurring droughts in the arid regions, the losses have alerted the cultivators to protect this important resource. Wild jujube has gained increased importance in the wake of the technique of *in situ* budding of improved varieties of *Z. mauritiana* on the existing rootstock, transforming it into reasonably high value fruit crop. However, high incidence of pests on *Z. mauritiana* limits profitable cultivation. The wild jujube shares the common pests of the improved varieties, facilitating their survival and multiplication and hence the concern. Desert teak, *Tecomella undulata* is fast losing its population in the endemic areas with evidence of the contribution of the insect pests like *Stegmatophora* and *Patialus tecomella* interfering its development into tree. Restoration of the population of this species could be achieved only after addressing these problems. Against this backdrop there is an urgent need to consider developing packages to shield these valued resources from the menace of the pests and educate the ignorant peasant communities about the same. The article presents the status of the problem, its implications and the available solutions with possible future lines of action.

Both intraguild predation and alternative prey disrupt conservation biological control

WE Snyder, RP Prasad
Department of Entomology, Washington State University, Pullman, WA 99164-6382, USA,
wesnyder@wsu.edu

We have been examining the use of unplowed refuge strips to conserve predatory beetles and improve the biological control of root maggot (*Delia* spp.) flies on radish. The community of predatory beetles at our site includes several species of smaller carabid and staphylinid beetles (< 1 cm in length) that eat root maggot eggs, and one common larger carabid beetle (> 1.5 cm), *Pterostichus melanarius*, that eats smaller beetles but not fly eggs. We conducted a series of field experiments designed to address two questions: 1) does intraguild predation by *P. melanarius* disrupt conservation biological control, and 2) would schemes to selectively conserve smaller beetles be effective at improving fly egg control? In two initial experiments we found that densities of smaller beetles were lower, and densities of fly eggs were higher, in the presence of *P. melanarius*. However, attempts to improve fly egg biocontrol by selectively increasing densities of small beetles in the absence of *P. melanarius* were not consistently effective, because the suppression of fly eggs broke down if alternative prey (aphids) were present. Overall, these results suggest that both intraguild predation and the presence of alternative prey can disrupt conservation biocontrol in this system.

Arthropod pests of Australian olives

RN Spooner-Hart, FD Page, S Learmonth
Centre for Horticulture and Plant Sciences, University of Western Sydney, Locked Bag 1797, Penrith South DC, NSW, 1797, Australia, r.spooner-hart@uws.edu.au

With the rapid expansion of the Australian olive industry during the past decade, plantings have been established in many parts of Australia in both temperate and sub-tropical regions, and the majority of growers have little or no previous horticultural experience. A national project conducted over 2001-2004 aimed to identify the major olive arthropod pests in Australia through collection of field samples, a written grower survey and grower meetings, as well as monitoring of eight grove sites in five mainland states over a two year period. The project revealed that while Australia appears to be free from a number of cosmopolitan olive pests such as olive moth, *Prays oleae* and olive fly, *Bactrocera oleae* some species such as black scale, *Saissetia oleae* and olive bud mite, *Oxycenus maxwelli* are widely distributed. Australia also has several native pests of cultivated olive, including olive lace bug, *Froggattia olivinia* and Queensland fruit fly, *Bactrocera tryoni.* The paper will introduce the major Australian arthropod pests of olives, and will discuss options for their sustainable control.

Managing tomato russet mite, *Aculops lycopersici*, in greenhouse tomato crops

M Steiner, S Goodwin, T Wellham
Gosford Horticultural Institute, Locked Bag 26, Gosford, NSW, 2250, Australia,
marilyn.steiner@agric.nsw.gov.au

Tomato russet mite is a common pest of greenhouse tomato crops in Australia during the summer months. Effective strategies to deal with this pest within an IPM program are needed. Some novel approaches are being undertaken in the area of reduced risk pesticides and use of indigenous predators such as phytoseiids and cecidomyiids.

Typhlodromips montdorensis (Schicha) (Acari: Phytoseiidae) - an effective predator for use against thrips in greenhouse vegetable crops

M Steiner, S Goodwin, T Wellham

Gosford Horticultural Institute, Locked Bag 26, Gosford, NSW, 2250, Australia, marilyn.steiner@agric.nsw.gov.au

The Australian predatory mite *Typhlodromips montdorensis* (Schicha) has been trialled in several crops of cucumbers, capsicums and tomato crops over several seasons. It is particularly effective against western flower thrips, *Frankliniella occidentalis* (Pergande), but also controls onion thrips, *Thrips tabaci* Lindeman. Rates of introduction are very low compared with the most commonly used predatory mite, *Neoseiulus cucumeris* (Oudemans). Two or three introductions of 10 per square metre are generally sufficient. This species operates best in warm, humid conditions.

Exploitation of male sex pheromone response polymorphism in *Helicoverpa armigera* IPM

A Tamhankar, S Nerkar, TP Rajendran, T Surulivelu, P Jeyakumar, D Monga, O Bambawale
Nuclear Agric. and Biotech. Division, BARC, Mumbai, 400094, India. ashtam20@hotmail.com

"Evaluation of responsiveness of *Helicoverpa armigera* males to blends containing 0-100 % Z-9-hexadecenal in Z-11-hexadecenal at various locations in India revealed that blends in the range of 3-15 % are significantly more attractive to males and the significantly most attractive blend(s) within this range change(s) with location and host. A hypothesis was tested that if pheromone polymorphism exists in *H. armigera* then catches in an area having traps with the usual 3% blend alone, would be significantly less than that of an area with traps baited with many blends. When equal number of traps either baited with 3% blend alone or with blends ranging from 2-15 % were deployed separately in two parts of a 170 ha institutional cotton field, the average trap catch/month was 49.8 males- (area with 3% blend) and 341 males- (area with 2-15 % blends). In another experiment covering 8 villages, even under farmer's field conditions use of multiple blends resulted in doubling of moth catches in cotton compared to the 3 % blend. Importance of this in IPM was emphasized; when on a farmer's field (6 ha), multiple blends based mass trapping eliminated thousands of males, effecting reduction in insecticide sprays used for pest suppression.
"

Thrips semiochemcals: a promising approach for thrips pest management

DAJ Teulon, MM Davidson, NB Perry, DE James, VL Glennie
New Zealand Institute for Crop & Food Research Ltd, Private Bag 4704, Christchurch,

The behavioural responses of walking and flying adult thrips (Thysanoptera: Thripidae) to chemical odours were studied to assess new options for management of these insects. Target thrips included the New Zealand flower thrips (*Thrips obscuratus*), onion thrips (*Thrips tabaci*), and Western flower thrips (*Frankliniella occidentalis*). Simple field bioassays, a Y-tube olfactometer and a wind tunnel were used to investigate fundamental aspects of thrips host finding behaviour (e.g. attractant vs arrestant responses), the physiological state (e.g. satiated vs starved) of the thrips, as well as differences in responses between walking and flying thrips. The spatial efficacy of chemical attractants was determined in field trials. The behavioural responses of thrips to approximately 30 chemicals (not previously known as thrips attractants/repellants) were tested with promising results. The use of these chemicals for improved thrips monitoring and trapping and for use with "push-pull" strategies in pest management and biosecurity is discussed.

Curious, cautionary, and inexplicable natural products used in pest control

JT Trumble
Entomology, University of California, Riverside CA 92521, USA john.trumble@ucr.edu

Interest in natural products is growing rapidly. Sales of dietary supplements alone (not even including all herbal remedies) increased from 3.3 billion dollars (US) in 1990 to over 9 billion dollars in 2001. Approximately one-half of the population in the United States uses these products. Given the size of the market, and an increasing interest in all things natural, it is not surprising that commercial products are being developed for a wide range of human and animal uses, including pest control. However, natural products are not always safer than synthetic products. Just because a plant has been used for centuries does not mean it is safe or even desirable. Plants contain many toxins, some of which we can use for pest control purposes. However, some of these toxins can cause significant human or animal health effects, and many deaths have been reported. A great many, if not most, of the compounds in plants used in pest control have not been scientifically evaluated for effectiveness and safety. This presentation discusses a variety of natural products used in pest control ranging from curious to cautionary to incomprehensible.

The landscape context of biological control

T Tscharntke, MH Schmidt, C Thies
Agroecology, Georg-August University of Göttingen, Waldweg 26, D-37073 Goettingen, Germany, ttschar@gwdg.de

Biological control has primarily relied on local facilitation of natural enemy populations, but recent studies found strong effects of landscape structure on the dynamic interactions between pests and their natural enemies. Here, we focus on case studies in two important arable crops, oilseed rape and winter wheat, showing how predators and parasitoids of major pests were enhanced by a high percentage of noncrop habitats in the landscape. Due to higher parasitism by wasps, pollen-beetle damage in oilseed rape was reduced in complex landscapes. In a two-year comparison, expansion or decrease in the area planted with oilseed rape led to a dilution or concentration of both damage by rape pollen beetles and its parasitism by wasps, respectively. Furthermore, parasitoids and predators may experience the surrounding landscape at different spatial scales. Parasitoids of cereal aphids were influenced at rather small scales up to 1km around a study plot, while highly dispersive linyphiid spiders responded to landscape structure in 2-3km surrounding. It is a major challenge for the future to understand the coaction of landscape effects on both pests and their multiple enemies, and thereby to identify applicable measures for landscape management that enhance natural pest control.

Challenges and strategies for controlling thrips spread of tospoviruses

DE Ullman
Department of Entomology, University of California, One Shields Ave., Davis, CA 95616,
deullman@ucdavis.edu

Increasing diversity among viruses in the genus *Tospovirus* (family *Bunyaviridae*) and their complex relationships with an increasing number of thrips vector species presents a global challenge to producers of ornamentals and food crops. Tospovirus epidemics require successful interactions between the thrips vector, the host plant for the thrips, and the tospovirus. Thrips vectors are usually highly resistant to chemical controls and there are no antiviral treatments to cure plants once they are infected. Therefore, successful control strategies must be based on interrupting the essential biological interactions. Given the global production of propagation materials, and international movement of cuttings and potted plants, pest managers must stay informed about emergence of new tospoviruses and new thrips vector species. The success of management strategies for thrips and the tospoviruses they transmit will depend upon a proactive approach aimed at prevention and a good understanding of the complex relationships occurring between the viruses and the thrips. This presentation will introduce the diversity of tospoviruses, the range of thrips species serving as vectors and highlight those aspects of their interactions that can be used in planning management strategies.

Effects of 'resource subsidies' on longevity of *Microctonus hyperodae***, a parasitoid of** *Listronotus bonariensis* **adults**

HD Vattala, SD Wratten, CB Phillips
PO Box 84, Lincoln University, Canterbury, New Zealand, vattalad@lincoln.ac.nz

Prior to the 1991 introduction of a biological control agent, *Microctonus hyperodae* (Loan) (Hymenoptera: Braconidae, Euphorinae), damage to New Zealand pasture by the Argentine stem weevil, *Listronotus bonariensis* (Kuschel) (Coleoptera: Curculionidae) was estimated to cost NZ$78 – 251 million per year. Potential exists to enhance the effectiveness of *M. hyperodae*, particularly in early summer when parasitoid adults fail to achieve much of their reproductive potential because they emerge up to four weeks before their hosts. It has been proposed that parasitism rates would be significantly increased if the longevity of these early-emerging parasitoid adults could be extended until *L. bonariensis* adults became abundant. Previous laboratory work has shown that the provision of sugar solutions can increase the longevity of *M. hyperodae* adults from 5 to 17 days. In this contribution, the effects of seven flowering plants on *M. hyperodae* longevity were measured in the laboratory. *M. hyperodae* lived a mean of 20.5 ± 3.5 days with buckwheat (*Fagopyrum esculentum* Moench), which was significantly higher than all other treatments ($P<0.001$). Survival analysis using a Kaplan-Meir survival function and Cox's Proportional Hazard Model for buckwheat compared with water showed 200% and 250% increases in parasitoid minimum and maximum survival, respectively. Results are discussed in relation to flower architecture and nectar quality, and future work is discussed.

Potential of behavioral components in insect pest management

C Vincent, E Lucas
Horticultural Research and Development Centre, Agriculture and Agri-Food Canada, 430 Gouin Blvd., Saint-Jean-sur-Richelieu, Qc Canada J3B 3E6 e.mail: vincentch@agr.gc.ca

Abstract: In theory, Integrated Pest Management is the science and art of combining tactics into a strategy that will keep insect damage under economic thresholds. In practice, pesticides are, on a financial basis, the main tactics employed and this situation is unsustainable. Although deliberate use or manipulation of insect behavior is tactic that is seldom employed in IPM practice, recent advances in both science and technology should improve that situation in direct and indirect ways. The availability of new technologies, such as genetically modified cultivated plants, may directly effect changes in insect behavior of pests (and their natural enemies) such that the damage they would cause is under control. Indirect approaches concerns both pests and natural enemies. Knowledge of insect behavior per se and of the behavior of pests in relation to their nearby habitats can be used to achieve success in IPM programs. Transgenic natural enemies with improved fitness should be better adapted to perform in otherwise hostile agricultural environments. The future of IPM relies a blend of knowledge and technologies of which behavioral ecology plays a central role.

Ecology and feeding of the tarnished plant bug in vineyards

D Fleury, C Vincent, J Paré, Y Mauffette
Horticultural Research and Development Centre, Agriculture and Agri-Food Canada, 430 Gouin Blvd., Saint-Jean-sur-Richelieu, Qc Canada J3B 3E6 e.mail: vincentch@agr.gc.ca

Tarnished plant bug, *Lygus lineolaris* (P. de B.)(Hemiptera: Miridae), is a highly polyphagous insect of North America. Its presence in vineyards of Southern Quebec during all the growing season suggest that it may be a pest that warrant insecticide treatments. We first studied the migratory activities of adults with sticky traps deployed all around and in the center of a vineyard. Captures were recorded weekly. Secondly, to assess potential damage by tarnished plant bug during bloom, we videofilmed the feeding behavior of nymphs and adults on inflorescences. Localized feeding wounds were fixed and prepared for electronic and scanning microscopy. Histological studies concluded that during bloom time, feeding is restricted to the nectaries, which do not have functional relationship with ovaries. Thridly, cage studies done on part of plants covered with fine muslin revealed that tarnish plant bug decrease damage at stages 15 and 31 (Eichhorn-Lorenz phenological scale). Overall the impact of tarnished plant bug depends on the phenology of the plant.

Using HPLC to assess nutritional state, sugar sources consumed, and feeding history of field collected insects.

FL Wäckers, A Steppuhn
Netherlands Institute of Ecology (NIOO-KNAW), Center for Terrestrial Ecology, Boterhoeksestraat 48, 6666 GA Heteren, the Netherlands, f.waeckers@nioo.knaw.nl

Adult parasitoids depend on sugar-rich foods like nectar and honeydew to meet their energy requirements. The potential fitness benefits of sugar feeding for parasitoids have been established in numerous laboratory studies. Nevertheless, we know little about the nutritional ecology of parasitoids in the field, chiefly due to the limited specificity of methods applicable for field studies. Here we use HPLC sugar analysis to study the sugar profile of *Cotesia glomerata* and *Microplitis mediator* relative to feeding-treatment. We identify the overall sugar level and the ratio of glucose to fructose as two parameters that in combination unambiguously characterize an individual's nutritional state and feeding history. In addition to revealing past feeding events, HPLC analysis also identifies and quantifies a wide spectrum of sugars present in individual specimen. When food sources contain specific sugars, so-called 'signature sugars', this can provide additional information about the type of sugar source consumed. In our field study, we collected *Cotesia glomerata* and *Microplitis mediator* in a cabbage field with flowering herbs in the field margin, as well as in a control field bordered by grasses. HPLC analysis of the collected individuals revealed that >The sugar reserves of parasitoids collected in proximity of the flowering herbs exceeded the reserves of parasitoids collected in the control field. >80% of *C. glomerata* and 55% of *M. mediator* had consumed honeydew

Artificial food supplements for improved IPM: New results and a review of the evidence

MR Wade, MP Zalucki, SD Wratten, BCG Scholz, RJ Lloyd, BA Franzmann
National Centre for Advanced Bio-Protection Technologies, PO Box 84, Lincoln University, Canterbury, New Zealand. Email: markrwade@yahoo.com.au

Artificial food supplements are a habitat manipulation tactic used in integrated pest management (IPM) systems to increase predator and parasitoid abundance and rates of predation and parasitism. The efficacy of using a single late season application and nine season-long applications of the commercial artificial food supplement Amino-Feed UV in cotton was assessed in two field trials. Measurements were made of entomophagous and pest arthropod abundance, crop yield and fibre quality in both trials, and mortality rates of sentinel prey and fruit counts in the second trial. In both trials, none of the above parameters was significantly affected by Amino-Feed treatment. To place these results in context, a hierarchical approach was used to review 82 trials from 38 publications on artificial food supplements. The hierarchical levels most commonly examined were the abundance of entomophagous (n = 51 trials) and pest (n = 26) arthropods. Although the abundance of entomophagous arthropods increased in 34 trials and the abundance of pest arthropods declined in 14 trials, increased profitability was not demonstrated in the four trials where it was examined. The likelihood of a positive outcome in a trial was not significantly affected by annual or perennial cropping systems, single or multiple applications of the supplement, or carbohydrate and/or protein components of the supplement. Recommendations for the direction of future artificial food supplement research are outlined.

The M3 bait station for fruit fly control – the IPM solution.

AB Ware
Citrus Research International (Pty) Ltd, P.O. Box 28, Nelspruit, South Africa, 1200. ware@cri.co.za

A bait station has been developed for the control of Mediterranean fruit fly (*Ceratitis capitata*), Natal fruit fly (*Ceratitis rosa*) and marula fruit fly (*Ceratitis cosyra*). Effectiveness of the control measure was demonstrated using both male and female lures placed outside, on the perimeter and in the centre of the orchards. The outside traps indicated the fruit fly "pressure" while those in the orchard indicated the effectiveness of the control measure. Fruit inspections confirmed the effectiveness of the treatment. The M3 bait station IPM compatibility rests in the facts that it does not attract many non-target insects (no repercussions), food and environmental safety is ensured as no pesticides are applied directly to the fruit, tree or the environment. Other plus aspects of the system are that only a single treatment is required in a season, it is not affected by rain, it is easy to use and requires no skilled labour or sophisticated machinery, it is an alternative to organophosphate treatments, it is EUREPGAP compliant and finally it is cost effective.

The influence of various intercropping ratios of cabbage and carrot plants on the incidence of important cabbage insect pests.

WJ Weeks
North West Scientific and Technical Support Services, Department of Agriculture, Conservation and Environment, Private Bag X804, Potchefstroom, 2520, South Africa, tel +27 18 299 6538, fax +27 18 2977135, gwswjw@potch1.agric.za

Integrated Pest Management (IPM) employs various strategies and relies on sound management for successful implementation. Shortages of quantitative information inhibit IPM efficiency. A trial was started at Potchefstroom (South Africa) during the 2001 / 02 season to address the problem. The aim, to determine the effect various intercropping ratios, involving cabbage and carrot plants, has on diamond back moth (*Plutella xylostella*) infestation and parasitism levels, as well as on aphid infestations. The trial consisted of five treatments *viz.* control (cabbage monoculture + chemical control), monoculture (cabbage), inter crop 1:1 (cabbage: carrots), inter crop 1:3 and inter crop 1:5, replicated six times. Insects were sampled weekly after removing leaves of similar age from plants. *P. xylostella* larvae were lab reared at temperatures above 20°C to determine parasitism levels. Aphid numbers were expressed per leaf area to allow for comparison between treatments. Feeding damage to cabbage plants was determined by calculating the R – Index of Attack for data from visual ratings. Preliminary results indicate no significant ($P \leq 0,05$) differences between *P. xylostella* infestations on monoculture and intercropping treatments. A high correlation ($r = 0,828$) existed between parasitism and *P. xylostella* infestations. No significant feeding damage differences ($P \leq 0,05$) were recorded between monoculture and intercropping treatments.

Spatio-temporal distributions of pests and their key parasitoids in a crop of winter oilseed rape: implications for integrated pest management

IH Williams, AW Ferguson, H Barari, J Campbell, DJ Warner, N Watts, JEU Schmidt
Plant and Invertebrate Ecology Division, Rothamsted Research, Harpenden, Hertfordshire, UK
ingrid.williams@bbsrc.ac.uk

The spatio-temporal distributions of four major pests (*Psylliodes chrysocephala, Meligethes aeneus,Ceutorhynchus pallidactylus* and *Dasineura brassicae*) and of their key larval endoparasitoids were studied in a crop of winter oilseed rape. Insects were sampled at 40 spatially-referenced points within the rape crop and the emergence of those that overwintered in the field was monitored in the following crop of winter wheat. Spatial distributions were mapped, analysed and compared using Spatial Analysis by Distance IndicEs (SADIE). The distributions of most pests and parastoids were complex with differing irregular patterns of aggregation. Some pests were markedly more edge-distributed than others. The environmental factors and behavioural responses of both pests and parasitoids that influence their spatial and temporal ecology will be discussed. The potential value of spatio-temporal information for the development of integrated pest management strategies designed to conserve parasitoids for bio-control by spatial and temporal targeting of insecticides will be considered.

Exploitation of herbivore-induced plant volatiles for conservation biological control of *Lygus* species

L Williams, III, C Rodriguez-Saona, SC Castle, V Manrique, JS Bernal
USDA-ARS, Southern Insect Management Research Unit, P.O. Box 346, Stoneville, MS 38776-0346 USA, lwilliams@ars.usda.gov

Herbivory induces production and release of plant volatiles that attract natural enemies of the herbivores. Using plant volatiles to manipulate behavior of beneficial insects may be a powerful tool to enhance conservation biological control of crop pests. To provide a better understanding of this phenomenon and its potential for pest control, we have conducted a series of studies with *Lygus hesperus* and an egg parasitoid, *Anaphes iole*. Our ultimate goal is to apply knowledge of plant volatile production toward biological control of *Lygus*. Initial studies using GC-MS demonstrated that plants damaged by *Lygus* feeding and oviposition emitted a complex mixture of volatile organic compounds that is released systemically throughout the plant. These results led to electroantennography studies that showed that *A. iole* perceived many of the plant volatiles released after *Lygus* damage. Heightened antennal sensitivity by female wasps to several induced volatiles suggests a role in host habitat location. Subsequent behavioral studies (olfactometer and flight cage) in the lab and greenhouse demonstrated that female *A. iole* were attracted to plants damaged by *Lygus* and to synthetic components of the plant volatile blend. Studies are currently underway to determine if synthetic components of *Lygus*-induced plant volatiles are attractive to *A. iole* under field conditions.

Responses of cotton to actual and simulated green mirid damage.

TT Lei, LJ Wilson

CSIRO Plant Industry, Locked Bag 59, Narrabri, NSW, 2390, Australia, lewis.wilson@csiro.au

Green mirids damage squares (flower buds) and bolls (fruits) of cotton. They are an increasing problem during fruit set in crops with reduced insecticide applications, such as transgenic cotton, but their effect on profitability is poorly understood. We investigated compensation for mirid damage and the effects of mirids on yield, maturity and fibre quality. Crops with high mirid numbers (up to 6/m) over 50 days during boll filling had yields half those of crops with low mirid numbers (up to 1.4/m). There was no evidence of intra-boll compensation. We injected pectinase, a component of mirid saliva, into 10-day-old bolls, mimicking mirid feeding. The seed cotton mass of injected bolls was reduced by 38%. Artificially damaged plants compensated by increasing the size of undamaged bolls indicating that compensation can be achieved through the re-allocation of resources from damaged to healthy bolls. Injection of pectinase into older squares induced parrot beak boll formation, similar to that caused by mirids. The proportion of parrot beaks was 8 – 34% of the injected squares and varied between varieties. There was no evidence of reduced fibre quality because ginning appeared to effectively remove damaged lint so the risk of a penalty for poor quality was minor.

Habitat manipulation for IPM

SD Wratten, B Lavandero, S Scarratt, M Urrutia, HD Vattala
National Centre for Advanced Bio-Protection Technologies, PO Box 84, Lincoln University, Canterbury, New Zealand, wrattens@lincoln.ac.nz

The efficacy of biological control as an ecosystem service can be improved by the provision of pollen, nectar, alternative prey/hosts and/or shelter. When flowers are provided, there is potential hierarchy of behavioural and population consequences. The hierarchy is: 1. Parasitoids aggregate on the flowers. 2. Parasitoid fitness (e.g., longevity, fecundity, searching efficiency) is enhanced. 3. Parasitism rate is increased. 4. Pest populations are decreased. 5. Pest populations are brought below an economic threshold. Achieving all five steps in the above hierarchy is difficult – this is compounded by the need for selective floral resources which ideally benefit the parasitoid but not the pest. However, recent research has reveled this “selectivity” also to have a hierarchical component. 1. Parasitoid benefits but pest does not. 2. Parasitoid and pest benefit, but the pest has higher longevity only. 3. Parasitoid and pest benefit but parasitoid benefits relatively more. 4. Parasitoid and pest benefit but the improved fitness of the pest leads to a further improvement in the parasitoid’s fitness because the developing parasitoid larva derives a higher level of nutrients from a host which has fed on, e.g., pollen. The last of these possibilities represents the novel concept of “indirect resource subsidies”. Examples of recent research illustrating the above two hierarchies in conservation biological control will be presented.

IPM in organic systems: an industry/university collaboration

SD Wratten
National Centre for Advanced Bio-Protection Technologies, PO Box 84, Lincoln University, Canterbury, New Zealand, wrattens@lincoln.ac.nz

Ecosystem services (ES) are those services provided by living things for the good of mankind. They include such processes as pollination, biological control, soil fertility maintenance, carbon dioxide sequestration etc. All agriculture depends on ES but in organic systems, these services assume a greater importance. "Western agriculture" has consistently reduced the provision of ES with its extreme reduction in biodiversity. In July 1999 a commercial organic cropping farm was established at Lincoln University, New Zealand as a commercial, research, demonstration and teaching unit for the university and for the company. Also, it has been the focus of a sustained programme of enhancing ES on farmland, with an emphasis on ES provided by insects. Pollinator populations have been enhanced and the efficacy of arthropod predators and parasitoids has been increased. A "Biodiversity Trail" has been established on the farm to demonstrate these enhanced ecosystem services.

Does pest management in organic agriculture work differently? Case studies in European organic research

E Wyss, H Luka, L Pfiffner, C Schlatter, G Uehlinger, C Daniel
Ackerstrasse, CH-5070 Frick, Switzerland, eric.wyss@fibl.ch

Organic agriculture was founded by Rudolf Steiner and Hans Mueller in the years between 1924 and 1940, but it was not until the 1980s when pest management researchers began to develop concepts to control pests in organic systems. Today, insect pest management in organic agriculture involves the adoption of scientifically-based and ecologically sound strategies as specified by international and national organic production standards. These include a ban of synthetic insecticides and genetically modified organisms (GMOs). The first phase of an insect pest management program for organic systems is the adoption of cultural practices including diverse crop rotation, enhancement of soil quality by incorporation of specific cover crops and/or the addition of soil amendments, and choice of resistant varieties that help to prevent pest outbreaks. In the second phase, habitat management (e.g., incorporation of hedgerows and wild flower strips) is implemented to encourage populations of pest antagonists. Third and fourth phases of the program include deployment of direct measures such as biocontrol agents and approved insecticides. However, the strategies for pest prevention implemented in the first two phases often obviate the need for direct control measures. The researcher and grower approaches to pest management in organic systems are different than in conventional agriculture because, conceptually, the indirect or preventative measures form the foundation of the system and direct, or re-active control methods are rare and must comply with organic production standards. The range of European research activities for these concepts is illustrated with case studies in organic apple, corn, and vegetable production.

Prediction of biological control of the greenhouse whitefly by combined use of *Encarsia formosa* and *Eretmocerus eremicus*

E Yano, T Mitsunaga
3-1-1, Kannondai, Tsukuba, Ibaraki, 305-8666, Japan, yano@affrc.go.jp

Imported parasitoid species, *Encarsia formosa* and *Eretmocerus eremicus* have been commercialized recently in Japan for controlling whiteflies on tomato crops in greenhouses. The combined release of these two parasitoid species might be applied as more effective method than the single species release of *E. formosa* or *E. eremicus*. To evaluate the effectiveness of this combined use to control the greenhouse whitefly on tomatoes, the response of *E. eremicus* on the whitefly and the interaction between *E. formosa* and *E. eremicus* were studied in laboratory or in glasshouse experiments. *E. eremicus* attacks all the whitefly instar larvae except the young crawling stage and the late fourth instar stage. The functional response to the whitefly larvae infesting tomato seedlings was studied using cages in glasshouse experiments. The functional response was Holling's type 2 response for all host larval stages. When whitefly larvae were parasitized by both *E. formosa* and *E. eremicus*, *E. eremicus* always survived and *E. formosa* was killed in the direct interference between two species. A simulation model was developed to predict the biological control when both parasitoids are released to control the greenhouse whitefly on tomatoes. When both species are released simultaneously of different release ratios, the intermediate ratios result in better control than the single species release of one of the two species.

Moth control using yellow fluorescent lamps

J Yase, K Naba, H Tanaka
1533, Minami-no-okakoh, Befu, Kasai, Hyogo, 679-0198, Japan, yase@rock.sannet.ne.jp

The yellow fluorescent lamp (YFL) is a main physical control implement for integrated pest management (IPM) in Japan. YFL is used for overnight lighting. When the nocturnal moth adults enter the lighting area, they undergo "light adaptation", thereby becoming inactive. Radiation specifications of YFL are a wavelength range of 500–700 nm with a peak of about 580 nm. Such light does not attract most insects, yet it retains the potential for inducing "light adaptation". YFLs have been used in orchards against the fruit-piercing moths *Adris tyrannus* and *Oraesia excavata* or the like since the 1970s. Over the last decade, this implement has become particularly useful for vegetable and flower producers in order to control nocturnal moth oviposition. Moth species showing marked YFL effects are *Helicoverpa armigera*, *Spodoptera exigua*, *S. litura*, and *Hellulla undalis* etc. Crops of practical use are tomato, strawberry, cabbage, eggplant, carnation, rose, etc. Compared with a no-lighting condition in tomato practice, YFL reduced damaged fruits by 90% using only 20% of usual insecticides. Illuminance on the crops should be maintained at over 1–2 lx for the control effect.

Industry perspectives on research priorities for IPM in organic crops

JM Aselage, GW Zehnder
IPM & Sustainable Agriculture Programs, 114 Long Hall, Clemson University, Clemson, SC, USA, zehnder@clemson.edu

Crop production and pest control methods in organic agriculture are governed by strict standards and rules imposed by IFOAM or the USDA. Enhancement of soil quality and crop rotation form the foundation for organic agriculture and are effective strategies for controlling pests in annual crops. However, these methods are not always successful in controlling pests. Where they are not helpful, other tools, such as approved pesticides are needed. It is unlikely that organic agriculture will have a wide range of accepted chemical controls similar to what we currently use in conventional agriculture; therefore, the role of insect ecologists and behaviorists will become increasingly important in the development of new methods of crop protection. It will likely fall to them to develop or refine better scouting methods and thresholds. They will also need to improve our understanding of the crop ecosystem both above and below the soil surface. Finally, it will be their task to reevaluate our current agricultural cropping systems, designing new systems for organic agriculture where the crop environment discourages pests or allows predators to proliferate.

Introduction: IPM in organic systems

Geoff Zehnder
IPM & Sustainable Agriculture Programs, 114 Long Hall, Clemson University, Clemson, SC, 29634, USA; zehnder@clemson.edu

IPM principles, strategies and tactics are highly applicable and adaptable to organic agricultural systems. Conventional farmers and ranchers are increasingly interested in approaches to IPM for organic systems since the release of USDA organic certification standards in 2002. Current applied research and extension programs are providing successful field-based working models of pest management for organic growers. Symposium speakers will give an overview of successful IPM programs that have been developed for organic field crop, fruit, and vegetable production systems. Research and educational needs will be identified to support the growing organic agriculture field for small and conventional-sized producers.

Effects of intraspecific competition on the levels of parasitism and progeny production between parasitic wasps for *Callosobruchus chinensis* host larvae

KN Ahmed, A Nargis, NC Dey
BCSIR Laboratories, Rajshahi, Rajshahi-6206, Bangladesh.

Effects of intraspecific competition between two solitary parasitoids, *Anisopteromalus calandrae* (Howard) and *Dinarmus basalis* (Rond.) have been assessed in respect of parasitism and progeny production. The parasitoid, *D. basalis* demonstrated significant increase in parasiutism and progeny production over *A.calandrae* while confined to 3rd-4th instar host larvae *of Callosobruchus chinensis* (L.) in different durations. The individual mated female *of D.basalis* produced 9.1 ± 3.66, 13.9 ± 3.38, 20.8 ± 2.44, 23.1 ± 9.98 and 31.9 ± 19.58 progeny during 24,48,72,96 and 120 hours duration, respectively compared to 7.8 ± 1.99, 6.8 ± 3.85, 10.3 ± 6.56, 15.5 ± 7.26 and 24.8 ±13.05 progeny produced from *A. calandrae* in the above mentioned durations. The highwest parasitism of 50 % and the lowest parasitism of 4 % in 24 and 120 hours duration, respectively were observed *in D. basalis*. A maximum sex ratio of 2.49 and 2.75 (female to male) in *A.* calandrae *and D. basalis*, respectively were also noted.

The effect of wheats differing in category of resistance on Russian wheat aphid biology

HY Al-Ayied
"Natural Resources and Environment Research Institute (NRERI),King Abdulaziz City for Science and Technology (KACST), P. O. Box 6086 Riyadh 11442

Kingdom of Saudi Arabia; alayedh@kacst.edu.sa"

Biology of Russian Wheat Aphid (RWA) *Diuraphis noxia* (Mordvilko) was investigated on three wheat genotypes varying in aphid resistant. The aphid density was low on resistant than the susceptible wheat genotypes. Wheat Genomic differences affected the RWA developments. Antibiosis was observed as primary resistance category for wheat variety tested. A very high correlation was found between the number of aphids and the levels of infestation. However, the initial high level of infestation significantly affected the plants and aphid parameters as compared to the low level of infestation. Also more parasitoid were observed on TAM 107 than on resistant wheat genotypes. High level of RWA infestation affected the quality of seeds significantly in CO940626 and TAM 107. However, increased protein level was observed in susceptible wheat which might be due to aphid stress or lower test weight.

Biological control of peelminer in California citrus

C Allina, D Headrick
637 Henderson Ave, San Luis Obispo, CA 93401, USA; callina62@hotmail.com

Peelminer, *Marmara gulosa* Guillen Davis (Lepidoptera: Gracillariidae), has been a persistent pest of citrus fruit in the San Joaquin Valley in central California since 1999. Larval stages create serpentine mines scarring the rind of citrus fruit rendering it unacceptable for fresh market sale. Erratic population increases and unexplained population movement into citrus and 65 other plant species from 28 different families leave many questions to be answered about this insect. Equatorial fruit diameter studies on grapefruit, pummelo and navel oranges showed no relationship between diameter and timing of egg deposition or mining initiation. Mining on oleander stems, *Nerium* spp., was recorded weekly from August to December of 2003 and showed significant population increases into the winter. Parasitoids of peelminer native to the San Joaquin Valley of California were composed only of eulophid species and have not demonstrated any population control. Peelminer also has been a persistent pest of citrus in the Coachella Valley of southern California since 1995. A gregarious eulophid parasitoid, *Cirrospilus coachellae* Gates, native to Coachella was released into the San Joaquin Valley starting in 2001. Successful establishment has not yet been observed in the San Joaquin Valley following the annual releases.

Effect of harvest management on pest and beneficial insects in alfalfa

WC Bailey, T Woods
1-87 Agriculture Bldg., University of Missouri, Columbia, MO 65211, USA; BaileyW@missouri.edu

The alfalfa weevil, *Hypera postica* (Gyllenhal), and potato leafhopper, *Empoasca fabae* (Harris), are important pest of alfalfa, *Medicago sativa* L., in Missouri. Many producers trying to avoid insecticide use and conserve beneficial insect populations have attempted to reduce pest insect numbers by early harvest of the crop. Two of the most common harvest strategies employed for insect control are mechanical harvest and forage removal by grazing with livestock, usually cattle. In this study, pest and beneficial insect populations were estimated prior to and after each of four harvests of alfalfa annually. Treatments included all harvests by mechanical means, all harvests by grazing with cattle, and two treatments with mixed harvest methods regimes. Data indicate that larval numbers of alfalfa weevil were reduced by approximately 99% for the all-mechanical or all-graze method of harvest. Potato leafhopper adults were reduced by 86% by mechanical harvest as compared to 67% in grazed plots. Similarly, numbers of potato leafhopper nymphs were reduced by 83% and 18% for mechanical and grazed harvest, respectively. A complex of 10 beneficial insects were grouped for statistical analysis. Insects in this complex were reduced by an average of 81% in plots harvested mechanically as compared to 64% in grazed plots.

Seasonal fluctuation of adult and larvae of *Agriotes spp.* **(Coleoptera:Elateriadae) in central Croatia**

R Bažok, S Bezjak, J Igrc-Barčić, L Furlan
Faculty of Agriculture, Svetošimunska 25, 10000 Zagreb, Croatia; rbazok@agr.hr

The seasonal larval and adults abudance of the five wireworm species was examined in central Croatia in a three-year period. Sex pheromone and soil bait traps were used and soil samplings were made. Sex pheromone traps operated from April to September. Soil bait traps were installed for 15 days in April. Soil samplings were made in April at a depth of 30 cm. The population density of *Agrotes lineatus* is described as high at both localities. The swarming period of *A.lineatus* lasted from April to mid August. The population density of *Agriotes ustulatus* on two lacalities was from low to high. The swarming period of *A.ustulatus* lasted from mid May to early July. The population density of the *Agriotes brevis* at both localities is described as medium. Before this investigations there was no literature data about A.brevis presence in Croatia The population densities of *Agriotes sputator* and *Agriotes obscurus* were low to medium. The swarming period of all three species lasted from April to July. In soil samples 1-12 larvae/50 soil samples were found. In bait traps 2-111 larvae/50 traps were found. Using soil bait traps and soil sampling larvae of all five species were collected.

Implementation of an environmentally friendly IPM program for the control of the most destructive pest of coffee crops: the coffee berry borer *Hypothenemus hampei.*

P Benavides, AE Bustillo, F Posada, A Perea, C Gongora, JC Lopez, Z Gil, C Valencia, JD Rubio
4112 Plant Science Bldg. University of Maryland. College Park , MD 20742; pbenavid@mail.umd.edu

An enormous research program aimed at controlling *Hypothenemus hampei* (Coleoptera: Scolytidae), the most destructive insect pest of coffee, has been initiated at the National Coffee Research Center - CENICAFE, the research branch of the National Coffee Growers Federation of Colombia. After the introduction of this insect in Colombia in 1988, CENICAFE started an ambitious program to implement an environmentally friendly IPM program focusing on cultural and biological control. Since then, cultural control strategies have been successfully implemented. Moreover, three African parasitoids have been imported, reared, and tested in the field. Research on entomopathogens has involved the use of *Beauveria bassiana, Metarhizium anisopliae,* and *Paecilomyces lilacinus*. Field and lab experiments have yielded impressive results, including the development of a genetically modified strain of *B. bassiana* with *M. anisopliae* genes that increased virulence and shortened mortality time. Other experiments have consisted of the estimation of the worldwide genetic variability and biogeography of this insect and the detection of *Wolbachia* as a probable distorter of gene determination. Ongoing research focuses on exploring the use of pathogenic nematodes. Studies on butterfly biodiversity in coffee habitats and the morphological description of the alimentary canal and the reproductive system of *H. hampei* females will be presented.

Evaluation of different plants as an ovipositional substrate for *Orius insidiosus* (Hem : Anthocoridae).

VHP Bueno, SM Mendes, LM Carvalho
Department of Entomology, Federal University of Lavras, P.O. Box 37, 37200-000 Lavras, MG, Brazil; vhpbueno@ufla.br

Orius insidiosus (Say) lays eggs inside and inserts them in the plant tissue. An obstacle for its massal rearing is the selection of a plant that is suitable as an ovipositional substrate, being one less expensive and easy to get and well accept by the female. The objective this work was to evaluate the preference and the suitability of different structures of several plants as ovipositional substrate for _O. insidiosus_. The trials were conducted in climatic chamber at 25±1ºC, RH 70±10% and photophase 12h. The plants site evaluated were amaranth stem (_Amaranthus virides_ L.), common bean's stem and pod (_Phaseolus vulgaris_ L.), green bean's pod (_Phaseolus vulgaris_ L.), and farmer's friend inflorescence (_Bidens pilosa_ L.). The daily and total numbers of eggs/female were higher in farmer's friend inflorescence (5.7 and 163.3 eggs, respectively) than another substrates evaluated. The results indicated the suitability of farmer's friend inflorescence as an ovipositional substrate for _O. insidiosus_ female, being the preferred one in no-choice and choice tests. Also the females showed better reproductive performance having farmer's friend inflorescence as an ovipositional substrate.

Insect damage in young eucalypt plantations in New South Wales, Australia: 1996-2003.

AJ Carnegie, DG Waterson, RG Cant, G Price
Forest Health Survey Unit, Forest Health Management Program, Research & Development Division, State Forests of NSW, PO Box 100, Beecroft, NSW 2119, Australia; angusc@sf.nsw.gov.au

State Forests of NSW manages over 27, 000 ha of young eucalypt plantations, planted since 1994. The Forest Health Surveillance program was established in late 1995 to help protect this valuable and expanding resource. Surveys are conducted annually in the majority of these plantations. Over 75 species of insect pests were observed damaging these plantations. Herbivorous insects were by far the main damaging insects, both in terms of numbers observed and damage sustained by plantations. Christmas beetles (*Anoplognathus* spp.) and Chrysomelid leaf beetles (*Chrysophtharta* spp. & *Paropsis* spp.) were the most common and damaging insects throughout the whole period of surveillance. *Eucalyptus dunnii* and *E. grandis* sustained the most damage from these insects. *Creiis lituratus* psyllids became a major pest of *E. dunnii* from 1998 onwards, but were not reported as a pest of eucalypts prior to this. Stem borers (longicorn beetles and giant wood moths) were a major problem in *E. grandis* greater than 3-years-old. Several new species of insects were identified during these surveys. The Forest Health Survey Unit provides expertise and training in all aspects of forest health to State Forests' operational divisions, and is an integral component of State Forests' risk management strategy.

Pest status of *Cosmopolites sordidus* (Germar) (Coleoptera; Curculionidae) in the Canary Islands

A Carnero, M Montesdeoca, A Padilla, F García del Pino, N Casañas, F Ortego, P Castañera.
Dpto. Protección Vegetal del I.C.I.A., Apdo. 60, 38200 La Laguna-Tenerife, Spain

The banana weevil *Cosmopolites sordidus* currently affects all the islands of the Canary Islands archipelago. Chemical control is proving very difficult, given the tunneling habit of the weevil. Alternative control methods, such as protease inhibitors and biological control using entomopathogenic nematodes and fungi, have shown to be very promising. Studies to determine geographical origin have to date revealed several different ecotypes. Banana cultivar susceptibility is under study and a new method to evaluate infestation is being developed.

Acaricidal and insecticidal properties of a Chenopodium-based botanical

H Chiasson, C Vincent, NJ Bostanian
Codena inc., 426, chemin des Patriotes, Saint-Charles-sur-Richelieu, QC, Canada J0H 2G0; hchiasson@udainc.com

The emulsifiable concentrate UDA-245 (25%EC, v/v), based on an essential oil extract from *Chenopodium ambrosioides* var. *ambrosioides,* a North American herbaceous plant, was compared to commercially available pesticides tested for their acaricidal and insecticidal effects on common pests of ornamental greenhouses. The products were tested with the adult stages and on egg hatch of the twospotted spider mite (*Tetranychus urticae* Koch) (Acari: Tetranychidae) and of the European red mite (*Panonychus ulmi* (Koch)) (Acari: Tetranychidae), with the adult and nymphal stages of the green peach aphid (*Myzus persicae* (Sulzer), Homoptera: Aphididae), and with the adult stages of the western flower thrips (*Frankliniella occidentalis* (Pergande) Thysanoptera: Thripidae) and of the greenhouse whitefly (*Trialeurodes vaporariorium* (Westwood) Homoptera: Aleyrodidae*).* Side effects on the adult stage of the whitefly parasitoid, *Encarsia formosa* Gahan (Hymenoptera: Aphelinidae) were also determined for the potential use of the product in integrated pest management programs using biological control agents. Results suggest that a greenhouse IPM program using UDA-245 could effectively and selectively control mite infestations by treating 'hot-spots' with negligible effect on biological control agents when treating before introduction or when natural enemies are absent.

Tart cherry IPM in the United States: on-farm trials of reduced-risk insecticides and surveys of IPM adoption

A Coombs, M Whalon, L Gut, D Epstein, J Haley
Department of Entomology, Michigan State University, East Lansing, MI, 48824, USA

The United States is the world's largest producer of tart cherries with approximately 75% grown in Michigan. Entomologists, plant pathologists, horticulturists, and soil scientists from Michigan State University, University of Wisconsin-Madison, and Utah State University are collaborating on a project to implement reduced-risk orchard management strategies across the US tart cherry industry. Although the Tart Cherry Orchard Management Program is wide in scope, this poster covers two major aspects of this program. The first aspect is the evaluation of reduced-risk insect management in on-farm trials in Michigan. These trials were conducted in Michigan's three major growing regions in blocks ranging from 3 to 5 hectares. Pest presence, damage, and non-target effects in reduced-risk blocks were compared to conventionally managed blocks. The second aspect of the Tart Cherry Orchard Management Program covered in this poster is results of an industry-wide grower survey. Self-reported use of IPM strategies and grower perceptions of IPM adoption challenges are presented.

Pheromones of cocoa mirids

DR Hall, A Cork, MCA Downham, PJ Innocenzi, B Padi, JE Sarfo
Natural Resources Institute, University of Greenwich, ME4 4TB, UK; a.cork@gre.ac.uk

Several genera and species of mirids (Heteroptera: Miridae) are pests of cocoa in Africa and Asia. In West Africa, the two main species are *Distantiella theobroma* and *Sahlbergella singularis*. Previous work showed attraction of male *D. theobroma* by conspecific females during late afternoon, and we have shown attraction of male *S. singularis* by females during the night. Analysis of volatiles collected from virgin female *D. theobroma* or *S. singularis* by gas chromatography (GC) linked to electroantennography (EAG) showed two EAG-active components in very small amounts. These were identified as the diester hexyl (*R*)-3-((*E*)-2-butenoyl)-butyrate and the corresponding monoester, hexyl (*R*)-3-hydroxybutyrate. Blends of these components attracted male *S. singularis* to traps and use of the traps for monitoring and control is being investigated in Ghana. These studies are already producing new insights into distribution and seasonality of the pests, but catches of mirids are extremely variable and we are investigating whether this is due to genuine aggregation of populations or to other factors.

Attract-and-kill for *Helicoverpa*: non-target effects

AP Del Socorro, PC Gregg
Australian Cotton CRC, School of Rural Science and Agriculture, University of New England, Armidale NSW 2351, Australia; adelsoc2@metz.une.edu.au

We have developed plant-based attractants for *Helicoverpa* moths that can be used as attract-and-kill in cotton and other crops like corn and legumes. We monitored the effects of these attractants on pest and beneficial species other than *Helicoverpa*. In large-scale field trials in which about 1.5% of the area was treated, we collected dead insects on rows adjacent to the treated ones, as well as on other rows up to 35m away from treated rows. Although a large proportion of dead insects were *Helicoverpa*, substantial numbers of other noctuid pest species such as loopers, armyworms, cutworms and small numbers of sphingids and pyralids were also killed. Small-scale field trials on faba beans compared the numbers and types of insects collected on rows treated with the plant volatiles alone (without the toxicant) with those on untreated rows at various distances from the treated ones, and at various time intervals after spraying. Large numbers of hemipteran pest species were collected in the treated rows, suggesting that our attractants might also work for sucking pests. In general, attractants were not significantly attractive to beneficial groups like predatory beetles and bugs, wasps, lacewings and spiders, though there was some attraction to a few species.

Use of native Michigan plants to provide resources to natural enemies

AK Fiedler, DA Landis
Department of Entomology, 204 Center for Integrated Plant Systems, Michigan State University, East Lansing, Michigan USA; fiedlera@msu.edu

The use of plants to provide nectar and pollen resources to natural enemies via habitat management is a growing focus of conservation biological control via habitat management. The current focus, however, is on plants not native to the area of study. There is no reason to suspect that plants native to an area cannot perform as well as non-natives that are currently recommended. Use of native plants for habitat management has several benefits. Most of the natural enemy species affected by conservation biological control are native insect species, which may be better adapted to feed on native plants. In addition, native plants are pre-adapted to the environment and its natural enemies. Use of them adds to native biodiversity and restores native communities. We compared of a set of fifty native Michigan, USA and five non-native plants for their effectiveness as resource plants for natural enemies. Insect abundance and diversity were measured at flowering plants during the 2004 growing season. Plant and flower characteristics were measured to determine which, if any, were best correlated with natural enemy visitation. This procedure allows rapid plant screening to maximize resource plant effectiveness before performing in-field trials.

Economic thresholds for sorghum midge and corn earworm on midge-resistant sorghum in Australia

BA Franzmann, DAH Murray, AT Hardy, JE Hopkinson, MP Zalucki
Department of Primary Industries & Fisheries, PO Box 102, Toowoomba, Qld. 4350; Bernie.Franzmann@dpi.qld.gov.au

In a series of field trials the relationship between numbers of attacking insects and resultant yield loss was determined for the two major pests of sorghum in Australia, the sorghum midge *Stenodiplosis sorghicola,* and the corn earworm, *Helicoverpa armigera.* One ovipositing female sorghum midge/panicle/day reduced yield by 1.4 g, and one corn earworm larva reduced yield by 2.4 g. The relationship was used to calculate economic thresholds for each pest, based on numbers of ovipositing females, for sorghum midge, and numbers of small-medium sized larvae for corn earworm. Midge-resistant sorghums have been developed over the past decade and are now extensively grown in Australia. The economic threshold for midge on resistant sorghum is increased by a factor equal to the level of resistance of the variety. For all new varieties coming on to the market the level of resistance is determined in a cooperative scheme between private seed companies and the Department of Primary Industries & Fisheries. The relationship between corn earworm larval numbers and yield loss is the same for midge-resistant and midge-susceptible sorghum. Successful IPM of the two major pests of sorghum in Australia is grounded on quantified economic thresholds.

Farmers participatory integrated pest management in scented rice

DK Garg, MD Jeswani, M Pathak, SP Singh, PV Verma
"National Centre for Integrated Pest Management, L.B.S. Building, Indian Agricultural Research Institute, New Delhi-110012, India; ipmnet@bol.net.in"

Scented rice, popularly known as 'Basmati' in India, is mostly grown in the north Indian states. It hosts many pests, which often cause substantial yield losses. The excessive use of pesticides in some scented rice growing areas has resulted in reduction of biodiversity of natural enemies, outbreak of secondary pests, development of pests resistant to pesticides, pesticides induced resurgence and residue problem in grains. In this context, Integrated Pest Management (IPM) is highly relevant. IPM validation has been carried out during *Kharif* (May-October) of 1999 to 2003 in a village Shikohpur in Uttar Pradesh, where farmers solely depended on the use of intensive pesticidal applications, over an area of 40, 120 and 160 ha during 1999, 2000 and 2001 respectively. Adoption of IPM approach (seed treatment, regular pest surveillance and monitoring, conservation and augmentation of natural enemies, need based application of pesticides and some improved crop management practices) led to consistent higher yield levels of 5.69 (1999), 5.80 (2000) and 5.74 t/ha (2001) in IPM, compared to 5.03, 4.82 and 4.56 t/ha for the same years in the farmers practices (non-IPM) with reduced input cost and high cost-benefit ratios. During the subsequent years (*Kharif* 2002 and 2003), majority of the farmers continued to follow IPM tenets and got enhanced yield and economic returns. This outcome emphasizes the need to further spread the message of IPM in scented rice growers.

Reducing pesticide inputs in nurseries through the use of a portable hot water re-circulation immersion system

S Gill, P Shrewsbury, D Ross, C Schuster, G Rosenkranz
University of Maryland Cooperative Extension, 11975 Homewood Road, Ellicott City, Maryland, 21042, USA; sgill@umd.edu

As part of our Integrated Pest Management efforts to provide an improved method for nursery managers to control pests on plant cuttings, we have devised a non-chemical, hot water re-circulation immersion system for killing insect pests such as spider mites, broad mites, scale insects, mealybugs, lace bugs, and aphids on woody and herbaceous propagation material. Research has been conducted to determine the optimum temperature and duration of time for several plant species to prevent phytotoxicity and effectively kill insects. Four Maryland, USA nurseries cooperated with this project. Success of this project was determined by the efficacy of the hot water immersion method at suppressing pest populations and by monitoring the adoption of this alternative insect pest treatment system by commercial plant propagators.

The pest manangment of screw bean seed pest *Caryedon serratus* (Col.:Bruchidae) on base biological control in Bushehr province.

SR Golestaneh, N Farrar
Research center of Natural Resources and Animal affairs , Bushehr , Iran; golestaneh53@yahoo.com

Prosopis cineraria (L.) Druce is a beautiful native plant that has an important role in the life and ecological conditions in Boushehr province. *Caryedon serratus* is the most important pest on *Prosopis cineraria* because it causes the most damage in coastal areas from Kangan to Bandar-abbas. I observed oviposition to occur with mostly solitary eggs being laid and less frequently in a group (3-5 egg) on seeds and pod surfaces. After hatching, larva penetrated the seeds and destroyed them. Then, became pupa in the seeds and adults made exit holes on surface fruits. The pupal parasitoieds of Encyrtid family isolated from this pest. In 1991, selected one hectare (10000m^1) of *Prosopis cineraria* forests and determined the best method for pest control. to pay attention to wide dispersal of forests , support and survival of environment and no-use or low-use of pesticides and emphasis on biological control by support of parasitoids from Encyrtid family , integrate pest manangment (IPM) performed with following methods and the pest *C. serratus* was controlled successfully.1- the collection of seeds and pods in june and November ,isolation of seeds and disinfection by Diazinon %60 or Sevin. 2- grazing to destroy infected seeds and pods. 3- the cutting of canopy around the *Prosopis cineraria* to destroy overwintering and summering of pest. 4-only two times spray with Malathion %75 or Diazinon %60 after falling flowers and beginning of pods for support of parasitoids.

Efficacy and ecological response to pseudostem and pheromone trapping of *Cosmopolites sordidus* (Germar) (Coleoptera: Curculionidae) in South Africa

J de Graaf, A Viljoen, P Govender
Department of Zoology and Entomology, Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria, 0002 South Africa; pgovender@zoology.up.ac.za

The dominant insect pest of bananas in South Africa is *Cosmopolites sordidus*. In developing an integrated pest management strategy for *C. sordidus*, different trapping methods were compared in banana plantation field trials during autumn, spring and summer along the south coast of KwaZulu-Natal. Pseudostem traps, two different pheromone lures and control traps (pitfall traps without pheromone lure) were evaluated for their efficacy in collecting adults over five weeks. A randomised block design was used for all trials. Pitfall traps contained diluted ethylene glycol, where attracted beetles were drowned. Pseudostem traps were covered with mulch to delay desiccation and replaced once a week during surveys. Dissected adults were sexed and the number of eggs recorded. Pheromone traps collected significantly more beetles than the pseudostem traps, which were significantly more effective than the control. Significant differences in sex ratio were observed, where pseudostem traps attracted about equal numbers of males and females while pheromone traps showed a female bias. Females attracted to pseudostem traps were usually more fecund than females attracted to pheromone traps. The efficacy of pheromone traps and their low labour requirements shows promise as a monitoring tool and possible control strategy against the banana weevil in South Africa.

Entomological diversity in carrot fields in Belgium and impact of close habitat

P Colignon, F Francis, E Haubruge
Department Of Pure And Applied Zoology, Gembloux Agricultural University, B-5030 Gembloux, Belgium; haubruge.e@fsagx.ac.be

This work aims to characterise the entomological diversity in carrot crop (*Daucus carota* L.) in South Belgium. During years 2000 and 2001, 271.083 flying insects were caught in 24 fields using yellow water traps. 133 insect families were identified. Results show that insect population diversity and stability increase with crop development. Aphid problems occur only at the beginning of the season, when young carrots are especially susceptible. When crop reaches maturity, beneficials control prevents any aphid infestation. We also asses the impact of vegetation close to fields: other crops, herbaceous strips hedges and woody borders. Results show also that agro-environmental measures enhance insect density and diversity, mainly for beneficial guilds. Results are discussed in relation to potential effects on aphid infestations.

Peelminer growth and development in California Citrus

DH Headrick, S Finch, C Allina
Horticulture and Crop Science Department, Cal Poly State University, San Luis Obispo, CA 93407; dheadric@calpoly.edu

Peelminer, *Marmara gulosa* Guillen and Davis (Lepidoptera: Gracillariidae), has been a persistent pest of citrus fruit in the San Joaquin Valley in central California since 1999. Peelminer caused widespread and extensive damage in a short period of time and was of major concern to growers being only one of four species to directly attack the fruit. Studies were initiated on three different varieties (grapefruits and navels) to determine growth and development, distribution, abundance, and feeding habits of peelminer in commercial settings. Larvae extensively mine fruit epidermis creating serpentine mines of up to 50 cm over the course of their development. Peelminer populations are multivoltine in the San Joaquin Valley and they overwinter as larvae on citrus fruit and stems as well as stems of several other host plant species. Peelminer populations expanded through the valley rapidly; within commercial citrus plantings, populations were typically localized upon initial discovery and spread throughout the grove within a single season. Peelminer populations were extremely high on fruit subsequent to its discovery and remained high with a range of 0.17 to 0.43 mines per fruit in grapefruit and 0.07 to 1.17 mines per fruit in navels in the 2003 season.

Triphelio - An international research project for sustainable control of lepidopterous pests in olive groves.

E Agamy, A Bento, B Hafez, SA Hassan, E Hegazi, A Herz, T Jardak, M Konstantopoulou, M Ksantini, B Mazomenos, T Moschos, F Nasr, JA Pereira, L Torres, B Wührer, A Youssef
Institute for Biological Control, Darmstadt, Germany; eshegazi@hotmail.com

The olive moth as well as the jasmine moth are serious pests on olive. The EU-funded project TRIPHELIO (Contract ICA4-CT-2001-10004) explores biological and biotechnical methods for control of these pests by:

Evaluating pheromone-based mating disruption in different regions and commodities of olive cultivation.
Developing strategies for enhancement of natural enemies in the olive ecosystem.
Exploring inundative releases of *Trichogramma*-wasps as control method.

Promising effects were found in current field trials of mating disruption as well as of enhancing vegetational diversity in the olive grove ecosystem. Concerning *Trichogramma*-releases, further improvement of their efficacy is needed, for instance by the use of local, environmentally well adapted *Trichogramma*-species.

Monitoring the rice leaf bug, *Trigonotylus caelestialium*, with synthetic sex pheromone

H Higuchi, A Takahashi, T Fukumoto, F Mochizuki
Inada 1-2-1, Joetsu, Niigata, 943-0193, Japan; hhiroya@affrc.go.jp

The rice leaf bug, *Trigonotylus caelestialium* (Heteroprea; Miridae), is widely distributed across Japan. The adults and nymphs of this stink bug attack the heads of rice plants and cause pecky rice. In 1999, the stink bugs had inflicted serious damage on rice plants in the northern part of Japan. It is well known that the females secrete sex pheromone to attract the males. The sex pheromone components of this stink bug have been reported. We made an attempt to employ the synthetic sex pheromone for population monitoring. Water pan trap baited with a rubber cap containing synthetic sex pheromone was used for monitoring the seasonal prevalence of the occurrence of adult stink bugs. The trap baited with 0.01mg synthetic sex pheromone attracted many males and was nearly equivalent to a trap baited with 10 virgin females. The attraction period of the lure was more than one month. These results suggested that the pheromone trap can be used more than one month as a tool for monitoring the population of stink bugs in the fields.

Effect of suppressing density for green rice leafhopper, *Nephotettix cincticeps*, on resistant near-isogenic lines and response of local populations to resistant varieties

M Hirae, K Tamura, Y Fukuta, S Oya
Hokuriku Research Center, National Agricultural Research Center, Inada, Joetsu, Niigata 943-0193, Japan; hirae@affrc.go.jp

Use of crop resistance has the advantages of environmental load reduction, reduced labor and lower costs and is an effective method for integrated pest control. We developed four types of near-isogenic lines (NILs) of the Kinuhikari variety of rice with different resistance genes for green rice leafhopper (GRH). The fact that the response to resistant varieties differs for local populations of GRH is known. Thus, GRH populations were collected from four locations in Joetsu, Mito, Chikugo, and Kagoshima and virulence to each NILs was investigated. The result was that it was lower in the Joetsu and Mito populations to lines having resistance genes Grh 1 and Grh 2. In contrast, virulent individuals were present for the Chikugo and Kagoshima populations on the order of 30-40 percent. With line having a combination of Grh 2 and Grh 4, the proportion of virulent individuals was lower for all populations. In addition, resistant NILs were cultivated in paddy fields in Joetsu and Chikugo and the effect of suppressing GRH density was examined. The result was that the density of GRH on each NILs was low in both Joetsu and Chikugo and a strong effect on suppressing density was noted.

Leafminers, *Liriomyza* spp. (Diptera: Agromyzidae), in Vietnam: distribution, biology and insecticide resistance

T Hofsvang, A Andersen, NS Johansen, TM Tao, OKT Le, E Nordhus
Norwegian Crop Research Institute, Plant Protection Centre, Høgskoleveien 7, N-1432 Ås, Norway; trond.hofsvang@planteforsk.no

Liriomyza sativae is the main polyphagous *Liriomyza* species appearing as a pest in vegetables in most of Vietnam. *Liriomyza huidobrensis* is a major problem in the highland area around Dat Lat in southern Vietnam. In addition, *Chromatomyia horticola*, *L. bryoniae* and *L. trifolii* are present, but their pests status on vegetable are not clear. Parts of the biology of *L. sativae* have been studied, and the native parasitoid complex seems to be important. *L. sativae* was collected from four locations in the Hanoi area and tested against five insecticides commonly used against leafminers in northern Vietnam. Resistance towards cypermethin was found in the three populations from locations with intensive insecticide use.

Effect of *n*C24 agricultural mineral oil on two-spotted mite (*Tetranychus urticae* Koch) and cotton aphid (*Aphis gossypii* Glover)

Z Hossain, GAC Beattie, R Spooner-Hart, O Nicetic
Centre for Horticulture and Plant Sciences, University of Western Sydney, Locked Bag 1797, Penrith South DC, NSW, 1797, Australia;
z.hossain@uws.edu.au

An *n*C24 agricultural mineral oil was evaluated under laboratory conditions for its bioefficacy against adult female two-spotted mite (Acari: Tetranychidae) and cotton aphid (Hemiptera: Aphididae) on cotton leaf discs. Sprays of water only, and aqueous emulsions that gave 20, 40, 60, 80 and 100 mg oil cm^{-2} deposits, were compared. All sprays were applied with a Potter spray tower. The impacts of sprays on arthropod mortality were assessed 24 h after sprays were applied to infested leaf discs. The impacts of spray deposits on oviposition by *T. urticae* females and nymphs produced by *A. gossypii* females were determined 24 h after release of the adult female arthropods onto dry spray deposits. All emulsions applied to adult mites and aphids led to significant mortality and mortality increased with dose. All emulsions significantly reduced oviposition by mite females but deposits < 60 mg cm^{-2} had no impact on numbers of aphid nymphs recorded on the leaf discs. The results are discussed in relation to recent field studies on cotton and other crops.

The 'tool kit' for extending IPM information for diamondback moth control to the Brassica industry of Australia

D Jevremov
SARDI Entomology Unit, GPO Box 397, Adelaide South Australia, 5001, Australia; jevremov.dijana@saugov.sa.gov.au

A range of tools has been selected to provide what is commonly called 'technology transfer' or 'extension' to Brassica growers and their advisors in Australia. The range comprises methods that are face-to-face, electronic, direct-mailed, and voluntarily collected. The subjects covered via these methods are tactics of IPM including: Biological - such as identification of natural enemies and pests, Managerial - such as monitoring and buying healthy transplants, Chemical - advocating the use of insecticides as a last resort and 'soft' option insecticides such as Bt's, as well as highlighting the use of the insecticide resistance management strategy (IRM) developed for Diamondback moth (DBM) specifically, and Genetic - cultivar selection based on research findings. Some examples of the tools include: Workshops and field education that includes selected local and overseas invited speakers. A national Brassica IPM newsletter informs about the latest in pest and disease management. A handbook of DBM management contains updated modules about the pest and the various IPM tactics recommended. Direct education about IRM to staff at chemical stores ensures the same level of knowledge across industry. Website information and downloadable crop sampling plans are yet another tool that is continuing to move the industry towards IPM practices.

Effect of soil fertility amendments on crop character and infestation by cabbage pests

J Karungi, B Ekbom, S Kyamanywa
Crop Science Department, Makerere University, P.O. Box 7062 Kampala, Uganda; Jkarungi@agric.mak.ac.ug

Field studies were conducted to assess the effect of market crop wastes (MCW) derived soil fertility amendments vs. a conventional fertilizer on crop character and population dynamics of aphids (*Brevicoryne brassicae* and *Myzus persicae*) and the diamondback moth on cabbage, *Brassica oleracea* var. *capitata*. Treatments were 1) MCW compost incorporated in the soil, 2) un-composted MCW incorporated in the soil, 3) Un-composted MCW applied as a surface mulch, 4) a conventional chemical fertilizer (NPK) incorporated in the soil, and 5) the untreated control. Response variables recorded included shoot length/width (cm), leaf area, leaf toughness, %tissue nitrogen, aphid infestation ratings, and diamondback moth counts. Results indicated that for growth parameters, plots receiving amendments did slightly better than the untreated ones, also, untreated plots had the lowest infestation of the diamondback moth.

Effect of *Eucalyptus* and *Tylophora* extracts on feeding of *Helicoverpa armigera* (Hübner) larvae.

V Kathuria, N Kaushik
TERI, Habitat Place, Lodhi Road, New Delhi, India; kaushikn@teri.res.in

Helicoverpa armigera is an important pest of many crop species. Environmentally benign strategies are required to manage this pest. Hexane and ethanol extracts of *Eucalyptus camaldulensis* and *Tylophora indica* leaves were evaluated for their antifeedancy against *H. armigera* larvae. Cabbage leaf discs (12.5 sq cm) dipped in the test solution for five seconds were used for feeding the larvae. Four fifth instars, starved for 4h, were fed on the treated cabbage leaf discs in eight replicates for 24h. Feeding values were calculated in comparison to solvent treated control. The calculated percent feeding inhibition values were analyzed by Probit analysis to calculate the EC_{50} values. Ethanol extracts of both the plant species exhibited high feeding inhibition activity having EC_{50} values of 6.92 and 2.81% for *Eucalyptus* and *Tylophora*, respectively as compared to hexane extracts which recorded the EC_{50} values of 9.28 and 5.21%. Feeding inhibition when computed against different concentrations showed a high exponential growth (R-sq change) indicating the linearity of the equation and sensitivity of the insect to different concentrations.

Predicting spring flights of *Etiella behrii* (Lepidoptera: Pyralidae): a pest of lentils in southern Australia.

CA Krawec, DC Hopkins, GJ Baker
South Australian Research and Development Institute, GPO Box 397, Adelaide, South Australia, 5001; krawec.chris@saugov.sa.gov.au

The Lucerne seed web moth, *Etiella behrii* (Zeller) (Lepidoptera: Pyralidae), is a serious pest of lentils in southern Australia. The larval stage of *E. behrii* bores into immature pods to feed on developing grain, resulting in yield losses and a reduction in grain quality. Current Australian receival standards for lentils allow no more than 1% damage by insects. Producers' ability to supply grain of this quality relies on the effective management of *E. behrii.* Insecticide treatments often fail to provide adequate control of *E. behrii* in lentil crops. We suspect a primary cause is the inappropriate timing of many of these treatments. Monitoring the activity of moths and timing spray applications to target peak adult activity prior to egg laying may prove to be an effective management strategy. To identify the seasonal occurrence of *E. behrii* activity we have analysed the relationship between the timing of spring flights in historical light-trap records and temperature. Degree-days have been used to predict the phenology of *E. behrii* and assist in targeting pesticide applications, thus furthering the development of integrated pest management procedures for this pest.

Efficacity of pheromone rates on male captures of potato tuber moth *Phthorimaea operculella* (Zeller)(Lepidoptera: Gelechiidae).

P Larraín, M Guillón, C Vásquez, F Graña
Apartado Postal 36/B. La Serena Chile; plarrain@intihuasi.inia.cl

Potato tuber moth (PTM), *Phthorimaea operculella* (Zeller) is one of the most serious insect pests of potatoes both in the field and in storage in regions with hot, dry summers throughout the World. Larvae develop on potato foliage and in tubers causing direct losses of edible product. Chemical treatments to control this pest have shown limited efficacy, especially when larvae are in the soil. The use of synthetic pheromones as a tool to interfere with mating has been widely demonstrated in numerous moths and in other insect species. During the summer season 2003-2004, a study was carried out at Valle del Elqui, IV Región, Chile, to evaluate the efficacy of different rates (0.2; 0.5; 1; 2 and 5 mg) per trap of PTM sex pheromone mixture (Trans-4, cis7-tridecadieno-1-ol.acetato and Trans-4,cis7,cis10 tridecatrieno.1.ol-acetato, at rate 1:1,5) on PTM male captures. The results showed that the pheromone capsules loaded with lower rates (0.2 and 0.5 mg.), captured higher numbers of male moths per trap. Mass trapping technique studies will be continued to optimize the rate of pheromone per trap in order to offer a non-chemical and environmentally safe method of control of PTM.

The efficacy of coloured pan traps in sampling local and distant hover-fly (Diptera: Syrphidae) populations.

E Laubertie, SD Wratten
National Centre for Advanced Bio-Protection Technologies, PO Box 84, Lincoln University, Canterbury, New Zealand; laubere2@lincoln.ac.nz.

Coloured traps are frequently used to attract and catch insects, such as in the monitoring of populations of beneficial insects in 'classical' or 'conservation' biological control. They are also used in the evaluation of the recovery of insect populations after disturbance. However the fact that traps may be visible to the insects over a considerable distance can influence the interpretation of catch data. In this work, traps consisted of two-litre plastic containers which were filled with water, detergent and a preservative. They were placed in a randomised block design in a 30m × 50m area of bare soil. The treatments were: inner and outer containers yellow; inner container yellow and outer green; both containers green. The hypothesis tested was that completely yellow traps would attract flies from a distance, while yellow/green traps would catch flies from above. Green traps were controls. *Melanostoma fasciatum* was the commonest species in each treatment, with twice as many captured than *Melangyrna novaezelandiae*. For both species, the largest number of hover flies was trapped in completely yellow traps, an intermediate number in green and yellow traps and the lowest number in green traps. It is suggested that if hoverfly numbers relating to a particular distance along a transect are required, consideration should be given to the ability of hoverflies to see yellow traps from a distance. Traps, which are green outside, would be more appropriate to reflect the local abundance of hover flies.

Managing soil insect pests of potatoes in Australia

S Learmonth, M Cannard, S De Faveri, J Duff, H Fay, P Horne, S Lanz, R Spooner-Hart, R Storey, S Trainer
Manjimup Horticultural Research Institute, Locked Bag 7, Manjimup, WA, 6258, Australia; slearmonth@agric.wa.gov.au

Soil insect pests consisting of a range of species of beetles and one species of aphid, the rice root aphid (*Rhopalosiphum rufiabdominalis*), have the potential to reduce yield and quality of Australian potatoes. A national collaborative project in the major potato growing regions is studying methods of monitoring these insects so farmers can introduce pest reduction practices on a needs basis. Some of the soil pests have not been identified, so a second objective of the project is to expand the known list of soil insect species that can affect potato crops. To date, monitoring methods involving pre-crop soil sampling for whitefringed weevil (*Naupactus leucoloma*) and African black beetle (*Heteronychus arator*) have proven to be of high order reliability in providing advice to farmers whether treatment is required to protect crops. For African black beetle, light traps are a useful warning tool for pest invasions of growing crops. For potato wireworm (*Haptesus hirtus*), baiting with potato tuber pieces has been shown to be an effective method of assessing insect distribution and abundance. The main insects whose identification is yet to be clarified include cockchafers and wireworms. We hope to reduce the pest status of soil insects in Australia's potato crops by producing a guide for farmers and crop scouts on pest identification and monitoring methods.

Occurrence, infection and research advancement of the vegetable leafminers in China

ZR Lei, Y Wang
Institute of Plant Protection, Chinese Academy of Agricultural Science, 2 West Yuanmingyuan Weat Road, Beijing 100094, P.R. China;
leizhr@publica.bj.cninfo.net

Liriomyza sativae and *L. huidobrensis* are two serious pests among four species of leafminers infested vegetables in China. Our investigation showed that their host plants infer to more than 20 families, 100 species, even including barley and wheat. The biology, such as adult eclosion, emergence from soil, feeding and oviposition, migration and dispersal, larval feeding and so on, of both *L. sativae* and *L. huidobrensis* was investigated systematically. Effects of temperature on development, mortality, fecundity and longevity of the two leafminers were examined in the laboratory. Overwintering and cold-hardiness of the pests, which provided basis for evaluating northern limit of overwintering, were also studied. The results showed that both *L. sativae* and *L. huidobrensis* had high productivity and strong adaptability to the environment. A preliminary study on diversity of feeding habits of *L. huidobrensis* revealed that the activities of carboxylesterase and acethylcholines increased with the adaptation of *L. huidobrensis* to wheat. We also investigated the parasites of the vegetable leafminers in China and found more than 30 species of parasites, of which the eulophid and braconid wasps are the main species. According to our study results we designed an integrated control protocol for the vegetable leafminers in China.

Influence of vineyard floor vegetation on the abundance of winged natural enemies

AD Loch
National Wine and Grape Industry Centre, Locked Bag 588, Charles Sturt University, Wagga Wagga, NSW, 2678, Australia;
andrew.loch@agric.nsw.gov.au

According to Conservation Biological Control, vineyards with vegetated floors should have greater numbers and performance of natural enemies than those with cleared floors because more resources like food and shelter are available. The influence of vegetated and cleared vineyard floors on winged natural enemies is being studied by evaluating sticky trap catches of insects at floor and canopy levels. Initial results show that both numbers of species and total numbers of potential natural enemies of grapevine pests were significantly higher in traps on a vegetated floor than a cleared floor. Canopy catches were significantly lower than floor catches and unaffected by floor treatment. Trap catches of most wasp species and the ladybirds *Diomus notescens* and *Hippodamia variegata* were significantly higher from the floor than in the canopy. Catches of the ladybirds *Harmonia conformis* and *Coccinella transversalis*, and several wasp species were significantly higher in canopy traps than floor traps. Inter-row vegetation increased numbers of natural enemies in vineyards but natural enemy activity was concentrated on the floor and not in the canopy indicating that commensurate increases in grapevine pest control are unlikely. Differences in species composition between canopy and floor traps highlight different patterns of flight and resource use by natural enemies.

Pheromones of *Crocidosema plebejana* (Lepidoptera: Tortricidae), *Creondiates dilutus* (Hemiptera: Miridae) and *Earias huegeliana* (Lepidoptera: Noctuidae),

S Lowor, P Gregg, A Del Socorro, C Moore
School of Rural Science and Agriculture, University of New England, Armidale, NSW 2351, Australia; slowor@metz.une.edu.au slowor@metz.une.edu.au

Extensive cotton growing areas in Australia are occasionally affected by pests like *Crocidosema plebejana*, *Earias huegeliana* and *Creontiades dilutus*. We have identified the major sex attractant pheromone components for these species from effluent air surrounding calling females, and pheromone gland contents, by GC-MS. We conducted studies using Delta traps arranged in Latin Square designs to determine optimum attractive blends for all three species. This poster will compare the results with closely related species from other countries and discuss the prospects of using the optimised blends to monitor and forecast outbreaks of these pests

Technology development for fruit fly detection and exclusion programs

SD McCombs
USDA APHIS PPQ CPHST Fruit Fly Genetics and Management Laboratory, 41-650 Ahiki Street, Waimanalo, HI 96795 USA;
Sue.D.McCombs@aphis.usda.gov

Fruit flies in the family Tephritidae are among the most destructive insect pests in the world. In countries where pest fruit flies are present, the negative economic impact results not only from the direct costs of crop damage and control activities, but also from limited access to market agricultural commodities in non-infested countries. Fruit fly detection and exclusion programs in the United States are supported by the United States Department of Agriculture, Animal and Plant Health Inspection Service, Center for Plant Health Science and Technology (CPHST). An overview of the technology development activities of CPHST laboratories in Florida, Guatemala, Hawaii, and Texas will be presented. These activities include: 1) technology for Mediterranean and Mexican fruit fly suppression programs that improve mass production and enhance field performance of males in the sterile insect releases; 2) integration of biological control and sterile insect releases for suppression of the Mediterranean fruit fly; 3) validation of new trapping and bait station technologies for APHIS, state and international fruit fly detection programs; and 4) molecular diagnostics for determining the population origin of exotic fruit flies detected in the United States.

Behavioural control of the boll weevil through BWACT in cotton farms in the northeast of Brazil

JE Miranda, CAD Silva
Embrapa Algodão, CP 714, 74001-970 Goiânia, GO, Brazil; miranda@cnpa.embrapa.br

The boll weevil, *Anthonomus grandis*, is the most important pest of cotton in the Brazilian Northeast and could cause significant losses in the production. The Boll Weevil Attract and Control Tube (BWACT) have been used by the producers as tactic of behavioural control. Because of their located and specific control, this method is considered an appropriate tool to the concepts of Integrated Pest Management (IPM), working as alternative to the chemical control. This study sought to evaluate the use of such devices in the control of the boll weevil in areas of cotton farms in the Brazilian Northeast. In comparative experiments among conventional management (where the use of the chemical control prevails), IPM, and their interactions with the use of BWACT, smaller number of applications of insecticides was verified for the control of the insect in areas in that it was allied MIP plus BWACT. The device was efficient on the control of the boll weevil when installed at the planting time. The BWACT reduced remaining populations of the insect after the stalk destruction. The adoption of IPM plus BWACT resulted in larger liquid incomes than the non adoption of IPM and the non use of the device..

Recording the occurrence of the bean bug by an automatically counting trap, "Altered Mushidas", baited with synthetic attractants of the bugs

S Moriya, N Mizutani, K Tabuchi, Y Nishimoto
National Agricultural Research Center, 3-1-1 Kannondai, Tsukuba, Ibaraki 305-8666, Japan; moriya@affrc.go.jp

The bean bug, *Riptortus clavatus* (Thunberg) (Heteroptera: Coreidae), is one of the major soybean pests in Japan. Since the adults invaded into the soybean field, monitoring of their movement is essential to control them. A *Mushidas* is an automatically counting trap equipped with wireless communication tools, originally developed for monitoring the occurrence of the lepidopreran pests baited with their synthetic sex pheromone. We improved the *Mushidas* attaching the collision board in the upper part of its body so as to catch the bean bug effectively by using synthetic attractants of the bug. The whole body was painted in green because a preliminary experiment showed that numbers of other insects caught were significantly fewer in the green trap than those in the white and yellow ones. Three sets of the trap were installed in the soybean field, and they were proved to continuously work for about 5 months with the records at an interval of 15 min. It was found that the most of the bugs were caught in the daytime, having no clear peak. Those traps might be able to monitor the occurrence of the bugs earlier than the conventional water pan traps.

The biology and management of the Madeira mealybug, *Phenacoccus madeirensis*

JH Chong, RD Oetting
UGA/CAES/Griffin Campus, 1109 Experiment Street, Griffin, Georgia 30223, USA

The Madeira mealybug has become a major problem on greenhouse grown ornamentals with control failure in many greenhouse operations. Experiments were conducted to determine the developmental biology of Madeira mealybug and efficacy of most available insecticides against this pest. Using chrysanthemum as the host plant, the total duration of development of Madeira mealybug was 66 days at 15°C, 46 days at 20°C, and 30 days at 25°C. More than 75% of eggs completed development to adult. The proportion of females in a given population was about 0.5. The insecticides acephate and bifenthrin and the growth regulators kinoprene and buprofezin where the most efficacious. The natural enemies, *Anagyrus loecki* and *Diomus austrinus*, were explored as potential biological control agents. The biggest management problem was associated with good spray coverage and the behavior of the insect to hide in difficult to reach places on the plant and to move to the pots and benches to hide.

Pest management in Honduran subsistence maize production: contribution of training, agro-landscape composition and region-specific pest pressure

KAG Wyckhuys, RJ O'Neil
Department of Entomology, Purdue University, 901 W. State Street, West Lafayette, IN 47907-2089, USA; kris_wyckhuys@entm.purdue.edu

A major pest in Honduran maize production is the fall armyworm (FAW), Spodoptera frugiperda. To manage pest outbreaks, small-scale farmers tend to rely on unsustainable practices, including improper use of pesticides. In the past, various institutions have conducted IPM extension programs to alter farmers' pest management. Despite those efforts, a formal impact assessment yet needs to be conducted and obstacles for IPM adoption await identification. IPM packages for subsistence agriculture consist partly of manipulating the pest's natural enemies. Since most natural control agents have ecological requirements beyond the field edge, success of IPM largely depends on the agricultural landscape. We assessed IPM adoption through farmer surveys. Surveys were conducted in communities with differing IPM training history and pest pressure. We evaluated farmers' agro-ecological understanding, knowledge and its influence on pest management behavior. Secondly, we quantified opportunities for efficient FAW management existing within the agro-landscape. Pest pressure and natural control were linked to the composition of the agricultural landscape and back-crossed to farmers' pest management. Farmers base their pest management on an overall appreciation of agro-ecology and FAW pest-pressure. Farmers' agro-ecological understanding is influenced by perceptive experience and traditional knowledge. Agro-landscape composition strongly affects the assemblage of generalist predators and parasitoids responsible for natural FAW control.

Integrated pest management to control California red scale *Aonidiella aurantii* (Maskell) in the Mediterranean area (Sardinia, Italy)

S Ortu, A Cocco, G Delrio, A Lentini
Department of Plant Protection, via E. De Nicola 07100 Sassari, Italy; ortusal@uniss.it

In Sardinian citrus groves, the use of *Aphytis melinus* DeB. and *Chilocorus bipustulatus* (L.) alone has not allowed to keep infestations of California red scale *Aonidiella aurantii* (Maskell) under the economic threshold. The use of a prediction phenological model, based on growing degree-day accumulation between the peaks of males flight and the highest density period of crawlers (100 and 250 °D accumulate in temperatures between 11.7 °C and 37.8 °C), allowed us to determine the optimal time for effective applications, to reduce chemical treatments and to apply low environmental-impact insecticides. In addition, specific surveys on within-tree spatial distribution of California red scale on orange trees were conducted, to determine the most infested parts of the canopy from which the insect spreads throughout the tree. Pruning the heavily infested twigs allowed to reduce the centres of infestation of *A. aurantii* population, to create unfavourable microclimatic conditions for population development and to reduce population density using low environmental-impact insecticides. These integrated control strategies were effective for both California red scale infestation control and protection of its natural antagonists *A. melinus* and *C. bipustulatus*. Research conducted in the MiPAF plan "Search and experimentation in the Italian citrus cultivation" publication

Sirex noctilio in Chile operational program for detection and control in the Arauco companies

MA Poisson, R Ahumada
Bioforest S.A. Casilla 70-C, Concepción, Chile; mpoisson@arauco.cl

Sirex noctilio was detected close to commercial plantations of *Pinus radiata* in Chile by 1999. This regulated pest is being monitored by the Plant Health Agency (SAG) over affected areas in the south of Chile. Radiata pine supports the forest industry of Chile, with US$ 2.218 million of total export in 2003. The government and private companies have now implemented a program for the early detection of *Sirex* over previously unaffected areas. Arauco is the largest forestry company in Chile, with 500.000 ha of Radiata pine plantations. About 370,000 ha are considered to be at risk to *Sirex* attack. Stands of Radiata pine are being classified in different levels of risk to *Sirex* establishment by means of a GIS system. The criteria to define stand susceptibility to *Sirex* were: silvicultural management, site index, age, average diameter, density, and distance of declared focus. The information generated by the GIS analysis was used to assist trap tree plots placement in Arauco plantations. A total of 340 trap tree plots were established over the main risk stands thus far. These plots included trials with different herbicides (Dicamba, Tryclopyr and Gliphosate), with aims to optimize the trap tree system in Chile.

Effects of regulatory pressures on pesticide use in New Jersey peach production

DF Polk, P Cottingham
Rutgers Fruit R&E Center, 283 Rt 539, Cream Ridge, NJ 08514, USA; polk@aesop.rutgers.edu

New Jersey peach growers regularly participate in a cooperative extension fruit integrated pest management program. Grower pesticide use records are annually collected from program participants. In 1997 an Access database was created as a repository for all IPM data. Pesticide use was analyzed for 1998 through 2003. All participating farms are profiled within the database, permitting accurate records of acreage, cultivar, and location. A 'back end' data file was created listing all pesticides used by material (trade) name, active ingredient (ai), % ai, chemical class, function type, and a standard retail price. Queries were designed to generate individual grower reports and analyze area and statewide pesticide use. Queries analyze by material name or ai, and track total use per acre, rate per acre, number of applications used, and the % of total crop acreage the pesticide was used on. In 1998 organophosphates (OP's) esp. azinphos-methyl (AZM) were the most commonly used materials, while synthetic pyrethroids (SP) showed only minor use. By 2003 the number of AZM applications decreased by 30%, while SP applications more than doubled. Changing trends were also seen with other materials, especially oil, neonecotines, and other OP's.

IPM of *Tanymecus dilaticollis* on maise in Romania

C Popov, A Barbulescu, S Vasilescu, C Spiridon
915200 Fundulea-Calarasi, ICDA Fundulea, Romania; fundulea@ricic.ro

Maize, cultivated over three million ha is one of the most important crops in Romania. The crop technology involves complex protection measures vs. pests and pathogens. The greatest damage is produced by *Tanymecus dilaticollis* attack even from the emergence. In order to avoid this damage or total crop spoiling, the adoption of a complex system based on seed treating is necessary, as follows:

- for areas where the preceding crop was a winter spike cereal, vetch-oats mixture, bean, soybean, pea or linseed, the chemical treatments are not indicated, because the density registers low values till 3 individuals/m^2;
- if the preceding crop was maize, sunflower, sugar beet or sorghum, the maize seed treating is recommended with the following ingredient: carbofuran (8,750 g.a.i/t seed), thiamethoxam (3,150 g.a.i/t), imidachloprid (4,800 g.a.i/t), bensultap (12,500 g.a.i/t).
- in the case in which, after plant emergence, there are favourable climatic conditions for pest appearance, the application of one correction treatment during vegetation is recommended on seed areas treated with: thiamethoxam (25,0 g.a.i/ha), t

A research team approach to solving strawberry pest problems in Florida

SI Rondon, JF Price, DJ Cantliffe
1301 Hull Road, Fifield Hall, Gainesville, FL 32611; srondon@mail2.ifas.ufl.edu

Florida produces winter, fresh-market strawberry fruit on about 2800 ha. valued at over $170 million annually. The fruit are produced in a environment hosting numerous damaging arthropod, nematode, and weed pests and diseases including twospotted spider mite (*Tetranychus urticae* Koch), melon aphid (*Aphis gossypii* Glover), strawberry root aphid (*Aphis forbesi* Weed), fall armyworm (*Spodoptera frugiperda* J.E. Smith), southern armyworm (*Spodoptera eridania* (Stoll)), nitidulid sap beetles, *Drosophila* sp. fruit flies, *Frankliniella* spp. thrips, root knot nematode (*Meloidogyne hapla* Chitwood), sting nematode (*Belonolaimus longicaudatus* Rau), gray mold (*Botrytis cinerea* Pers.), powdery mildew (*Sphaerotherca macularis* (Wallr. Ex Fries) Jacz.), anthracnose (*Colletotrichum* spp.), angular leaf spot (*Xanthomonas fragariae* Kennedy and King) and numerous weeds. The University of Florida has assembled an interdisciplinary team of entomologists, nematologist, plant pathologists, weed scientist, and a breeder who are developing and refining integrated approaches for management of these pests. The team approach will be presented.

Weeds and native vegetation as hosts for pest and beneficial thrips (Thysanoptera) in a horticultural landscape

GM Wood, NA Schellhorn
South Australian Research & Development Institute, PO Box 397, Adelaide, South Australia, 5001, Australia; wood.glenys@saugov.sa.gov.au

Revegetation programs have not progressed in the main horticulture-producing region of South Australia because of perceptions that native plants harbour pest thrips of horticultural plants. To determine the distribution and abundance of thrips, we sampled flowers from twenty-two species of weeds and twelve species of native plants at monthly intervals for a year. *Frankliniella occidentalis* was found on all species of weeds sampled throughout the year. *Thrips tabaci* and *F. schultzei* were found on most species of weeds. At least one of these thrips was more likely than not to be found on weeds in the Brassicaceae, Solanaceae, Malvaceae or Zygophyllaceae. However, these pest thrips were only found on four species of native plants, and infrequently. *Thrips imaginis*, a native thrips, was found on all species of weeds and native plants sampled, but was more likely to be found on plants greater than 100 m from crops than on plants less than 10 m from crops. *Haplothrips victoriensis*, a predatory thrips, was most frequently found on weeds in several plant families and rarely on native plants. These results suggest that pest management can be improved by replacing weeds with native plants that do not harbour pests of horticultural crops.

Overwintering of *Heliothis virescens* (F.) and *Helicoverpa zea* (Boddie) (Lepidoptera: Noctuidae) in cotton fields: implications for pest and resistance management

JC Schneider
Box 9775, Mississippi State, MS 39762 USA; jschneider@entomology.msstate.edu

Following the 1995-2001 crop seasons, population densities of pupae of tobacco budworm (TBW), *Heliothis virescens* (F.), and corn earworm, *Helicoverpa zea* (Boddie), overwintering in cotton fields in Monroe County, Mississippi, USA, were estimated by digging a total of 43,542 m-row. The total, area-wide TBW population emerging from all overwintering sites was estimated from catches in pheromone traps whose absolute efficiency is known. Before introduction of *Bacillus thuringiensis* Berliner (*Bt*)-transgenic cotton in 1996, cotton fields are estimated to have typically accounted for less than 10% of the total, overwintered TBW population. During 1996-1999, cotton fields accounted for less than 2% of overwintered TBW. During 2000-2001, the contribution of cotton fields to overwintered TBW remained low despite a dramatic increase in use of herbicide resistant (*HR*)-transgenic cotton cultivars starting in 2001. Consequently, preemptive tillage of cotton fields to kill overwintering TBW pupae would not appreciably suppress in-season population densities of this pest. However, given that movement is short-range during the crop season and fall generations, overwintering TBW pupae resistant to insecticides or counteradapted to host plant resistance traits [e.g. (*Bt*)-transgenic cotton] should be concentrated in cotton fields. Failure to destroy these pupae by tillage would reduce the time to control failure.

Managing *Helicoverpa* spp. on cotton with semio-(signalling) chemicals

E Wang, A Singleton, C Moore, R Mensah, Dr H. Dang
NSW Agriculture, Australian Cotton Research Institute, Locked Bag 1000, Myall Vale, Narrabri, NSW 2390 Australia; angela.singleton@agric.nsw.gov.au

This study is focused on the non-volatile chemical components of organ surfaces of cotton and alternative host plants that influence acceptance or rejection of such plants by adults and larvae of *Helicoverpa* spp. Solvent extracts of both leaf surfaces and whole leaf homogenates of three cotton genotypes, as well as plants used as trap and refuge crops in *Helicoverpa* spp. management, were assessed for bioactivity towards both adult and larvae of *Helicoverpa* spp. in the laboratory. Different specific bioactivity properties have been demonstrated in crude extracts of the various plants. Bioassay-directed fractionation of the extracts using solid phase extraction methodology was followed by analysis and compound isolation by HPLC, with a view to identifying particular compounds responsible for the bioactivity. A leguminous plant, herein referred to as Plant X, has shown oviposition and feeding deterrence towards *Helicoverpa* spp. Two potential deterrent chemical compounds in Plant X have been isolated and identified. Most of the active fractions in all plants contain compounds showing UV spectroscopic properties characteristic of flavonoids and/or flavonol glycosides. We conclude that natural chemical tools for the modification of insect behaviour could be an important tool in an integrated pest management program targeted at *Helicoverpa* spp. in cotton.

The tobacco budworm, *Heliothis virescens* (F.), in North Carolina tobacco: decommissioning a prominent pest?

CE Sorenson, PS Southern, TR Juba, E Kennedy, MR Abney
North Carolina State University Department of Entomology, P.O. Box 7630, Raleigh, NC USA 27695-7630; clyde_sorenson@ncsu.edu

The tobacco budworm, *Heliothis virescens* (F.), has long been regarded as a key pest of tobacco in North Carolina and other areas in the southeastern United States. This insect causes at least two main types of damage: defoliation of expanding leaves (the far more common type of damage), and destruction of the apical meristem of the plant. Historically, the threshold for the tobacco budworm in North Carolina has been 10 % infested plants. Flue-cured tobacco crops in the eastern part of the state have averaged about 1.5 insecticide applications a year for control of this insect. A growing body of evidence assembled over the last 7 years suggests that the tobacco budworm's ability to compromise tobacco yield and quality in North Carolina is far lower than previously thought. The critical form of damage is destruction of the apical meristem, which is a relatively rare event in the field. In light of this evidence, the threshold for this insect will likely be raised substantially. This action should substantially reduce insecticide use in North Carolina tobacco.

Flight pattern of the overwintering generation of *Archips podana* (Lep.: Tortricidae) based on data from pheromone traps

J Stará, F Kocourek
Research Institute of Crop Production, Drnovská 507 – Prague 6 – Ruzyně, 161 06, Czech Republic; stara@vurv.cz

In 1993 – 1999 and 2002 – 2003 the flight activity of *Archips podana* was investigated by pheromone traps placed in four apple orchards in Central and East Bohemia. The course of the flight activity of *A. podana* was expressed in relation to calendar dates and biological time (degree-days) and the effects of pest control strategies and weather conditions on total catches were determined. The cumulative catches of *A. podana* males were plotted against time of the catch expressed in sum of degree-days (DD) above 10 °C and approximated by Richards´ function. The common parameters of Richards´ function could be found for the overwintering generation of *A. podana* from all localities. The reasonable predicting of the beginning, the peak and the end of the flight activity of the overwintering generation of *A. podana* population in Central and East Bohemia was ascertained. The flight activity of *A. podana* started at 200 DD (5% catch), median catch (50% catch) was at 320 DD and the flight ceased at 420 DD (85% catch).

Arthropod pest management in Christmas trees in the Pacific Northwest

JD Stark, A Antonelli, G Chastagner
Washington State University, 7612 Pioneer Way East, Puyallup, Washington 98371;
stark@puyallup.wsu.edu

Several arthropod pest species attack commercial Christmas trees in the Pacific Northwest United States. We have been evaluating various control agents for several pests that Christmas trees. In particular, we have focused on root aphids, adelgids and eriophyid mites. The insecticide, Aphistar has been found to be a particularly effective control for root aphids. Aphistar is applied to foliage and when applied at a rate of 8 oz. product /acre, controls these root pests for up to 6 weeks on Noble fir. A new insecticide, Acetamidprid was evaluted for control of adelgids. Acetamidprid applied to foliage at rates of 0.05 lb ai/100 gallons water and 0.1 ai/100 gallons water provided excellent control of adelgids on Douglas fir. Thiodan and Mesa were evaluated for control of an eriophyid mite, *Nelepella longoctonema* on Noble fir. Thiodan was the most effective product, but Mesa also provided control of this species. Although we have focused on pesticides for control of Christmas tree pests so far, our goal is to develop integrated pest management for pests attacking Christmas trees that will integrate selective pesticides and biological control.

Regional integrated pest management centers in the United States

RE Stinner, SJ Toth Jr.
Department of Entomology, North Carolina State University, Raleigh, NC 27695-7613 USA; Steve_Toth@ncsu.edu

The United States Department of Agriculture's Cooperative States Research, Education and Extension Service funds four geographically-based Regional Integrated Pest Management (IPM) Centers (North Central, Northeastern, Southern and Western) to promote regional collaboration among universities in IPM research, education and regulation. Objectives of the Regional IPM Centers include: 1) organizing and maintaining multi-state IPM information networks; 2) involving stakeholders in identifying IPM needs and priorities within the regions; 3) managing regionally-based IPM grant programs; and 4) facilitating the development, review and communication of scientific and regulatory documents concerning IPM. The Southern Region IPM Center at North Carolina State University serves as a repository for IPM information from all four regions of the United States. More than 600 "crop profiles" (i.e., pest management profiles for U. S. agricultural crops generated by university scientists with funding from the Regional IPM Centers) are maintained in a searchable database on the World Wide Web (http://pestdata.ncsu.edu/cropprofiles/cropprofiles.cfm). Information on the Regional IPM Centers is available at the following website: http://www.ipmcenters.org.

Development and implementation of integrated pest and disease management (IPDM) in prune orchards in Australia

WG Thwaite, DK Knihinicki, SP Marte
NSW Agriculture, Orange Agricultural Institute, Forest Road, Orange, NSW, 2800, Australia; graham.thwaite@agric.nsw.gov.au

Prunes (*Prunus domestica*) are grown in three areas in southern Australia. A study from 1999/2000 to 2002/2003 on 12 representative prune orchards in two areas in New South Wales identified the main pests as *Aculus fockeui* (Nalepa & Trouessart) (Acarina: Eriophyidae), *Tetranychus urticae* Koch (Acarina: Tetranychidae), *Quadraspidiotus perniciosis* (Comstock) (Hemiptera: Diaspididae) and *Maroga melanostigma* (Wallengren) (Lepidoptera: Oecophoridae). Main diseases were prune rust, caused by the fungus *Tranzschelia discolor* Tranzschel & Litv. and brown rot (*Monolinia* spp.). IPDM techniques were introduced to manage the pest and disease complex. Eight species of predatory mites (F. Phytoseiidae) were endemic in Murrumbidgee Irrigation Area orchards and two species in the Young area. Successful biological control of pest mites was demonstrated. Winter application of 2% dormant oil, with or without 1% horticultural mineral oil sprays timed to coincide with the first generation of crawlers was proposed as an IPDM alternative to the organophosphate insecticide methidathion for *Q. perniciosis*. Biological control of *M. melanostigma* is the subject of a separate study. Neither prune rust nor brown rot were serious problems during the investigation and were successfully managed with protective fungicides. Implementation of IPDM was promoted through workshops held in each of the three growing areas.

The suitability of different plants as food sources for larvae of garden weevil, and fuller's rose weevil.

SM Trainer, S Learmonth
Manjimup Horticultural Research Institute, Locked Bag 7, Manjimup, WA, 6258, Australia; strainer@agric.wa.gov.au

Garden and Fuller's rose weevil are pests of deciduous fruit orchards in Western Australia. Damage by these weevils includes poor orchard establishment, fruit downgrading, defoliation and blocking of mini-sprinklers. Methods of control are limited to the adults through the application of broad-spectrum insecticides. Disadvantages of which include inconsistent control, potential to cause secondary pest outbreaks and insecticide residues on fruit. A new research project examined the role of ground cover plants common in orchard interrows on the survival and growth of the soil dwelling larval stage. The aim was to identify suitable plants to reduce the abundance of the weevil larvae. This research was based on pot trials and single plant species. For garden weevil, survival on subterranean clover was very poor either from being an unsuitable food source or antibiotic activity. Subsequent research clarified clover as an unsuitable food source when grown with a commercial crop. The research protocol for assessing plants now includes a combination of a tree crop and a ground cover species.

Aphaereta debilitata **(Hym., Braconidae) as a biocontrol agent of the shore fly** *Scatella tenuicosta* **(Dipt.: Ephydridae)**

I Vanninen, M Linnamaki
Agrifood Research Finland, Fin-31600 Jokioinen; Irene.Vanninen@mtt.fi

The biological parameters of *Aphaereta debilitata* were determined and the parasitoid's efficacy tested in cages to assess the species' potential in controlling *Scatella tenuicosta*, a cosmetic pest of potted herbs, lettuce and seedlings in greenhouses. *Aphaereta debilitata* appears to be a solitary koinobiont endoparasitoid of *S. tenuicosta*. At constant 25^{o}C, females preferred host larvae of the age of 1 or 2 days to those that were <1 or 3 days of age at the time of parasitization. With continuous access to hosts, females lived 6.4 + 0.3 (s.e.) days, peaking their progeny production on day four at 43.5 daughters and sons. Life time progeny production was 215 (48% females). Males developed into adults in 13.0 ± 0.3 days, females in 14.0 ± 0.03 days. The intrinsic rate of increase of *A. debilitata* was 0.261 day^{-1}, the net reproductive rate R_0 was 85.3 female offspring per female, and generation time T was 5.6 days. In insect cages, the application of a total of 2.35 *A. debilitata* females per 8 x 8 cm peat pot at 4-6 days intervals resulted in control efficacy of 70-92 %, based on adult fly counts per pot every four days during the four week experiment.

The efficacy of three soil-living predatory mite species as predators of thrips pupae

M Linnamaki, I Vanninen
Agrifood Research Finland, Fin-31600 Jokioinen; Irene.Vanninen@mtt.fi

The predatory mites *Geolaelaps aculeifer* (a Queensland population GAQ, and a commercial population), *G. queenslandicus* and *Lasioseius* sp. were compared as predators of *Frankliniella occidentalis* pupae in peat pots using predator:prey ratios 2, 1, 0.5 and 0.25. The experiment was repeated three times. During 10 days, the commercial *G. aculeifer* had a control efficacy of 97.6% and 95,8% with predator:prey ratios of 2 and 1, respectively, followed by GAQ with efficacies of 91.2% and 88.6%. The control efficacy of *G. queenslandicus* was between 33.9% and 74.3% for all predator:prey ratios, and that of *Lasioseius* sp. between 41.5% and 70.9%. The predation rates of female GAQ and *G. aculeifer* were further compared on charcoal-Plaster of Paris arenas. During five days, GAQ-females killed 13,8 ± 3,14 pupae per day, and those of *G. aculeifer* 13,5 ± 3,22 (std) pupae per day. GAQ, however, laid statistically fewer eggs per day (4.4 ± 1.44) than *G. aculeifer* (5,0 ± 1,50). These short-term experiments with fixed prey densities need to be complemented with long-term experiments to see if differences in development times and reproduction rates of the mites are reflected in their long-term ability to suppress the prey in a manner different from the short-term experiments.

A rapid method in laboratory to screen resistance of potato plants against *Myzus persicae*

V Le Roux, C Vincent, J Saguez, P Giordanengo
Horticulture Research and Development Centre, Agriculture and Agri-Food Canada, 430 Gouin Blvd., Saint-Jean-sur-Richelieu, Qc, Canada J3B 3E6;
vincent.leroux@u-picardie.fr

In the objective to develop potato resistance against aphids, we propose a rapid screening method with *Myzus persicae* (Sulzer) in laboratory. Our study focussed on two objectives, i.e. to optimize the duration of the whole procedure and to decrease the frequency of measurements. In a first experiment, no significant differences were observed between intrinsic rate of natural increase (r_m) values of adult aphids reared throughout their entire life and adults reared only during a period equivalent to their pre-reproductive period. In a second experiment, four groups of aphids were distinguished according to the sampling frequency, i.e. those whose biological parameters were evaluated every single, second, third and fourth day. Except for the fourth day experiment, the r_m values estimated every single, second and third day were not significantly different for all potato lines. Thus screening efforts in laboratory can be largely optimized by checking adult aphids only during a period equivalent to their pre-reproductive period and assessing *M. persicae* populations every third day. Our method is reliable and adapted to screen a large number of potato plants against *M. persicae* as it leads to an average 70% reduction in the time required for the whole experimental process. Our laboratory screening method must be complemented with a field screening program.

Granulovirus for management of codling moth, *Cydia pomonella* L. (Tortricidae)

C Vincent, L Lacey, J Cossentine
Horticultural Research and Development Centre, Agriculture and Agri-Food Canada, 430 Gouin Blvd., Saint-Jean-sur-Richelieu, Qc Canada J3B 3E6; vincentch@agr.gc.ca

Codling moth granulovirus -based insecticides were assessed in apple orchards in Washington State, USA, British Columbia and Quebec, Canada, against *Cydia pomonella* L. (Tortricidae). In all studies, the virus provided effective control of neonate codling moth. CydX, Virosoft CP4, and Carpovirusine were assessed in orchard trials. All treatments remained significantly effective after 14 days. When Virosoft CP4 was applied alone and with Surround (kaolin), seven sprays of Virosoft CP4 provided adequate codling moth control and Surround did not increase the pathogenicity of CP4. In semi-field trials, significantly higher codling moth mortality was recorded after neonates fed on apples from trees treated with the virus compared to untreated apples up to one and eight days post-treatment with Carpovirusine and Virosoft CP4, respectfully.

IPM of *Xyleborus fornicatus* Eichh. (Coleoptera: Scolytidae), the shot-hole borer of tea in Sri Lanka

RS Walgama
Division of Entomology, Tea Research Institute, Talawakelle, Sri Lanka; sampathwalgama@hotmail.com

The shot-hole borer first recorded in 1892 is one of the most destructive pests of tea grown in Sri Lanka at altitudes between 150m to 1350m. The concealed habit of this pest makes it notoriously difficult to control. The pesticide approach using persistent organochlorine, DDT in 1940 and its successors like endrin, aldrin and dieldrin, lead to secondary outbreaks of other minor pests like Twig & looper caterpillars. This led to the development of the concept of IPM in tea production in parallel to the trend all over the world in 1970's. The elements of IPM include the use of varietal resistance, an escape strategy where pruning is done to avoid the overlap of the susceptible primary branch stage of the plant with peak colonization period of the beetle, sanitation pruning to reduce the wood rot in subsequent cycles with limited use of fenthion (Lebycide®), an organophosphate insecticide currently in recommendation. Biological control has not been successfully employed against the pest but recently there were some indications that the fungus *Beauvaria bassaiana* could be used effectively in controlling the beetle and hence, another prospective tactic for the IPM programme in the future.

Morphological and cytological changes in leaves of cucumber and tomato injured by western thrips, *Frankliniella occidentalis* Pergande

B Nawrocka, B Dyki
"Research Institute of Vegetable Crops, 96-100 Skierniewice, Poland. bnawrocka@inwarz.skierniewice.pl"

Direct damages due to feeding of western thrips on plant's juice result from injuring the epidermis and mesophyll. Morphological changes of the epidermis of cucumber leaves are typified by the presence of amorphous structures generated on the surface of the cuticle. The stomatal apparatuses become invisible and the hairs on parts of the disturbed epidermis are subjected to deformation. On under surface of the epidermis instead, a collapse of tissue is observed. Formation of amorphous structures is here present too, but unlike the upper surface, the stomatal apparatuses are opened. Amorphous changes on a tomato leaf injuried by western thrips are decidedly more soft as compared to cucumber, however, the hairs within the reach of the injury are more deformed. Cytological changes in cucumber are visible as necroses. They are generated due to injuring the cells of both the upper epidermis and palisade mesophyll. Extremely, the complex of deformed cells expands from the upper epidermis beginning, through palisade and spongy mesophyll up to the under epidermis. In tomato, at first inconsiderable necroses within the epidermis appear. They can reach as far as palisade or even spongy mesophyll, but allways they are smaller in size, as compared to cucumber.

Modelling winter flight activity of sterile Queensland fruit fly, Bactrocera tryoni (Frogatt) (Diptera: Tephritidae) in Leeton, Australia

GJ Bowman
Yanco Agricultural Institute, PMB Yanco, NSW, 2703, Australia; glenn.bowman@agric.nsw.gov.au

Sterile Queensland fruit fly (Qfly), Bactrocera tryoni (Diptera: Tephritidae), were released across the township of Leeton, New South Wales, Australia, as part of an eradication program. Releases were conducted until mid May 2003 and targeted urban households and adjoining orchards. Although releases did not resume until mid August 2003, sterile males were caught in cue-lure baited Lynfield traps throughout June, July and August. Flies released in autumn are generally able to achieve sexual maturity and remain attracted to cue-lure. Trap records suggest that flight is possible at certain times during winter. This paper examines climatic data for the period June through August 2003 for the Leeton area in relation to modeling flight activity of Queensland fruit fly. Hourly data was corrected for daylight hours, rainfall, wind-chill and tree-canopy wind-drag variables for the period. When corrected only for daylight there was found to be a total of 192 hrs where flight was possible. This was reduced to 136 hrs when further corrected for wind-chill, and to 94hrs including wind-drag corrections. Rainfall events were few and reduced these figures to 179 hrs, 129 hrs and 82 hrs respectively. Wind-chill had the most influence on reducing potential flight periods. These results are discussed in relation to other data formats and behavioural aspects of Queensland fruit fly.

Effect of Body Size on Reproductive Fitness in Aphidius ervi (Hymenoptera: Aphidiidae)

X. Z. He, Q. Wang and D. A. J. Teulon
Institute of Natural Resources, Massey University, Private Bag 11222, Palmerston North, New Zealand, xiong.he.1@uni.massey.ac.nz

Aphidius ervi Haliday is an important parasitoid of several aphid species on economically important crops such as legumes and cereals. To improve its mass rearing and field release efficiency, we studied the relationships between body size and reproductive fitness of A. ervi on pea aphid, Acyrthosiphon pisum (Harris), in the laboratory. Large females lived significantly longer (14.10 ± 0.72 d), had significantly higher searching efficiency (1.50 ± 0.37 10^{-4}min), fecundity (574.25 ± 23.76 eggs) and fertility (338.74 ± 19.41 eggs), and parasitized significantly more aphids (410.70 ± 17.74) than did small females (11.60 ± 0.57 d, 0.97 ± 0.09 10^{-4}min, 302.74 ± 17.61 eggs, 213.39 ± 15.17 eggs and 257.07 ± 14.18 aphids for longevity, searching efficiency, fecundity, fertility and parasitism, respectively). However, fertility rate was significantly higher for small females (0.6923 ± 0.0238) than large females (0.5819 ± 0.0252). Male size was positively correlated with fertility ranging from 246.60 ± 20.43 eggs for small males to 305.53 ± 20.02 eggs for large males, and with fertility rate ranging from 0.5771 ± 0.0276 for small males to 0.6971 ± 0.0199 for large males. Male size had no effect on fecundity and parasitism. Implications from this study were discussed.

Bee-eaters: Ravager of beekeepers but saver of farmers

S. Wongsiri, R. Thapa, and P. Chantawannakul
Department of Biology, Faculty of Science, Chulalongkorn University, Bangkok, Thailand 10330. Email: siriwat.w@chula.ac.th

The wild birds have been offered food and water as a traditional custom in many religious communities in Asia for centuries as well as Australian feed their domestic birds. Just as the expensive name reveals, bee-eaters predominantly eat huge number of insect pests and other invertebrate pests. All insectivorous birds can eat harmful herbivorous insects to keep under control of pest populations in agro ecosystems. Bee-eaters consume a large number of bees causing direct impact on quantity honey production during honey flow season in Thailand (Singh, 1962; Jenn, 1973; Esmaili, 1974; Buys, 1975; Fry, 1984). Mostly they become to be the honeybee pest when *Apis mellifera* was introduced to the country and during the migration seasons of native bees (*A. cerana*, *A. dorsata* and *A. florea*).

Key arthropods for the control of *Epiphyas postvittana* (Walker) (Lepidoptera: Tortricidae) in Coonawarra vineyards, South Australia

C Paull, AD Austin, N Schellhorn
Centre For Evolutionary Biology & Biodiversity, The University Of Adelaide, Sa 5005 Australia, 5064 Australia; email: catherine.paull@adelaide.edu.au

Epiphyas postvittana (Walker) light brown apple moth (LBAM) is indigenous to Australia and a major pest of horticultural crops including grapevines. We conducted studies to identify predatory and parasitic arthropods of LBAM, from Coonawarra vineyards in South Australia and investigate the density-dependant response of key parasitoids to varying host densities of LBAM in the field. Arthropods in Coonawarra vineyards were surveyed for 12 consecutive months using pit-, pan-, sticky-traps and beating techniques. More than 60 species of beneficial arthropods were identified. However few occur in the canopy. The species that attack LBAM include a predatory mite *Anystis baccarum* and four parasitoids. The most dominant parasitoid is a braconid *Dolichogenidea tasmanica* (Cameron) followed by two species of Ichneumonidae and a tachinid *Voriella uniseta*. To evaluate the response of hymenopteran parasitoids to varying host densities we experimentally manipulated the number of larvae in vineyards on three occasions. Our results show that parasitism at the scale of a panel (four grape vines) was inversely density-dependent. Percentage parasitism was 29% and 38% for high and low host densities respectively. Evaluating predation and parasitism will contribute to moving one step closer to integrated pest management of LBAM in Coonawarra vineyards.

Citrus pests and their natural enemies; integrated pest management in Australia – a photographic tour

C. G. Freebairn & D. Smith
Queensland Department of Primary Industries & Fisheries, Maroochy Research Station, PO Box 5083, SCMC, NAMBOUR, 4560; chris.Freebairn@dpi.qld.gov.au

The book 'Citrus pests and their natural enemies; integrated pest management in Australia', and its companion, 'Citrus pests a field guide' were published in 1997. The CD (an updated, html version) 'The Good, the Bug & the Ugly', was published in 2003. These publications represent the state of the art in Australian citrus IPM, distilled from the experience of numerous researchers, field scouts & extension officers. Reviews, local and overseas, have been very favourable, these volumes regarded as exemplifying a highly readable and practical approach to the implementation of IPM. Invariably, reviewers have complemented the quality and variety of the more than 400 colour photographs, many of which show close-ups of live insects in action. In this paper a high impact selection of these photographs, most of which were taken by its authors, will be projected, organised along the same lines as the book. That is - Mites, Ants, Soft scales, Hard scales, Mealybugs, Aphids, Planthoppers & leafhoppers, Cicadas, Whiteflies, True bugs, Moths & Butterflies, Beetles, Katydids crickets & grasshoppers, Flies & midges, Wasps, Thrips, Termites and Spiders. Special emphasis will be given to the beneficials - parasitoids & predators - crucial to the success of citrus IPM in Australia.

Behavioural fever in acridids: potential impact on biological control

J. Brodeur, *R.M. Ouedraogo*
Centre de Recherche en Horticulture, Université Laval, Québec, Qc, Canada, G1K 7P4, jacques.brodeur@plg.ulaval.ca

Arthropods can respond to microbial infection by developing a behavioural fever. We assessed the occurrence of behavioural fever in seven acridid species from different ecological habitats, using three entomopathogenic fungi. Except for one species, all infected insects developed a behavioural fever as their preferred body temperatures were usually higher than those of healthy, uninfected counterparts. The three pathogen species elicited behavioral fever, athough differences were observed among fungus-insect associations. We used the association between *Locusta migratoria* and *Metarhizium anisopliae* to further study the implication of such behaviour on both the host and the pathogen. Variations of thermoregulation regimes affected insect mortality: mortality decreased with increasing duration of thermoregulation, delayed onset of thermoregulation increased mortality, and interruption of thermoregulation was followed by resumption of mycosis. In the absence of thermoregulation, hemocyte concentrations decreased dramatically, along with a colonization of hemolymph by blastospores. The phagocytic activity was hampered in locusts that were not allowed to thermoregulate. We further demonstrated a differential protein expression between thermoregulating and non-thermoregulating locusts. These results indicate that infection-induced behavioral fever is common in acridids and may limit the potential of fungal pathogens as biological control agent under certain ecological conditions.

Release of *Peristenus digoneutis* (Hymenoptera: Braconidae) in Canada for biological control of *Lygus lineolaris* (Hemiptera: Miridae)

A. B. Broadbent, P. G. Mason, J.W. Whistlecraft, H. Goulet and D.R. Gillespie
Agriculture and Agri-Food Canada, 1391 Sandford St., London, Ontario, Canada; broadbentb@agr.gc.ca

This national project targets suppression of *Lygus* spp. in non-cropping and low-intensity situations by releases of the European parasitoid *Peristenus digoneutis* [Hymenoptera: Braconidae], thereby decreasing pest levels in adjacent agricultural crops. Pre-release parasitism by native larval parasitoids, *Leiophron* and *Peristenus* spp. [Hymenoptera: Braconidae], on *Lygus lineolaris* in Ontario, was consistently below 10%. From 2001 to 2003, more than 11,000 *P. digoneutis* from Europe were released on alfalfa in London, Ontario. We monitored parasitoid overwintering, and dispersal and potential non-target hosts. In the lab we have investigated interspecific competition of parasitoids; the acceptance and suitability of non-target mirid hosts including the predatory mirid *Dicyphus hesperus*; and interaction of two biological control agents: an imported parasitoid and the entomopathogenic fungus *Beauveria bassiana.*

Eretmocerus mundus Failure to Control *Bemisia tabaci* on Sage

PG Weintraub
ARO, Gilat Research Center, D.N. Negev, 85280, ISRAEL, phyllisw@volcani.agri.gov.il

Bemisia tabaci (Grennadius) is a serious polyphagous pest of many agronomic and ornamental crops on all continents. Of the herbs grown for fresh-market in Israel, sage (*Salvia officinalis* L.) is a particularly problematic crop due to its susceptibility to whitefly infestations. Studies were conducted to determine the effect of the parasitoid, *Eretmocerus mundus* Mercet (Hymenoptera: Aphelinidae) on *B. tabaci* infesting sage grown in walk-in tunnels. *Eretmocerus mundus* pupae were obtained from a commercial insectary and released at total rates of 10, 20 and 30/m^2. No *E. mundus* parasitized nymphs were found; however, there was natural parasitization by *Encarsia* spp. In contrast, parasitization by *E. mundus* released in neighboring basil tunnels was about 5 – 16%. Laboratory trials to confirm these findings on sage were conducted. Since *E. mundus* lays its eggs under the whitefly nymph, it is suggested that the morphological changes in the nymphs due to the densely hairy leaf surface are responsible for these results.

New opportunities for biological control of olive fruit fly

K. Hoelmer, A. A. Kirk
USDA-ARS European Biological Control Laboratory, Campus International de Baillarguet, Montferrier 34980, FRANCE, khoelmer@ars-ebcl.org

Bactrocera oleae is a key pest of olives in the Mediterranean region and in California. Indigenous natural enemies do not provide adequate control in Europe, and early attempts to introduce parasitoids from South Africa were unsuccessful. Although the fly is often assumed to be native to the Mediterranean region its origin remains an open question. It occurs widely in Africa and Asia where cultivated and wild olives are found but little is known regarding its biology and ecology in wild olives. Previous surveys in Africa early in the 20th century revealed a rich diversity of olive fly parasitoids not present in the Mediterranean basin. Other parts of the fly's range have never been surveyed for natural enemies and it is likely that additional diversity in natural enemies remains to be discovered. Exploration for natural enemies offers an excellent opportunity to examine the genetic variability in populations of the fly, which may help to answer questions regarding the native range of the olive fly. Renewed foreign exploration throughout the range of olive fly was initiated in 2000. African and Asian collections to date have yielded new information on the ecology of olive fly in wild olives, which will be reviewed. Entomopathogens may also have a role in olive fly management.

Importation, host specificity testing, establishment and assessment of *Diversinervus* sp. near *stramineus* Compere (Hymenoptera: Encyrtidae), Kenyan parasitoid introduced for green coffee scale Coccus viridis (Green) in Queensland and northern New South Wales.

D. Smith, D.Papacek and C. Neale
Queensland Department of Primary Industries and Fisheries, Maroochy Research Station, PO Box 5083 SCMC, Nambour, Qld 4560.

The Encyrtid parasitoid *Diversinervus* sp. near *stramineus* Compere, was introduced from coastal Kenya to Australia for the biological control of green coffee scale, *Coccus viridis* Green, infesting citrus, coffee and ornamentals. After quarantine testing against 16 other native and introduced insect scales and mealybugs, *D.*nr.*stramineus* was found to be specific to *C. viridis,* and releases were made throughout Queensland and northern New South Wales. The parasitoid's efficacy was assessed in three citrus blocks in Southeast Queensland and in a coffee block in North Queensland over three-four years. The parasitoid established readily, becoming the dominant natural enemy within 12 months of release, with parasitism levels of up to 80%. *D.*nr.*stramineus* has established throughout Queensland and northern New South Wales, and together with the existing Aphelinid parasitoids, *Coccophagus ceroplastae* (Howard) and *Eurischomyia flavithorax* (Girault and Dodd), and the fungal pathogen, *Verticillium lecanii* (Zimmerman), has reduced *C. viridis* to minor pest status.

Three other parasitoids *Metaphycus baruensis* (Noyes), *Metaphycus stanleyi* Compere and *Coccophagus bogorensis* (Koningsberger), were introduced to quarantine but not successfully reared on *C. viridis*.

Surveillance and control of exotic mosquitoes in metropolitan France

Schaffner F., Besnard G., Chouin S., Karch S., Mathieu B., Rey D. & Guilloteau J.
EID Méditerranée, 165 av. Paul-Rimbaud , F-34184 MONTPELLIER Cedex 4, FRANCE, fschaffner@eid-med.org

Aware of the importation risks of exotic mosquitoes into West European countries, an entomological surveillance has been set up in France. The main risk is the introduction and dissemination of the tiger mosquito *Aedes albopictus* by the used tyre trade. Investigations at the main used tyres importers' sites have permitted the detection of *Ae. albopictus* in France in 1999, then in Belgium in 2000. A second Asian mosquito, *Ochlerotatus japonicus*, as well as a North-American mosquito *Oc. atropalpus* have also been discovered in 2000 and 2003 respectively. *Aedes albopictus* and *Oc. japonicus* are potential vectors of arboviruses (such as West Nile virus) and dirofilariasis. Moreover, *Ae. albopictus* is responsible of an important biting nuisance in all the colonised temperate regions. Aware of this, the French public mosquito control agencies decided in 2001 to stop the expansion of the species and therefore to treat the infested sites. Surveillance and control operations are supported by the French Ministry of Health. Due to the permanent reintroduction risks, the surveillance is extended and an immediate spraying is applied on all the colonised sites. Regular surveys and rapid action should, if not stop, at least delay the settlement in France of exotic potential vectors mosquitoes.

Fungal biopesticides for control of aphids in cotton and grains.

D Cupitt, C Hauxwell, D Holdom
Queensland Department of Primary Industries & Fisheries, Agency for Food and Fibre Sciences, Biopesticides Unit, 80 Meiers Road, Indooroopilly, Qld, 4068,Australia. Damien.Cupitt@dpi.qld.gov.au

Microbial insecticides have been shown to be a valuable component of integrated pest management in Australia for control of *Helicoverpa* sp. in broadacre crops. We are evaluating potential new biopesticides based on entomopathogenic fungi for control of aphids in cotton, sorghum and pulses. We have assessed 50 isolates of *Metarhizium* and *Beauveria* for activity against the cotton aphid (*Aphis gossypii).* Laboratory assays have shown three *M. anisopliae* isolates and one *B. bassiana* isolate have significant potency against aphid nymphs at five days post infection. A field trial in cotton compared efficacy of *Metarhizium* isolates, and showed that one isolate significantly reduced aphid populations compared to unsprayed controls. Further work will focus on improving the efficacy of the agents through formulation and targeting of pests.

The biological control of Kelly's citrus thrips in Australian citrus orchards.

GJ Baker, Dr MA Keller, P Crisp, D Jackman, D Barbour and S Purvis.
South Australian Research and Development Institute, GPO Box 397, ADELAIDE, SA, 5001, baker.greg@saugov.sa.gov.au

Kelly's citrus thrips (KCT) (*Pezothrips kellyanus* (Bagnall)) (Thysanoptera: Thripidae) has emerged in the 1990's as a serious citrus pest in southern Australia, New Zealand and parts of the Mediterranean Basin. The feeding of KCT on young and mature fruit causes scurfing (or halo) marking and rind bleaching, respectively. These blemishes reduce fruit quality, thereby reducing the packout of export quality fruit and rendering some fruit unsaleable. Information about KCT biology and ecology has been scarce, and in Australia the management of KCT has been limited to the use of several insecticides. Having established that KCT pupate in the soil below the citrus canopy, we initiated a search for both arboreal and soil-dwelling natural enemies with the aim of developing an IPM system for KCT in Australian citrus orchards. The study has identified a range of mite species that are either demonstrated or likely predators of KCT. The relationship between the diversity and abundance of these predators and the incidence of KCT in study orchards is examined. The potential implications for the IPM of KCT are discussed.

Sirex wood wasp oviposition in *Pinus caribaea* & *P. caribaea x P.elliottii* hybrids.

J King, D Kent, CJ Fitzgerald
Department of Primary Industries and Fisheries, Agency for Food and Fibre Sciences, Forestry Research, PO Box 631, Indooroopilly, QLD, 4068, Australia; judy.king@dpi.qld.gov.au

Sirex wood wasp (*Sirex noctilio*) is a destructive introduced pest of *Pinus radiata*, which is the main exotic softwood plantation species in New South Wales, A.C.T., Victoria, South Australia and Tasmania. Sirex was detected in mainland Australia in 1962, and posed a major threat to the softwood industry. The successful implementation of a biological control program reduced the population to low levels but it spread, and is now close to the Queensland border. In Queensland the exotic softwood plantation estate is mainly *Pinus caribaea, P. elliottii* and *P.caribaea x P. elliottii* hybrids. The potential of *P. caribaea* and the hybrids to host Sirex or its biological control agents was unknown and the threat to Queensland plantations could not be assessed. We investigated the susceptibility of *P. caribaea* and the hybrids to Sirex infestation. Billets of *P. caribaea* were exposed to field-collected *P. radiata* billets with newly emerging Sirex and parasitoids. Billets of *P. taeda* and the *P. caribaea x P. elliottii* hybrids were exposed to female Sirex wasps newly emerged from field-collected *P. radiata* billets. During and following exposure the billets were stored in an insectary. We comment on susceptibility and development times.

Video monitoring nocturnal predation of *Helicoverpa armigera* larvae

JE Hopkinson, DAH Murray, RJ Lloyd
Department of Primary Industries & Fisheries, PO Box 102 Toowoomba QLD 4350 Australia; Jamie.Hopkinson@dpi.qld.gov.au

Numerous studies have looked at diurnal predators of *Helicoverpa armigera* but few researchers have attempted to study nocturnal predation of immature and adult *H. armigera.* In our current study we are using 4 digital B&W cameras fitted with infrared illumination. Each camera records the nightly activity in a 50 x 50 cm arena of soil surface in the inter-row space. A four-channel digital recorder stores images at 1 frame per second on a removable 80 GB hard disk drive. Trials have been conducted in summer field crops including maize, cotton, mungbean and sorghum. For each arena we tethered sentinel prey (5 helicoverpa larvae or moths) and recorded which predators consumed them. We recorded the activity of predators over the duration of the night and the time taken to consume all prey. Pitfall traps were used to aid identification of predators active at each site. A species list of animals recorded by the cameras has been compiled for each site and includes field mice (*Mus musculus),* carabid beetles (*Gnathaphanus pulcher* and, *Helluo costatus),* predatory earwigs (*Labidura truncata)* and wolf spiders *(Lycosa godeffroyi).* These video studies identified several important predators that have potential to reduce the numbers of large larvae surviving through to pupation.

Effect of transgenic potato (GNA) in the tritrophic system with aphids (*Myzus persicae*) and aphid parasitoids (*Aphidius colemani*).

S Aasen, E Hågvar, T Hofsvang
Department of Ecology and Natural Resource Management, Agricultural University of Norway, P.O. Box 5003, N-1432 Ås; solveig.aasen@ina.nlh.no

A gene encoding snowdrop lectin (*Galanthus nivalis* agglutinin) has been engineered into a number of crops, including potato. Experiments have shown that such GNA potato plants are partial resistant towards aphids, and have a potential to affect the aphid parasitoids, which are important biological control agents. We have studied effects of GNA potato on the aphid *Myzus persicae,* and the aphid parasitoid *Aphidius colemani.* No significant effects have been found on aphid development or fecundity. Preliminary results on the searching behaviour, development time, longevity and adult size of *A. colemani* are presented. All experiments have been conducted in laboratories using transgenic plants, instead of artificial diet, as the transformation process can cause unexpected effects that might influence the insects.

Assessment of *Trichogramma embryophagum* **(Hymenoptera:Trichogrammatidae) against** *Sesamia* **(Lepidoptea:Noctuidae)**

A Agamirkarimi
College of Agricultural of Aboureyhan,Tehran University; mkarimi@ut.ac.ir

The role of *Trichogramma embryphagum* (Hymenoptera:Trichogrammatidae) (reared on *Heliothis zea* Boddie eggs) as parasitoid of the sugarcane and corn stem borers *Sesamia cretica* Led. And *S. nonagrioides botonephaga* T.&B.,was assessed under laboratory and greenhouse condition .Data on seven biological parameters are presented.The laboratory results showed that *T.embroypham* reared on *H. zea* eggs parasitized 50% of *S.critica* gggs,compared to 58.5% of *S .nonagrioides* eggs.percentages of emergence (87%), female progeny (71%),deform females (2.5%), and development time (8.9d) in *T. embroypham* reared from *S. cretica* gggs did not differ significantly from those reared on *H. zea* eggs (93%,69%,3.2%,2d and 8.5d respectively).However,*T. embroypham* females reared form *S. cretica* eggs had greater body length (39mm) than females reared on *H. zea* (0.33mm). in the greenhouse conditions, *T. embroypham* parasitized an average of 56.4% of the *S.cretica* eggs masses were distributed on the corn plants).about 21.6% of the eggs were dessicated,probably due to puncturing by the parasitoid,compared with 4.1% in the control,where egg masses were distributed on the plants without release of *Trichogramma*. Results showed the potential for use *Trichgramma* to control corn stalk borers in a field IPM program.

Historical perspective on *Xenorhabdus*/ *Photorhabdus* research

RJ Akhurst
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia; Ray.Akhurst@csiro.au

Xenorhabdus and *Photorhabdus* are Gram negative bacteria that are symbiotically associated with entomopathogenic nematodes of the families Steinernematidae and Heterorhabditidae, respectively. They have progressed from being a microscopic oddity, through being recognised as critically important for the success of their nematode partners to being a key element of a range of biological insecticides. Along the way, they have raised some intriguing scientific questions and developed as sources of insecticidal and antibiotic activity in their own right. The discovery of a *Photorhabdus* sp. in human clinical specimens opened a new view on their evolutionary history. The recent sequencing of a *Photorhabdus* genome increases the attractiveness of these bacteria as a model system for the investigation of symbiotic relationships and of pathogenesis.

Rearing the potential predator *Geocoris lubra* Kirkaldy (Hemiptera: Geocoridae).

S Armitage, ML Johnson, B Scholz, S Mansfield.
Zoology and Entomology Department, University of Queensland, St Lucia, Qld, 4072, Australia; s.armitage@uq.edu.au

Geocoris lubra Kirkaldy (Hemiptera: Geocoridae) or the big-eyed bug, is considered to be a major predator of *Helicoverpa armigera* Hübner (Lepidoptera: Noctuidae) in Australian crops – particularly cotton and soybean. *G. lubra* is therefore of potential value as a biological control agent of *H. armigera* in pest management strategies such as integrated pest management. Despite this, very little is known about the biology and ecology of *G. lubra* and until recently a rearing method had not been developed. We describe a successful rearing method for *G. lubra* and determine the impact of photoperiod on aspects of *G. lubra*'s biology. Temperature was found to be the key parameter required for successful rearing of the predatory bugs. However, photoperiod could greatly increase the percentage of viable eggs and significantly shorten development time from egg to adult.

"Integration of transgenic rice with IPM"

"*JS Bentur, IC Pasalu, NV Krishnaiah, G Katti, AP Padmakumari*"

"`Directorate of Rice Research, Hyderabad 500 030, AP India;` jbentur@yahoo.com"

"Transgenic rice lines with *Bt* and *Gna* genes against stem borers and hopper pests, respectively, are being field evaluated in India. While greenhouse and initial limited field tests have identified some of the lines to be promising against the target pests, no extensive data on field performance of these lines, impact on non-target arthropods are available yet. However, based on our experience of rice insect pest management in India we anticipate following opportunities, problems and challenges ahead in deploying transgenic rice as component of rice IPM. It is imperative that transgenic rice line proposed to be deployed needs to be effective not only against most species of the target stem borers and hoppers but also against non target pests like leaf folders, if farmers are to refrain from insecticide application. Since natural biological control is effective under most circumstances, study on effect of transgenic line on natural enemies is critical. Distinct economic impact of transgenic rice will be felt only in some parts of the country and hence may act as disincentive to farmers in other parts if seed cost and grain quality does not match their expectation. There may not be major barriers to integrate transgenic rice with IPM.
"

Dispersal, biology and impact of the introduced biocontrol agent *Zygogramma bicolorata* Pallister (Coleoptera : Chrysomelidae) on the weed *Parthenium hysterophorus* L. in Jammu (J&K), India

S Bhatia, R Choudhary
Department of Zoology, University of Jammu, (J&K) – 180006, India; siya98@sancharnet.in

Parthenium hysterophorus L. is a weed of national significance in India. It is the most predominant weed of wastelands, pastures and agricultureal fields and has spread throughout India. It has achieved the status of a worst weed owing to its adverse effects on human beings, animals, and natural diversity. In Jammu and Kashmir state, parthenium has spread to all the six districts of Jammu division and is moving fast and far in other high altitude areas including the Kashmir valley. Biological control trials against this weed were initiated in Jammu region by the release of the leaf - feeding beetle *Zygogramma bicolorata.* This beetle established readily and started building up damaging population levels and has dispersed to most parts of Jammu causing large scale defoliation of parthenium. In this study we have recorded the dispersal of this beetle in Jammu and studied its biology and performance in different climatic conditions. Besides, impact of defoliation by *Z .bicolorata* on parthenium has been discussed.. The results of the studies carried out to date indicate that *Z .bicolorata* has the potential to bring about reduction in the density of parthenium in Jammu.

Functional morphology of parasitoid immatures

G Boivin, R Romani, F Bin
Centre de Recherche et de Développement en Horticulture, Agriculture et Agroalimentaire Canada, 430 Boul. Gouin, St-Jean-sur-Richelieu, Québec Canada J3B 3E6; boiving@agr.gc.ca

The immatures of egg parasitoids develop inside host eggs and, because of their minute size and their special habitat, are considered as morphologically specialized when compared to other Hymenoptera immatures. Among the constraints of using insect eggs as host, the small size of insect eggs and the short period during which the host stage is available are major forces that shaped the behavior and physiology of egg parasitoids. Most egg parasitoids are idiobiont species and their immatures have to develop on the finite resources within the host egg. These immatures may either share these resources with conspecifics, in the case of gregarious species, or eliminate surnumerary conspecifics in the case of solitary species. Both physiological and morphological adaptations to this competition are found, mostly in the first instar larvae. The host egg is more than a simple container for the parasitoid immature and its chorion is important in the regulation of oxygen and water within the egg. In some egg parasitoid species, successful development is only possible in host eggs where the chorion has completed its formation while some other species perforate the chorion to access directly atmospheric air.

Recombinant baculovirus insecticide expressing a novel intrahemocoelic toxin

RL Harrison, AJ Boughton, JJ Obrycki, BC Bonning
Department of Entomology, Iowa State University, 418 Science II, Ames, IA 50011 USA;
bbonning@iastate.edu

Basement membranes surrounding the tissues of lepidopteran larvae serve as a potential barrier to baculovirus movement and establishment of systemic infection. To counteract this barrier, we constructed a recombinant *Autographa californica* nucleopolyheovirus (AcMNPV) that expressed a basement membrane-degrading cathepsin L protease from the flesh fly, *Sarcophaga peregrina*. In survival time bioassays, this recombinant, AcMLF9.ScathL, killed neonate *Heliothis virescens* 50% faster than wild-type virus and 30% faster than viruses expressing the scorpion toxins AaIT and LqhIT2 (AcMLF9.AaIT, AcMLF9.LqhIT2). Baculovirus-expressed *S. peregrina* cathepsin L was optimally active at pH 5.0 and not active at pH 6.0, suggesting that *S. peregrina* cathepsin L may be operating at locally acidified microenvironments within the larvae. AcMLF9.ScathL caused premature cuticular melanization and melanization of internal tissues. Infections of fifth instar *H. virescens* with AcMLF9.ScathL yielded fewer polyhea than wild-type AcMNPV and AcMLF9.AaIT, indicating that the insecticidal properties of *S. peregrina* cathepsin L may be independent of any effect on virus movement or systemic infection. Risk assessment studies indicated that AcMLF9.ScathL had no detrimental impact on two nontarget insect predators, the ladybeetle *Coleomegilla maculata* and the green lacewing *Chrysoperla carnea*.

A mechanistic and predictive framework for predicting the efficacy of biocontrol agents: the application of competition and keystone predation theory to invasive species.

WP Carson, DE Bunker, AJ Baumert.
A234 Langley, Biological Sci., Univ. of Pittsburgh, Pittsburgh, PA, 15260, USA; walt@pitt.edu

We tested a rigorous approach for predicting whether insect herbivores will be effective biocontrol agents. Resource competition theory predicts that dominant plant species (whether exotic or not) are capable of persisting at the lowest level of a shared limiting resource or reducing the shared limiting resource more than competing species. Furthermore, keystone predation theory predicts that herbivores will alter competitive outcomes only if they sufficiently impede competing species from acquiring or reducing the limiting resource. We field-tested these two theories for 12 plant species (invasive and native) in both terrestrial and wetland habitats. Though work in the terrestrial habitat remains preliminary, in wetlands, our results suggest that the release of a leaf-feeding Chrysomelid beetle (*Galerucella calmariensis*) will not halt the spread and dominance of the invasive plant purple loosestrife (*Lythrum salicaria*) in the USA. Nonetheless, an enormous amount of resources have already been invested into releasing this beetle throughout the USA.

In vitro antimicrobial effects of herbal extracts on pathogens causing chalkbrood and European foulbrood diseases in honey bee (*Apis mellifera*)

P Chantawannakul, M Chaiharn, T Puchanichantranon, S Wongsiri
Department of Biology, Faculty of Science, Chiang Mai University, Chiang Mai, Thailand 50200; panuwan@chiangmai.ac.th

Brood diseases in honeybee (*Apis mellifera*) found in Northern Thailand during 2001-2002 were Chalkbrood and European foulbrood. Based on their characteristic symptoms, European foulbrood pathological samples were collected from Chiang Mai, Chiang Rai, Payao, and Phrae Province whereas Chalkbrood samples were collected from six apiaries (five apiaries in Chiang Mai, and one in Payao Province). Six isolates grown in anaerobic condition were *Melissococcus plutonius*, an European foulbrood pathogen. Endospore forming bacilli found in culture were identified as *B. stearothermophilus*, *B. macerans*, *B. laterosporus*, *B. circulans*, *B. firmis*, *B. coagulans*, and *B. licheniformis*. None of them was *Paenibacillus larvae* subsp. *larvae*, a causative agent causing American foulbrood. Forty-six isolates of fungi were identified as a Chalkbrood pathogen (*Ascosphaera apis*). Our aim is to control the diseases by using natural products, the screening of potential compounds from medicinal plants, therefore, was carried out. Dichloromethan extract of *Glycyrrhiza glabra* exhibited the best inhibitory effect on all *M. plutonius* strains (both Thai and Australian strains). Hexane *Cinnamomum cassia* extract and Ethyl acetate *Piper betle* extract gave good inhibitory effects on *A. apis* growth. The cocktail of these selected herbs is proposed as an alternative for potential disease control.

The biological control programme for the obscure mealybug, *Pseudococcus viburni*, **using** *Pseudaphycus maculipennis* **(Hymenoptera: Encyrtidae)**

JG Charles, DJ Allan, DJ Rogers, PW Shaw
HortResearch, Mount Albert Research Centre, Private Bag 92 169, Auckland, New Zealand; jcharles@hortresearch.co.nz.

Pseudaphycus maculipennis is one of the few known encyrtid parasitoids of *Pseudococcus viburni*, and was recognised as a potential and practical biocontrol agent for this mealybug in New Zealand in the early 1990s. *P. maculipennis* was imported into quarantine in Auckland in December 1997, before new environmental legislation (the Hazardous Substances and New Organisms Act) was implemented. After host testing in quarantine, application for approval to release was made to the Environmental Risk Management Authority in April 1999. Approval to release was given on 9 August 2000, after extensive consultation and provision of further technical information, and a public hearing. The first *P. maculipennis* were released in February 2001. By 2004, approximately 765,000 *P. maculipennis* ("Peemac") had been released to nearly 50 pipfruit orchards in Hawke's Bay, Nelson/Motueka and Auckland, and to the Wellington Botanic Gardens. *P. maculipennis* has dispersed at least locally, but no studies of its impact on obscure mealybug populations have yet been carried out. Using 'trap' mealybugs, Peemac have been recovered from c.50% of the release properties over 2-3 years, and it is concluded that the species has established in New Zealand.

Identification, synthesis and exploitation of the pheromone for the goldeneyed lacewing, *Chrysopa oculata*.

KR Chauhan, QH Zhang, JR Aldrich
USDA-ARS Chemicals Affecting Insect Behavior Laboratory, B-007, BARC-West Beltsville, Maryland, 20705, and Department of Entomology, University of Maryland, College Park, Maryland, 20742, USA

Four distereomers of iridodial have been synthesized in 5 steps from 4a*S*,7*S*,7a*R* and 4a*S*,7*S*,7a*R*-nepetalactones, major components of catnip oil. In the field-trapping experiments, 1*R*,2*S*,5*S*,8*R*-iridodial was the only male-specific compound that exhibited significant attraction to *Co. oculata* males. 1*R*,2*S*,5*R*,8*R*-Iridodial is identified as a male-produced male-aggregation pheromone for *Chrysopa oculata*, the first pheromone of any kind for lacewings. Preliminary studies using 1*R*,2S,5R,8R-iridodial for the practical utility in manipulating natural or artificially augmented populations of lacewings for enhanced biological control will be discussed.

Recruitment of egg parasitoids by oviposition-induced synomones: a review.

S Colazza, JG Millar, T Meiners, M Hilker
S.En.Fi.Mi.Zo. Department - Section of Entomology, Acarology and Zoology – Università di Palermo, Viale delle Scienze, 13 90128 Palermo, Italy; colazza@unipa.it

"Studies that have investigated herbivore-induced volatiles have focused primarily on insects that damage plants by chewing. However, plants also respond to herbivore egg deposition by releasing volatiles which can attract egg parasitoids. Plants that are able to attract egg parasitoids soon after herbivore eggs are laid benefit from increasing the parasitoid's effectiveness and from shielding themselves against insect pests before any damage can occur. Evidence on oviposition-induced synomones has been reported for only three tritrophic systems. In two of these, *Ulmus minor* and *Pinus sylvestris* respond to oviposition of their herbivores, *Xanthogaleruca luteola* and *Diprion pini* respectively, by emitting volatiles that attract the *Oomyzus gallerucae* and *Chrysonotomyia ruforum*. The third tritrophic system consists of *Vicia faba* and *Phaseolus vulgaris*, which, under the combined feeding and oviposition activity by a piercing/sucking herbivore, *Nezara viridula*, emit volatiles that attract *Trissolcus basalis*. We will present data on the attraction of the egg parasitoid by oviposition-induced plant volatiles, the mechanisms of induction by egg deposition, and the specificity and the chemistry of volatiles induced, showing similarities and differences between the three tritrophic systems.
"

Potential and risks of deploying transgenic entomopathogens

JS Cory
Laboratory of Virology, Wageningen University, Binnenhaven 11, 6709 PD, Wageningen, The Netherlands; jennycory@tiscali.co.uk

Insect pathogens have shown considerable potential as control agents of insect pests, however their widescale adoption has been limited by concerns about factors such as their relatively slow speed of action, narrow host range and variable environmental persistence. Genetic manipulation has been proposed as one route to circumvent these limitations. The first wave of transgenic entomopathogens mainly addressed the issue of speed of kill as this trait has a direct impact on crop damage. In insect baculoviruses in particular, numerous laboratory studies have shown that the insertion of foreign genes can result in a fast-acting pathogen. More importantly, field trials also indicate that these changes can result in reduced crop damage. While it is clear that genetic manipulation can produce entomopathogens with altered characteristics likely to enhance their potential as pest control agents, these transgenic organisms cannot undergo widescale release into the environment without appropriate ecological risk assessment. The limited risk assessment studies carried out to date indicate that the introduction of foreign genes is unlikely to result in a pathogen with enhanced fitness. However further studies are needed, in particular relating to longer term persistence, alternative hosts and mixed pathogen infections.

Factors defining *Trichogramma* abundance in the Ord River Irrigation Area in remote northern Australia

AP Davies, MP Zalucki
School of Life Sciences, The University of Queensland, St Lucia, QLD, 4072, Australia; adavies@zen.uq.edu.au

Advances in insect pest control technology and renewed interest in re-establishing a cotton industry in tropical northern Australia led to recent cotton trials in the Ord River Irrigation Area (ORIA). The introduction of transgenic cotton varieties and modern Insect Resistance Management (IRM) techniques effectively minimized chemical pesticide use. Eggs of *Helicoverpa* collected during trials produced high numbers of *Trichogramma* egg parasitoids. Their impact on the potentially resistant pest species *Helicoverpa armigera* (Hübner) is considered integral to the IRM strategy for transgenic cotton production in the ORIA. Our research examined aspects of *Trichogramma* ecology pertinent to this strategy. Principal investigations focused on host egg collection providing indications of *Trichogramma* activity. Measured as percentage parasitism, *Trichogramma* activity appears highly variable in space and time and does not necessarily coincide with periods of peak insect pest abundance. Host abundance alone does not define conditions suitable for *Trichogramma* activity. Environmental constraints on wasp survival, such as the impact of temperature, humidity and chemical applications, are equally important factors limiting their effectiveness in biological control. Subsequent investigations targeted survival and distribution of adult *Trichogramma* to complement host interaction data. The aim was to isolate factors that limit the biological control potential of *Trichogramma* in the ORIA.

Present status of olive fruit fly SIT development

AP Economopoulos
Dept. of Biology, University of Crete, Heraklion-Crete, Greece; economop@biology.uoc.gr

The olive fly is the sole key insect pest for the olive tree in most of cultivated olive tree areas around the world. Among others, extensive research has been undertaken on the sterile insect technique against the olive fly. In spite of more than 20 years of research and development (1963-1983), no effective application of the methodology has been achieved. Consequently, since about 1980 the emphasis on this particular methodology with the olive fly has progressively diminished. The main obstacles connected with the difficulties of SIT with this particular insect were: laborious and expensive mass rearing, reduced quality of mass reared flies (e.g. different mating time than the wild insects under natural photoperiod), and lack of essential information on the complete role of fly's symbionts, and population changes in nature. Recently, work has been resumed in 3 main directions: a) developing cheaper, less "deleterious" to the fly (because of antibiotic, preservatives) and of more practical use diets, b) exploring in detail and possibly resolving the problem of differential mating time of laboratory insects as compared to wild ones, and c) developing transgenic strain(s) towards practical mass separation of sexes.

Biological control of pest mole crickets in Florida, USA

JH Frank
Entomology & Nematology Dept., University of Florida, Gainesville, FL 32611-0630, USA; jhf@ifas.ufl.edu

Three South American pest mole crickets occur in Florida. They arrived in Georgia or Florida in 1899-1904 in ship ballasts. For >100 years, chemicals were the control method, at great annual cost, in vegetables, turf, and pastures. In the 1980s, three specialist biological control agents were introduced into northern Florida against them, all from southern South America. These were a wasp, *Larra bicolor* (Hymenoptera: Sphecidae), a nematode, *Steinernema scapterisci* (Rhabditida: Steinernematidae), and a fly, *Ormia depleta* (Diptera: Tachinidae). The nematode was applied as a biopesticide in many counties but spreads slowly. The wasp has spread to >15 counties after release in northern Florida. The fly spread fastest, now occupies southern and central Florida, but is limited by inability to overwinter north of »29^{o}N. Trapping stations in northern Florida established in 1979 showed no trend in total annual catches of mole crickets for nine pre-release years. After the biological control agents reached the vicinity of the trapping stations, numbers began to decline. They have declined for 12+ years. In 2003, the total annual catch of the worst of the three pests (*Scapteriscus vicinus*) achieved less than 0.5% of the annual average catch for the pre-release years. Statewide control is within reach.

The potential for a classical biological control programme against painted apple moth (*Teia anartoides* Walker) in New Zealand.

PJ Gerard, JG Charles, MB Malipatil, F Page, A Chagan, MR McNeill, L Semeraro.
AgResearch, Ruakura Research Centre, Private Bag 3123, Hamilton, New Zealand;
pip.gerard@agresearch.co.nz

The painted apple moth *Teia anartoides* Walker, a minor native Australian pest, is the target of an eradication programme in Auckland, New Zealand, where it poses a serious threat to indigenous and modified environmentsAs a precursor to a possible classical biocontrol programme in the event of eradication failure, searches for natural enemies of *T. anartoides* were carried out in autumn and in late spring to early summer 2003 in south-east Australia. At least 18 species of egg, larval and larval-pupal parasitoids were reared, the majority being Hymenoptera from the families Braconidae, Ichneumonidae and Eulophidae, and Diptera (at least two species of Tachinidae). The most common species from Victoria and Tasmania was *Cotesia* sp. (Hymenoptera: Braconidae), a solitary parasitoid of young larvae. The parasitoid guild showed greater diversity in spring-early summer than in autumn, and had some structural similarity with guilds of other Lymantriidae around the world. The guild was compared with existing natural enemies of *T. anartoides* in New Zealand and with those attacking other Lymantriidae occupying the same Australian habitats and host plants. Several Hymenoptera attacking *T. anartoides* larvae appear to be host specific and could act as effective biological control agents for this pest in New Zealand.

Prospects for biocontrol of mealybugs (Hemiptera:Pseudococcidae) in South African fruit orchards

WM Wakgari, JH Giliomee
Department of Zoology, University of Stellenbosch, 7602 Matieland, South Africa; jhg@sun.ac.za

Mealybugs can cause extensive damage in South African fruit orchards and their presence on exported fruit may cause rejections if endemic species are present. We discuss the current status of natural biocontrol of the most important species, the effects of the commonly used insecticides on the commercially available parasitoid *Coccidoxenoides peregrinus* and the host range of this species. We conclude that there is good potential for natural biocontrol, especially if parasitoid numbers are augmented early in the season; that *Anagyrus pseudococci* is a good biocontrol candidate as generalist parasitoid; that most insecticides are disruptive to biocontrol agents, but that some insect growth regulators are biocontrol compatible; that *C. peregrinus* is selective on *Planococcus* spp. and therefore not useful for general mealybug control.

Pathology caused by infection of heliothine larvae with a small, midgut-specific, RNA virus.

KHJ Gordon, TN Hanzlik
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia; karl.gordon@csiro.au

The tetravirus *Helicoverpa armigera* stunt virus (HaSV) is a small positive-stranded RNA virus infecting only midguts of heliothine caterpillars. Two genomic RNAs encode three proteins including a replicase and capsid protein. Transmitted horizontally *per os*, and also vertically, HaSV is acutely virulent towards very young larvae, causing rapid cessation of feeding, cessation of growth, and death. Older larvae show developmental resistance, even towards high doses. The complex pathology elicited by this simple virus has been studied using novel histopathology techniques and the genetic manipulation of HaSV to express reporter genes. Infection of young larvae leads to rapid virus spread throughout the midgut. Infected cells are rejected from the midgut epithelium, whose integrity is degraded despite a phase of rapid cell regeneration. In older larvae, infection foci are established but disappear as the virus is cleared from the midgut, in contrast to their spread in younger larvae. HaSV's efficacy and specificity give it significant potential as a biocontrol agent, as demonstrated in recent field trials. The capsid's simplicity led to the study of novel approaches for pest control involving virus production in non-host systems. Assembly of infectious HaSV was achieved in plant cells upon transfection of plasmids expressing viral RNAs and capsid protein.

Using transgenic maize in a prescriptive integrated pest management program

ME Gray, KL Steffey
Dept. Crop Sciences, Univ. Illinois, Urbana, IL 61801, USA; megray@uiuc.edu

Unlike the use of transgenic insecticidal cultivars for European corn borer (*Ostrinia nubilalis* Hübner), management, the use of transgenic hybrids for corn rootworms, *Diabrotica* spp., could work in concert with existing scouting programs and established economic thresholds. In essence, by monitoring their fields for corn rootworm adults in late summer, farmers could base their decision to use transgenic corn rootworm hybrids the following spring upon scouting input and knowledge of thresholds. Crop consultants and other essionals in the agribusiness sector could take a very active role in this decision-making process. Nearly half the continuous (non-rotated) cornfields in Illinois fail to support economic infestations of corn rootworm larvae. If only those fields judged to be infested with economic densities were planted to transgenic cultivars, in effect, a rather large refuge across the landscape could be created. Arguably, this would lessen the selection pressure for resistance development. In contrast to soil insecticides, transgenic insecticidal cultivars for corn rootworms will likely place greater selection pressure on the corn rootworm population. Important differences exist between a banded application of a granular soil insecticide and transgenic hybrids from a selection pressure perspective, and on this basis, a prescriptive approach for transgenic cultivars appears more justified.

The assassin bug, *Pristhsancus plagipennis* (Walker) (Hemiptera Reduviidae) – a potential biocontrol agent for IPM

P Grundy, D Maelzer
LMB 1, Biloela, QLD, 4715, Australia; paul.grundy@dpi.qld.gov.au

The Australian reduviid, *Pristhesancus plagipennis* (Walker), is a predator of Hemipteran and Lepidopteran pest insects in a range of cropping systems. As with many reduviid species, its biological control potential has been largely ignored because of low abundance in cropping areas coupled with the challenge of augmenting it for pest management purposes. This presentation outlines our research from the perspective of overcoming the barrier of augmenting *P. plagipennis* for biological control. A basic rearing methodology has been developed along with release techniques for field crops. Field studies on this predator have focussed on the biological control of *Helicoverpa* spp. (Lepidoptera: Noctuidae) and *Creontiades dilutus* (Hemiptera: Miridae) as well as the side effects of insecticides likely to be used within an IPM program. Both laboratory and field work indicate that *P. plagipennis* holds considerable promise as an applied biological control agent. However, to realise its full potential and be used commercially, the cost-effectiveness of the mass-production system needs to be optimised. Rearing technology options and their prospective impact on the feasibility of this predator will be discussed.

Advances in protein marking for mark-release-recapture and mark-capture studies

JR Hagler, VP Jones
USDA-ARS, 4135 E. Broadway Road, Phoenix, Arizona, USA; jhagler@wcrl.ars.usda.gov

We describe recent advances toward improving protein marking procedures for mark-release-recapture (MRR) and mark-capture studies. For MRR studies, a series of tests were conducted to determine if the sensitivity of an established rabbit immunoglobulin (IgG)-specific ELISA could be improved for detecting protein marks on insects. Five variations of ELISA were examined for their ability to detect rabbit IgG-marked *Hippodamia convergens*. The sandwich ELISA format was the most sensitive immunoassay. ELISAs with immunoreagent incubation intervals held constant at 5, 10, 20, or 60 minutes were examined for their ability to detect rabbit IgG-marked beetles. Results showed that the ELISA with 60 minute incubations yielded significantly higher ELISA readings. For mark-capture studies, inexpensive protein markers are being developed for studying landscape-level movement patterns of insects. Our approach is to utilize ELISAs that detect inexpensive proteins such as egg white, non-fat dry milk, and soy milk applied directly in the field using conventional insecticide spray rig equipment. The ELISA used to detect each protein is highly specific and sensitive, facilitating the use of multiple marks for studying various aspects of intercrop dispersal. The benefits and challenges of protein marking for MRR and mark-capture studies will be discussed.

Host-parasitoid dynamics in fragmented landscapes: patterns of dispersal and genetic variation

I Hanski, M Kankare, S van Nouhuys
Metapopulation Research Group, Department of Biological and Environmental Sciences, PO Box 65, FI-00014 University of Helsinki, Finland; ilkka.hanski@helsinki.fi

The Glanville fritillary butterfly (*Melitaea cinxia*) has a large metapopulation in the Åland Islands in Finland and is attacked by two specialist parasitoids, *Cotesia melitaearum* (Braconidae) and *Hyposoter horticola* (Ichneumonidae). The two parasitoids have a striking difference in their range of dispersal, which is shorter than in the host butterfly in *C. melitaearum* but longer than in the host butterfly in *H. horticola.* Because of this difference in dispersal, and other differences in the biology of the parasitoids, *C. melitaearum* exhibits classic host-parasitoid metapopulation dynamics whereas *H. horticola* experiences the host metapopulation as a more continuous though patchy population. The genetic spatial structures of the two parasitoids, investigated with microsatellite markers, show a corresponding difference, with clusters of multilocus genotypes corresponding to the microgeographical population structure in *C. melitaearum* but not in *H. horticola.*

Development of microbial insecticides and their integration into farming systems in Australia.

C Hauxwell, K Knight, D Holdom, B Bidstrup, A Reeson
Agency for Food and Fibre Sciences, Department of Primary Industries & Fisheries, Biopesticides Unit, 80 Meiers Road, Indooroopilly, Qld, 4068, Australia; caroline.hauxwell@dpi.qld.gov.au

Biopesticides based on insect pathogens have enjoyed significant success in mainstream broadacre cropping in Australia. A number of commercial products based on nucleopolyheoviruses (NPVs) (Baculoviridae) have been registered for control of *Helicoverpa* sp. Primarily introduced for use in sorghum, NPVs have been widely adopted in cotton and other crops in IPM and insecticide resistance management. Consistent availability and quality of product, initially from the USA, has allowed the development of a significant market and subsequent development of new products produced in Australia supported by our research. NPVs are effective in controlling *H. armigera* that are resistant to chemical insecticides, with minimal disruption of natural enemies. Our work has shown significant improvements in performance of NPVs through formulation and application, and has established a baseline of susceptibility to NPVs in field populations across Queensland that suggests that there is little threat of resistance to these biopesticides. The success of biopesticides in Australian IPM has prompted our research and development of new potential products against *Helicoverpa*, mirids, pentatomids, diamondback moth and aphids. We will present our results on the identification, production, formulation, field-testing and integration into IPM of biopesticides based on entomopathogenic fungi and baculoviruses against these key pests.

A review of the surveys for natural enemies of *Mimosa pigra*: what does it tell us about surveys for broadly distributed hosts?

TA Heard, W Pettit
CSIRO Entomology, 120 Meiers Rd, Indooroopily 4068 Australia; tim.heard@csiro.au

The weed *Mimosa pigra* has been the target of a long running biocontrol project. This woody legume occurs naturally in all tropical American countries from Mexico to Argentina as well as many Caribbean islands. Surveys of natural enemies were made in seven countries and revealed a total of c. 420 insects and 5 fungi. This review focuses on assessing the collection effort in relation to the natural distribution of the host. We show species accumulation curves for some sites to estimate the number of visits required to find most species at a site. We examine the distribution of the agents where that information is available and compare it to the host distribution, to enable the prediction of the number of species that our surveys missed. We draw general conclusion that are applicable to biocontrol surveys of any host that occurs over a wide geographic range.

Inundative releases of *Trichogramma evanescens* **against the olive (***Prays oleae***) and jasmine (***Palpita unionalis***) moths**

EM Hegazi, E Agamy, S Hassan, A Hertz, Khafagi, A El-Shazly, A El-Minshawy, M Hafez, A Zitone, S Showel, H Karam, L Abo-Abdalla, S El-Said, N Khamis, S El-Kemny
Faculty of Agriculture, Alexania University, Alexania, Egypt; eshegazi@hotmail.com

Field releases of mass-reared egg parasitoid were applied against the flower and fruit generations of the olive moth, *P. oleae* and the permanent presence of the jasmine moth, *P. unionalis* during two successive olive seasons of 2002 & 2003. The number of male moths captured in sex pheromone traps in treated plots was significantly lower than untreated one. Parasitism in eggs of target pests was higher in treated sites than control site. In the latter, parasitism on *P. unionalis* was mostly encountered than on *P. oleae* eggs. This is may possibly due to the activity of a *Trichogramma* strain other than *T. evanescens*. The strain is a theletokous species, a little bit darker than *T. cacoeciae*. It was bred from eggs of both moth species. The percentage of infestation of fruits that fell by *P. oleae* was generally higher in control site than treated one. Fruit harvest/tree was significantly greater in treated plots than control one. The outcome of inundative releases of *Trichogramma* wasps was partially successful and could provide a model for control of lepidopterous pests of olive trees, especially when the endemic species is used. When the right adapted candidate of wasp would be reached, it should be taken in consideration the right time and dose of each release, the emergence time of adult wasps and duration of activity of wasps under field conditions.

Feeding status of the parasitoid *Diadegma semiclausum* affects biological control of *Plutella xylostella*: implications for pest management.

L Hemerik, MA Keller
BIOMETRIS, Department of Mathematical and Statistical Methods, Wageningen University, P.O. Box 100, 6700 AC Wageningen, The Netherlands; Lia.Hemerik@wur.nl

In Australia the solitary larval parasitoid, *Diadegma semiclausum*, a specialist on diamondback moth *Plutella xylostella* (DBM) has established as biological control agent. In field cages, fed and starved individuals of this parasitoid species foraging for hosts have been shown to have patch-leaving tendencies that differ considerably in host patches with the same host density. For this species, the movements in the field were continuously observed. The patterns emerging from these and other behavioural studies are built into a spatially explicit model to quantify the difference in the pattern of parasitism, when parasitoids are starved or fully fed. In the model, we mimic the spatial structure in Australian fields where year-round broccoli (*Brassica oleracea* var. *italica*) is planted. A cohort of new plants starts every fortnight. For studying how the physiological differences affect the parasitism levels in the field and therewith the biological pest control of DBM we used an individual based, spatially explicit, simulation model. We discuss the implications for biological control of DBM by relating the difference in longevity and the variation in foraging behaviour of the parasitoids due to different physiological state (fed versus starved) to variation in parasitism.

Competition and cannibalism in the gregarious egg parasitoid *Trichogramma carverae*: time-lapse imaging of development.

LM Heslin, DJ Merritt

School of Life Science, University of Queensland, St Lucia, 4072, Australia; lheslin@zen.uq.edu.au

Wasps of the genus *Trichogramma* have gregarious larvae that develop within lepidopteran host eggs. We address the question of whether gregarious larvae are completely tolerant of each other, and competition is solely due to a scramble for food, or whether physical attack occurs. Video microscopy was used to record feeding behaviour of larval *Trichogramma carverae* at different densities in *Epiphyas postvittana* eggs. Single larvae show a rapid food ingestion phase, followed by a period of extensive saliva release. The larva completely consumes the egg contents then extracts excess moisture from the egg before pupating. When multiple larvae are present, they rapidly consume all of the egg contents. Subsequently, further growth occurs by larvae feeding upon each other. The process continues until the surviving larvae reach a developmental stage beyond which competitive interactions seem to be no longer effective. Thus the number of larvae remaining at the end of the rapid ingestion stage dictates how many will survive to emerge as adults. We conclude that larvae are tolerant of siblings at low density if there is sufficient food for all to reach the threshold developmental stage. If not, their physical proximity results in attack and consumption of siblings.

Choosy egg parasitoids: specificity of response of egg parasitoids to plant volatiles induced by egg deposition

M Hilker, R Mumm
Freie Universität Berlin, Institute of Biology, Haderslebener Str. 9, D-12163 Berlin, Germany; hilker@zedat.fu-berlin.de

Plants may respond to insect egg deposition by release of volatiles which attract egg parasitoids (1). Recently Scots pine (*Pinus sylvestris*) was shown to respond to egg deposition by the pine sawfly *Diprion pini*. Pine twigs with host eggs emit volatiles that attract the eulophid egg parasitoid *Chrysonotomyia ruforum,* a species specialized on diprionid eggs (2, 3). We tested whether this response is specific for the plant and herbivore species. *C. ruforum* shows a high specificity for oviposition-induced plant volatiles with respect both to the plant and herbivore species. Furthermore, the parasitoid´s response to these volatiles depends on its experience prior to the bioassay. While numerous generalist parasitoids are well-known to learn a wide range of volatiles when they had the opportunity to associate them positively with a host , the specialist *C. ruforum* was shown just to be able to learn specific volatile blends.

Patch use by egg parasitoids: theory, facts, and biological control

Y Hirose
349 Asano, Munakata 811-3415, Japan

This is a critical review of theoretical and empirical studies on patch use by egg parasitoids, determining if theory explains observed facts. It explores the possibility that egg parasitoids aggregate in host patches of high density or large size because classical patch-use theory predicts that foraging parasitoids should spend a relatively longer amount of time in high-quality patches, and the possibility that parasitoid aggregation results in density dependent parasitism. It stresses the fact that host age oundly influences patch use by parasitoids of eggs laid in masses because host quality declines with host age; this occurs simultaneously in all hosts in a patch (i.e. egg mass). When parasitoid females discover low-quality host patches just before host hatching, they should leave the patches as soon as possible to search for another patch. The case of *Anagrus sophiae* (= *delicatus*) females that attack only a small fraction of hosts in an egg mass and leave high-quality patches still carrying apparently mature eggs (Cronin & Strong, 1993) seems to be exceptional among quasi-gregarious egg parasitoids. Characteristics of patch use by egg parasitoids are discussed in relation to their use in biological control.

Selecting arthropod biological control agents: improving agent selection to minimize non-target impacts and maximize target impacts

MS Hoddle

Department of Entomology, University of California, Riverside, CA 92507, USA; mark.hoddle@ucr.edu

Non-target impacts and establishment of ineffective arthropod biological control agents targeting arthropod pests are receiving increased levels of research either through retrospective studies or via *a priori* evaluations before release to from quarantine. Glassy-winged sharpshooter, *Homalodisca coagulata*, an invasive xylophagous hemipteran in California, is the focus of a major classical biological control program with mymarid parasitoids that have been recruited from the pest's home range in the southeast U.S.A. Native sharpshooters potentially at risk from exotic parasitoids are being evaluated for susceptibility to attack as are native sharpshooters in French Polynesia, where *H. coagulata* established *circa* 1999. Laboratory studies assessing risk and parasitoid efficacy have indicated that screening parasitoids for potential efficacy is strongly influenced by parasitoid species and experimental conditions such as the complexity of the environment searched and relative host abundance provide. These different metrics for evaluating parasitoid efficacy can provide different answers as to which parasitoids will be most effective. Our work suggests that greater thought needs to be given to prevailing pest densities at the start of the biological project and how host-parasitoid dynamics will change as successful agents control the target pest making it less common. Lower pest densities because of successful biological control may affect which species or guilds of parasitoids come to dominate and regulate the system at low host densities compared to observations at the start of the program where pest numbers were higher.

Attractants for *Aleochara* spp. (Coleoptera: Staphylinidae), natural enemies of *Delia radicum* (Diptera: Anthomyiidae), in canola

K Riley, NJ Holliday, U Kuhlmann, LJ Donald
Dept Of Entomology, University Of Manitoba, Winnipeg, Mb, Canada R3T 2N2;
Neil_Holliday@umanitoba.ca

Defatted mustard seed meal has been shown to attract *Aleochara* species in vegetable brassicas in Sweden, and crop damage was reduced in plots with this treatment (Ahlström-Olsson & Jonasson, I0BC/WPRS Bull. 1992; 15:171). In trials with mustard flour in Canada and with defatted mustard meal in Switzerland, pitfall traps in canola plots with mustard preparations spread at 20 g/m² did not catch higher numbers of *Aleochara bilineata* than did traps in untreated control plots. However, in the Swiss trial, *A. bipustulata* catches in traps in mustard meal plots were almost 2.5 times those in control plots. Parasitism of *Delia radicum* pupae by *A. bipustulata* was significantly higher in mustard meal plots than in control plots, but parasitism by *A. bilineata* was not affected by the treatment. In Y-tube olfactometer studies, *A. bipustulata* exhibited preference for mustard meal compared to a blank control, but *A. bilineata* showed no preference. We are conducting further olfactometer studies comparing mustard meal and mustard flour in the presence and absence of soil and of moisture. Additionally, we are comparing the chemical composition of volatiles from potential attractants using gas chromatograph mass spectrometry.

Influence of host density on the dispersal of a specialist parasitoid

CL Hsu, G Heimpel, DA Andow, R Venette
Dept. of Entomology, UMN, 219 Hodson Hall, 1980 Folwell Ave., St. Paul, MN 55108, USA; hsux0049@umn.edu

The use of genetically modified corn in the United States to control the European corn borer, *Ostrinia nubilalis*, is creating a amatic shift in the spatial dispersion of hosts available to the specialist parasitoid *Macrocentrus grandii*. The persistence of this parasitoid in the Midwestern corn belt may be limited by its dispersal abilities, and its behavioral response to large regions of low host densities created by the widespread use of genetically modified corn. We marked parasitoids developing on *O. nubilalis* using foliar applications of rubidium chloride to 0.2 ha corn plots. Marked parasitoids were presented with transgenic (low host density) and nontransgenic (high host density) corn fields and their dispersal in the two types of fields was monitored using sticky traps. More than 10,000 parasitoids were captured in the first year and preliminary results show differences in the behavior of male and female *M. grandii* dispersing into transgenic corn fields. Parasitoids were captured throughout the 8 ha transgenic corn fields demonstrating that dispersal into low host density fields is possible at this scale. Rubidium levels in parasitoids collected from the 0.2 ha treated plots were 8 times higher than in unmarked parasitoids.

Biological control of *Bemisia tabaci* **by predators**

J Huang, Y Jing, HW Luo, ZH Wang
College Of Plant Protection, Fujian Agriculture And Forestry University, Fuzhou 350002, P.R.China; jhuang@fjau.edu.cn

The sweetpotato whitefly, *Bemisia tabasi* (Gennadius), is a widespread pest of crops in the world, which recently seriously occurrs in China, and damages the most economically significant crops of cotton, vegetables and ornamentals, showing a tendency of annual outbreaks with the trouble problem urgent to be solved in agricultural productions. The predatory enemies of *Bemisia tabasi* in China have some species of ladybeetles, thrips, aphids lions and predatory mites, of which the ladybeetles *Serangium japonicum* and *Delphastus catalinae* are active as the dominant species. Both the two species of ladybeetles have a good efficiency feeding on the different stages of *Bemisia tabasi*, especially preferring to the whitefly eggs. At the laboratory, *Delphastus catalinae* develops a generation by 17-22 days at 25-28°C, with the ladybeetble population increases 21.61 times more than that of the fore generation, and develops about 15 generations per year. The predatory quantity per day reaches up 1198 and 670 of whitefly eggs fed by a 4th instar larva and an adult female of *Delphastus catalinae* respectively. The mass rearing of ladybeetbles carries out followed by the rearing process of host plant – host whitefly – ladybeetble.

The Sirex woodwasp control programme in South Africa

BP Hurley, MJ Wingfield
Forestry And Agricultural Biotechnology Institute (FABI), University Of Pretoria, Pretoria, 0002, South Africa; Brett.Hurley@Fabi.Up.Ac.Za

The Sirex woodwasp, *Sirex noctilio*, was first detected in South Africa in the Tokai plantation, Cape Town in 1994. *Sirex noctilio*, together with its symbiotic fungus *Amylostereum areolatum*, inhabits and kills pine trees. Since its initial detection in South Africa, this exotic pest has spread rapidly and is causing increasing losses to the pine industry. Three biological control agents were introduced into South Africa soon after *S. noctilio* was first detected. These included the parasitic nematode, *Beddingia siricidicola*, which is considered to be the best biological control agent against the woodwasp. Unfortunately, the biocontrol agents have not spread together with *S. noctilio*. To address this problem, *B. siricidicola* has been re-introduced on a much larger scale and on a more continuous basis than was previously attempted. The aim here has been to ensure that the nematode becomes established and that it achieves sufficient control of the wasp in South African pine plantations. Studies are also underway to investigate possible differences in the life-cycle of *S. noctilio* in different climatic zones of South Africa. Furthermore, we are considering evidence to suggest that the wasp has been introduced into the country more than once.

Associative learning of plant chemicals by the egg-larval parasitoid, *Ascogaster reticulata* **Watanabe (Hymenoptera: Braconidae)**

Y Kainoh, K Shoji, M Satoh
Institute of Agriculture and Forestry, University of Tsukuba, Tsukuba, Ibaraki 305-8572, Japan; parasite@sakura.cc.tsukuba.ac.jp

We examined the learning response to authentic chemicals in *Ascogaster reticulata* Watanabe, an egg-larval parasitoid of the smaller tea tortrix, *Adoxophyes honmai* Yasuda (Lepidoptera: Tortricidae). After 3 times' conditionings of chemicals associated with the host egg mass, the strength of the learned response in a female was evaluated by the distance walked along the chemical cues with her characteristic antennating response in 9-cm Petri dish assays. We compared the learned response of females to 5 authentic chemicals, i.e., linalool, geraniol, methylsalicylate, *(Z)*-3-hexenol and benzyl alcohol. The order of learned responses was as follows: linalool = geraniol > methylsalicylate > *(Z)*-3-hexenol = benzyl alcohol. When the females were conditioned with geraniol, they responded to geraniol significantly longer in a choice between geraniol and linalool. The linalool-conditioned females positively chose linalool in the same choice situation, but not significant. Use of the mixtures of these chemicals in different ratio also had similar effect.

Augmentation of parasitoids by mass-hatching devices: a new biocontrol technique

P Kehrli, S Bacher

Ecology and Entomology Group, PO Box 84, Lincoln University, Canterbury, New Zealand; kehrlip@lincoln.ac.nz

Augmentation can be an effective biocontrol strategy to increase the impact of antagonists. However, mass-reared beneficials are generally expensive and often poorly adapted to field conditions. The goal of this study was the development of a device, which selectively permits parasitoids to emerge out of pest-infested plant material. Plant material containing the host and its parasitoids can be collected and stored in large closed devices from which the generally smaller parasitoids can emerge through a selective tissue filter of appropriate mesh size. We used mass-hatching devices to augment populations of indigenous parasitoids of the invasive horse chestnut leafminer, *Cameraria ohridella* (Lepidoptera, Gracillariidae). Whereas more than 75 % of the 15'000 parasitoids passed the separator only 1 % of the 50'000 leafminers overcame the tissue filter. Furthermore, the set-up of mass-hatching devices in the city of Basel, Switzerland, significantly increased parasitism rates of *C. ohridella*. Mass-hatching devices may thus contribute to an integrated control strategy against *C. ohridella* in Europe. In general, mass-hatching devices are a promising new augmentative approach to control insect pests with a dormant stage in or on plant residues and should be considered as a supplementary, cost-effective biocontrol technique.

Molecular genetic investigation of local adaptation and incipient speciation in a tritrophic system

KM Kester, BL Brown
Dept. of Biology, Virginia Commonwealth University, 1000 W. Cary St., RICHMOND, VA, 23284-2012 USA, kmkester@vcu.edu

Seven polymorphic microsatellite loci were assayed in two groups of the insect parasitoid, *Cotesia congregata* (Say) [Hymenoptera: Braconidae]. One group originated from *Manduca sexta* L. and *Manduca quinquemaculata* (Haworth) on tomato and tobacco ("solanaceous group") and the other from *Ceratomia catalpae* (Boisduval) on catalpa ("catalpa group"). Allelic distributions differed significantly between the solanaceous and catalpa groups (Fisher's exact test $P = 0$ overall and for each locus). Across all loci, F_{ST} was < 0 for within-group comparisons and > 0.47 for between-group comparisons. Wasps from the solanaceous and catalpa groups were examined for mtDNA sequence variation to investigate their possible status as sibling species. One conserved mtDNA gene (16S) showed a single fixed nucleotide difference between the two groups. The results support the hypothesis that host plant association is a significant factor influencing population structure of *C. congregata*.

Selecting arthropod biological control agents against arthropod pests: how can the science be improved to decrease the risk of releasing ineffective agents?

KA Hoelmer, AA Kirk
USDA-ARS European Biological Control Laboratory, Campus International de Baillarguet, Montferrier 34980, France; khoelmer@ars-ebcl.org

From the practitioner's viewpoint, there are several principles that, if observed, will improve the chances for successful agent selection:

1) Involvement of morphological and/or molecular characterizations is needed from the inception of the project. When the native range/origin of a pest is unknown, this will help to identify significant differences in pest populations and may reveal their actual native range. Identification and characterization of the natural enemy geographic populations and possible host range differences is equally important.
2) Use of climate matching tools is a good starting point for locating climatically-adapted populations of natural enemies.
3) Native range studies should be conducted to evaluate the impact of exotic agents on the target pests.
4) Concurrent and parallel studies should be conducted in the potential release area to document gaps in native enemy activity or other ecological factors that contribute to high pest populations. This also means that a committed practitioner is in place in the receiving area.
5) Collection of natural enemies of species that are taxonomic relatives or ecological homologues of the target pest and which occur in the same or neighboring habitats may reveal field specificities.
6) Quarantine evaluations can provide a preliminary screening of potential effectiveness.
7) Field cage/semi field evaluations are desirable to validate the results of preliminary screenings under more realistic conditions.

These approaches will be discussed in relation to examples of recent projects.

Management of sucking pests in broadacre crops using *Beauveria bassiana* and *Metarhizium anisopliae*.

K Knight, C Hauxwell, D Holdom
Agency for Food and Fibre Sciences, Department of Primary Industries & Fisheries, Biopesticides Unit, 80 Meiers Road, Indooroopilly, Qld, 4068, Australia; kristen.knight@dpi.qld.gov.au

Biopesticides based on insect pathogens have been widely applied in an integrated pest management (IPM) strategy against *Helicoverpa* species in Australia, maintaining beneficial insect populations and minimising the development of resistance to chemical insecticides. As reliance on chemical control has reduced in cotton and grain crops, sucking pests such as mirids (*Creontiades* sp.) and green vegetable bug (*Nezara viridula*) are emerging as significant problems. Application of broad-spectrum insecticides against sucking pests threatens the successful IPM strategy by destabilising natural enemy populations and triggering outbreaks of *Helicoverpa sp,* however there are currently no selective insecticides registered for sucking pests. We have identified *Beauveria bassiana* and *Metarhizium anisopliae* isolates active against these pests. Field trials demonstrated control of mirids equal to that achieved with the chemical Dimethoate by four to six days after treatment for both isolates at 1 x 10^{13} spores/hectare. There was no significant impact on natural enemies in any of the field trials. Monitoring has indicated that sucking pest populations build up in pulse crops through the vegetative stage. We are modelling pest populations and developing a pest management strategy based on population management using biopesticides as an alternative to reactive knockdown using broad-spectrum chemical insecticides.

Red imported fire ant: benefit or detriment to conservation biological control in cotton?

AE Knutson, R Diaz , J Bernal.
Texas A&M Research & Extension Center, 17360 Coit Road, Dallas, TX , USA. 75252; a-knutson@tamu.edu.

Predation of sentinel eggs of *Helicoverpa zea* and *Spodoptera exigua* (Noctuidae) was 1.5-2.0 and 4.1 times greater, respectively, in the presence of red imported fire ant, *Solenopsis invicta* (Formicidae), than when fire ants were excluded from 3-ha plots of cotton in central Texas in 2001-2002. Most (68%) of the observed predation events on beet armyworm eggs was due to *S. invicta*. Densities of cotton aphid, *Aphis gossypii*, were 5.5 times greater in the presence of fire ants compared to ant exclusion plots, although aphid densities did not reach economic levels. In additional field trials conducted in 2003, densities of cotton aphid were not significantly different between ant treatments and again did not exceed the economic threshold (50 aphids/leaf). Densities of *Hippodamia convergens* (Coccinellidae) adults and larvae were significantly greater in the ant exclusion treatment Red imported fire ants are intraguild predators in cotton. However, our results suggest that the overall impact of the red imported fire ant is beneficial to cotton pest management in Texas and efforts to enhance fire ant densities have the potential of increasing biological control of nocutid pests.

Oral toxicity of *Photorhabdus* bacterial toxins against thrips species

LJM Gerritsen, WJ de Kogel
Plant Research International, PO Box 16, 6700 AA Wageningen, The Netherlands; willemjan.dekogel@wur.nl

Photorhabdus and Xenorhabdus bacteria are symbiotic to entomopathogenic nematodes. These bacteria are released by nematodes after infection of insects. The oral toxicity of excretion products of several Photorhabdus and Xenorhabdus strains was tested on two thrips species: Frankliniella occidentalis and Thrips tabaci. Out of 46 Photorhabdus isolates and 6 Xenorhabdus isolates only 6 North American P. temperata isolates were toxic to the thrips species. After 7 days of inking from P. temperata supernatant a mortality of 90% was recorded and reproduction was inhibited. Thrips were also killed after feeding from leaves that were treated with the toxins. Possibilities of using P. temperata for the control of thrips will be discussed.

Understanding target weed population dynamics can improve our ability to select effective agents against weeds

D Kriticos
Forest Research, PB 3020, Rotorua, 3201 New Zealand; Darren.Kriticos@forestresearch.co.nz

Understanding the population dynamics of a weed and the role of environmental factors in influencing these dynamics can help us prioritise insect and pathogen guilds in terms of their likely efficacy in controlling target weeds. In order to be effective, an agent needs to inflict sufficient damage, on appropriate organs or lifestages, and do so in a timely manner. Modelling the population dynamics of a weed can indicate the likelihood of agents from different guilds being able to inflict these desirable damage patterns under the range of environmental conditions that are likely to be encountered in the introduced range. The most desirable agents are those that, when released from their own predators or parasitoids, would act upon the plant population in the manner that most amatically reduces the problems caused by the weed – characteristics that will vary from weed to weed. The characteristics of the most desirable agents can then be used to influence the suite of agents that are specifically targeted for searching, and to help prioritise them for importation and host-specificity testing. If agent establishment follows the lottery model, then prioritising agents that, should they establish, are most likely to be effective should improve our overall success rate.

Efficacy of nuclear polyheosis virus with azadirachtin on the mortality, feeding, biological, biochemical and histopathological profiles of *Helicoverpa armigera.*

N Senthil Kumar
P.G Department of Biotechnology, N.G.M College, Pollachi 642001,India; nskbiotech@rediffmail.com

The mortality of third instar larvae of *Helicoverpa armigera* larvae was observed in a dose dependent manner and the time to kill was significantly reduced in the combined treatment of Nuclear Polyheosis Virus (NPV) and Azadirachtin (AZA). The average leaf disc consumption of *H. armigera* larva fed with NPV (5 x 10^4 PIB/ml) treatment was 1.90 cm^2/larva and AZA treatment (4 μg/cm^2) was 0.63 cm^2/larva whereas it was significantly reduced to 0.21 cm^2/larva in the low dose combined treatment. Significant reduction in the larval and pupal weights, elongation of larval and pupal duration and a astic reduction in the adult longevity, fecundity and survivability were observed after the combined treatment. Reduced amounts of protein (35.8 mg/g), lipid (47.4 mg/g), carbohydrate (35.7 mg/g), amino acids (32.6 mg/g), DNA at 96 hrs post-treatment (82 µg/g) and RNA at 96 hrs post-treatment (2.4 µg/g) were observed after NPV and AZA treatment. These biochemical changes suggest that AZA did not affect the multiplication of NPV and further there is a synergistic interaction between NPV and azadirachtin. The combined treatment caused a severe necrosis of the midgut epithelial cells and loss of cell shape. The combined treatment of NPV and azadirachtin had much greater effect in relation to the pest management strategy.

Suitability of parasitized greenbugs (*Schizaphis graminum*) as food source for predatory Coccinellidae.

M Lebusa, T Royer, K Giles
Oklahoma State University, Stillwater, Ok 74078.

Laboratory studies were conducted to determine first, the stage of development at which the predatory coccinellidae, *Hippodamia convergens*, *Coccinella septempunctata* and *Coleomegilla maculata* are able to start feeding on the parasitized greenbugs "mummies" (*Schizaphis graminum*), and second to determine the nutritional effects of mummies on the growth, development and survival of *Coccinella septempunctata*. Lady beetles were collected from the field and fed unlimited amount of pea aphids (*Acyrthosiphon pisum*) until when they laid eggs. A batch of coccinellid larvae at each instar was fed fresh mummies on daily basis and observed. The preliminary results showed that *Hippodamia convergens* start feeding on mummies at the third instar, even though *Coccinella septempunctata* start feeding on mummies at the second instar, and each instar larva was able to molt to the next stage of development. Further results of the experiment show that *C.septempunctata* take long to develop and they survive through one molt when they are fed mummies. More results will be obtained at a later stage of the study. This study confirms that *Coccinella septempunctata* and *Hippodamia convergens* are able to feed on the parasitized greenbugs at both larval and adult stages of development.

Isolation and characterization of novel insecticidal *cry1*-type genes from *Bacillus thuringiensis* strains

MS Li, JY Choi, JY Roh, HJ Shim, JN Kang, KS Boo, YH Je
School of Agricultural Biotechnology, College of Agriculture and Life Sciences, Seoul National University, San 56-1, Shinllimdong, Kwanakgu, Seoul, 151-742, Korea; mshli7125@hanmail.net

To identify new *cry1*-type insecticidal genes, 56 lepidopteran-specific *Bacillus thuringiensis* (Bt) strains were isolated from Korea. Universal oligonucleotide primers, K5un2 and K3un2, were designed and used to amplify all known *cry1*-type genes with PCR from 56 Bt isolates. The restriction fragment length polymorphism (RFLP) patterns of the PCR-amplified fragments revealed 7 distinct patterns, and a standard isolate was selected from each one of the RFLP groups. Through cloning and sequence analysis of the PCR-amplified fragments showing unique RFLP pattern, 7 novel *cry1*-type genes were identified. Bt K-1 and Bt 2385-1 strains were selected to isolate and characterize the active regions of the novel genes, and then 5 novel genes were cloned from them. To verify the activity against lepidopteran larvae, the novel genes were expressed using baculovirus expression vector system and the bioassay was performed to *Plutella xylostella* (Px) and *Spodoptera exigua* (Se). All novel *cry1*-type genes had high toxicities against Px larvae and, *cry1-44* and *cry1-5* had the highest toxicity against Px and Se larvae, respectively. Also, *cry1-1* and *cry1-5* had dual toxicities against Px and Se larvae. Finally, each novel gene must be a very useful resource for development of microbial insecticide and insect resistant plants.

Bats feed on crop pests in California's Sacramento Valley

RF Long
UC Cooperative Extension, 70 Cottonwood St. Woodland, CA 95695; rflong@ucdavis.edu

Food habits of Mexican free-tailed and Yuma bats were examined in the Sacramento Valley in California. Analyses of guano samples indicated that these two species of bats fed on moths, beetles, and plant bugs suggesting they might help control crop pests. Further studies in cotton, walnuts, pears, and alfalfa showed that bats forage extensively in these crops; however, their impact on biological pest control remains unclear. A colony of 150 bats will feed on more than a million insects a year. In addition, bats may protect crops by their echolocation calls alone. Many insects, including moths, are sensitive to bat calls and take evasive action when they detect bats by turning or diving to the ground, which may disrupt their mating and egg-laying behavior. Given the beneficial nature of bats, growers in California have been putting up bat houses to attract bats to their farms for pest control. Analysis of 175 bat houses in California showed that bats prefer houses that were attached to wooden barns, at least ten feet off the ground, that received morning sun and afternoon shade.

What hypervariable molecular markers tell us about parasitoid population structure and dynamics at both landscape and geographic scales

HD Loxdale, C Macdonald, DA Baker
Rothamsted Research, West Common, Harpenden, Hertfordshire, AL5 2JQ, UK; Hugh.Loxdale@bbsrc.ac.uk

We here discuss the use of polymorphic microsatellite markers to study natural populations of the hymenopterous primary parasitoid, *Diaeretiella rapae* (M'Intosh), a polyphagous parasite of crucifer and cereal aphids. Using five such markers, its population structure and dynamics was examined at the field and landscape scale when attacking cabbage aphid, *Brevicoryne brassicae* (L.) infesting oilseed rape, *Brassica napus* at two sites in southern Britain. Parasitoid samples were collected at different spatial scales ranging from individual racemes to field corners. The data were analysed using Bayesian and other statistics to provide new insights into parasitoid movement, persistence and breeding structure. In addition, the same markers were later used to study the genetic variability of *D. rapae* at four geographic sites (Western Australia, France, Morocco and Kazakhstan) reared on the Russian wheat aphid (RWA), *Diuraphis noxia* (Mordvilko). When compared with Old World populations, Australian parasitoids had low allele length and frequency variation, suggesting a significant founder effect. Marked genetic differentiation between populations was also apparent, potentially important for host utilization in this species when introduced to a new geographic area/s. Low genetic variation and gene flow in a founder population could limit evolutionary potential, including the ability to switch to novel introduced hosts, e.g. RWA.

The density and diversity of parasitic Hymenoptera as bio-indicators of habitat disturbance in a cotton producing region

R Magallanes-Cedeño, JJ Ellington, A González-Hernández, G Díaz-López
E Marcelin Lotes 5 y 7, Magisterial. Tapachula, Chiapas. México, C.P. 30770; ricardomagallanes@doctor.com

The presence and diversity of hymenopteran parasitoids were compared in cotton with sprays of chemical insecticide, and protected with a bioinsecticide in Huehuetán, Chiapas, México from September, 1999 to January, 2002. Parasitoids were collected weekly from phytophagous insects on upper, middle and lower leaves, squares, flowers and bolls, held in styrofoam cups, with a semi-transparent lid. During the last two years, parasitoids were also collected by vacuuming above the plant canopy. Chemical insecticide decreased both the incidence and diversity of parasitoids early in the first year; however, the guild of natural enemies reappeared and became more abundant and diverse in the chemical treatment. This was associated with the protection brought to the crop by chemical insecticide sprays which resulted in more productive plants, furnishing more refuge to parasitoids late in the season. However, when the crop was rainfed, and phytophagous insects did not cause significant plant damage, natural enemies were affected by the chemical insecticide. Over 300 morphospecies of hymenopteran parasitoids were collected during the experiment. The fact that parasitic Hymenoptera occur at the top of the arthropod food chain makes this group of insects particularly useful in evaluating factors which control and often simplify natural and man-made ecosystems.

The impact of predatory bugs on *Helicoverpa armigera* in Australian cotton crops

S Mansfield
CSIRO Entomology and the Australian Cotton Cooperative Research Centre, Australian Cotton Research Institute, Locked Bag 59, Narrabri, NSW 2390, Australia and Forest Research, Private Bag 3020, Rotorua, New Zealand (current adess); sarah.mansfield@forestresearch.co.nz

The bigeyed bug, *Geocoris lubra*, and the damsel bug, *Nabis kinbergii*, are two common insect predators in Australian cotton crops. These predators are known to feed on the lepidopteran pest, *Helicoverpa armigera*, however such predation is difficult to observe and quantify under natural conditions. The detection of specific protein markers in predator gut contents allows direct measurement of predation from field-collected individuals. Here, I outline the development of ELISA protocols to detect predation by these two species on *H. armigera* using a species-specific monoclonal antibody. Although prey-specific proteins were detectable for only short periods within the predators, positive examples of predation have been recorded. Adult and juvenile predators of both species were collected from commercial cotton farms in northern NSW during the 2001-02 and 2002-03 seasons. Approximately 12% of *G. lubra* and 24% of *N. kinbergii* tested positive for recent predation on *H. armigera*. Predation rates were similar in both seasons although the relative abundance of *H. armigera* was lower in 2001-02 than 2002-03. This suggests these insect predators can contribute to the suppression of *H. armigera* even when pest populations are low.

Viral pathogens for the control of painted apple moth *Teia anartoides* (Lepidoptera: Lymantriidae)

NP Markwick, J Poulton, VK Ward, VL Young, Z Li, C Hauxwell, TR Glare
HortResearch, Mt Albert Research Centre, Private Bag 92169, Auckland, New Zealand;
nmarkwick@hortresearch.co.nz

The painted apple moth (PAM), *Teia anartoides* (Lepidoptera: Lymantriidae) is a native of Australia, where it is a horticultural pest. Recently, PAM was found in Auckland, New Zealand and poses a threat to horticulture, pine forests and native plants. An eradication campaign was mounted in the Auckland suburbs including aerial applications of the biopesticide Foray (based on *Bacillus thuringiensis*) and releasing sterile male moths. To supplement eradication, we have investigated the availability and potential of microbial insect pathogens to control PAM. Efforts to identify potential biological control agents have included evaluation of several nucleopolyheovirus (NPV) strains from related species (e.g. other lymantriids) and from commonly found forest or horticultural pest insects. Most were non-pathogenic or showed minor sub-lethal effects and one appeared to potentiate a virus present at low levels in PAM larvae. However, an NPV (*Oran*NPV), discovered in PAM in Australia in the 1960s, was highly virulent as were two NPV stains isolated from other lymantriid species (*Orygia pseudotsugata* and *O. leucostigma*). Finally, a cypovirus, isolated from PAM in New Zealand, was infective in bioassays. Preliminary sequence data suggests that this cypovirus is an undescribed member of the *Cypoviridae*. Host range testing of these viruses is underway.

Occurrence and abundance of spiders in cotton ecosystem of Tamil Nadu, India

VG Mathirajan, A Regupathy
Department of Entomology, Tamil Nadu Agricultural University, Coimbatore- 641 003, India; mathirajan@mailcity.com

Agricultural entomologists have acknowledged the importance of spider species as a major factor in regulating pest populations of crops. Despite their importance were highlighted in various ecosystems by several workers, the role they play in regulation of pest populations in cotton ecosystem has received scant attention in India and few workers have attempted on faunistic survey in recording the spider fauna in cotton ecosystem. A survey was conducted at major cotton growing areas of Tamil Nadu *viz.,* Attur, Bhavanisagar and Coimbatore during winter cotton 1998 (July- December) and at Kovilpatty and Srivilliputur during summer cotton 1999 (February – June). The survey yielded 21 species *viz.*, *Araneus* sp., *Argiope catenulata* Doleschall*, A. minuta* Karsh, *Neoscona theisi* Walcknear, *Cyrptophora cicatrosa* Stoliczka, *C. viridanus* Cambridge, *Oxyopes javanus* Thorell, *O. rufisternum* Thorell, *Peucetia viridana* Stoliczka, *Plexippus paykulli* Audouin, *Tetragnatha javana* Thorell, *Thomisus cherapunjens* Tikader, *T. pugilis* Stoliczka, *Leucage decorata* Blackwall, *Gasterocantha citricola* Forskal, *Neoscona elliptica* Tikader, *Clubiona* nr. *assodes* Cambridge, *Lycosa pseudoannulata* Boes. et Str., *Pardosa* sp., *Bianor* sp. and *Salticus* sp. grouped under 16 genera belonging to eight families (Araneidae, Argiopidae, Clubionidae, Oxyopidae, Lycosidae, Salticiade, Tetragnathidae and Thomisidae).

Genetic differentiation of hymenopteran parasitoids

RF Medina, P Barbosa
4112 Plant Sciences Bldg. University of Maryland, College Park MD 20742 USA; rfmedina@umd.edu

The ecology of parasitoids is strongly influenced by the host plant. Parasitoid fitness is affected by a variety of plant traits. Thus, it is reasonable to assume that adaptation to plant traits could promote phenotypic and genotypic differences among populations of parasitoids. We present data on phenotypic and genotypic differences of two braconid parasitoids ovipositing on the same host on different host-plants. We compare the developmental time, percent parasitism, and adult weight of a generalist (*Cotesia marginiventris* (Cresson)) and of a specialist parasitoid (*Aleiodes nolophanae* (Ashmead)) of the green cloverworm and use AFLP data as a measure of genotypic differences in parasitoids emerging from hosts on alfalfa versus those reared from hosts on soybeans. AFLPs have been widely used in ecology to explore genetic differentiation among populations in several species and cluster analysis methods have been applied to visualize these differences and to test all sort of hypotheses. However, these analyses are potentially flawed because there is no agreed upon criteria for determining the appropriate number of individuals and bands for such representations to capture variation in the field. We present a method for determining the number of individuals to collect and number of bands to consider when studying genetic differentiation.

Habitat manipulation for insect pest management in Australian cotton cropping systems

R. K. Mensah, RV Sequeira
NSW Agriculture, Australian Cotton Research Institute, Locked Bag 1000, Narrabri, NSW 2390, Australia; robert.mensah@agric.nsw.gov.au

Adoption of within-field monocultures of cotton crops in Australia discriminate against and reduce the establishment and activity of natural enemies of pests because they lack ecological diversity. Increased habitat diversity in the cotton cropping systems has been achieved by planting refuge crops adjacent to cotton fields or as strips or centrally located blocks. The use of refuge crops in this way has enhanced (1) the conservation and establishment of natural enemies on cotton crops early in the cotton season to suppress pest populations and (2) the diversion of pests away from cotton onto the refuge crops resulting in the reduction of pest population. Interplanting cotton crops with refuge crops such as lucerne, the strips should be 8-12 metres wide and 300 metres apart and should run the whole length of the adjacent cotton field. The problem associated with the use of refuge crops for pest management in cotton is that natural enemies may not be inclined to move from the refuge crops to forage the adjacent cotton crops. The movement of the natural enemies can be improved by either applying a natural enemy food attractant to the cotton crops or by reducing the size of the strips planted to refuge crops. The criteria for the selection and management of the refuge crops as well as their deployment in IPM programs in cotton will be discussed.

Selecting parasitoids for biological control introductions: codling moth as a case study

NJ Mills
Insect Biology, Wellman Hall, University of California, Berkeley CA 94720-3112, USA; nmills@nature.berkeley.edu

The parasitoid assemblages of lepidopteran pests are more diverse and interactive than those of homopteran pests, posing a greater dilemma for the biological control practitioner in selecting candidates for introduction. How do we identify the single best candidate for introduction, or if more than one species is selected, how important is it that they show no direct interactions? The recent biological control program against codling moth in California will be used to illustrate both theoretical and practical aspects of parasitoid selection for introduction. From a theoretical perspective, the importance of pest refuges from parasitism, antagonistic interactions, and parasitoid aggregation will be emphasized. In contrast, from a practical perspective, the importance of ease of collection, rearing success, and risk will be considered. These contrasting perspectives provide an interesting example of parasitoid selection as both an art and a science.

RESPONSE OF *TRICHOGRAMMA PLATNERI* AND *T. PRETIOSUM* TO PATCHES OF SINGLE AND CLUSTERED HOST EGGS

NJ MILLS, U KUHLMANN
INSECT BIOLOGY, WELLMAN HALL, UNIVERSITY OF CALIFORNIA, BERKELEY CA 94720-3112, USA; NMILLS@NATURE.BERKELEY.EDU

COMMERCIALLY PRODUCED TRICHOGRAMMA SPECIES ARE WIDELY USED IN AUGMENTATIVE BIOLOGICAL CONTROL PROGRAMS. HERE WE TEST WHETHER TWO NORTH AMERICAN SPECIES *T. PLATNERI* AND *T. PRETIOSUM*, DIFFER IN THEIR RESPONSE TO AND EFFICIENCY OF USE OF SINGLE AND CLUSTERED HOST EGGS. THE OVIPOSITION BEHAVIOR OF INDIVIDUAL EXPERIENCED PARASITOID FEMALES WAS MONITORED CONTINUOUSLY IN PATCHES (3.5 X 3.5 CM CARD) WITH 16 SINGLE SPACED OR CLUSTERED EGGS OF *EPHESTIA KUEHNIELLA* AT 25°C FOR UP TO 1 H OR UNTIL THE FEMALE LEFT THE PATCH. THE OVIPOSITION BEHAVIOR OF EACH PARASITOID SPECIES IN EACH PATCH TYPE WAS SUMMARIZED AS GENERALIZED ETHOGRAMS, PATTERNS OF PATCH USE, TIME BUDGETS AND THE SEQUENCE OF SEX ALLOCATION. *T. PLATNERI* HAD A GREATER RATE OF OVIPOSITION IN PATCHES WITH SINGLE HOST EGGS, AND AN INDETERMINATE ALLOCATION OF SEXES IN PATCHES OF CLUSTERED HOST EGGS. IN CONTRAST, *T. PRETIOSUM* SHOWED BOTH A GREATER RATE OF OVIPOSITION AND A MORE EFFICIENT SEX ALLOCATION IN PATCHES OF CLUSTERED HOST EGGS. THE MORE EFFICIENT USE OF HOST EGG CLUSTERS BY *T. PRETIOSUM* THAN BY *T. PLATNERI* SUGGESTS THAT CLOSER ATTENTION SHOULD BE PAID TO MATCHING THE OVIPOSITION BEHAVIOR OF TRICHOGRAMMA SPECIES TO THE OVIPOSITION STRATEGY OF THE TARGET PEST.

Metarhizium anisopliae as a mycoinsecticide for taro beetles (*Papuana* spp.) in Papua New Guinea and other Pacific Islands.

RJ Milner, R Masamdu

BioPesticide Consultant, 81 Birriwa Road, Bungendore, NSW, 2621, Australia; rmilner@alphalink.com.au

Taro is an important root crop for Melanesian and Polynesian people. It is extensively cultivated in PNG as well as Solomon Islands, Fiji, and Vanuatu. The adults of several species of Taro beetle are naturally occuring pests in PNG and the Solomons and recent introductions into other countries such as Fiji. The larvae are detritus feeders and are not an economic problem. The adults burrow down through the soil and eat large holes in the developing corm resulting in the death of the plant or a non-marketable product. An isolate (FI-1452) of *Metarhizium anisopliae* found on *P. woodlarkiana* in PNG is virulent for that species as well as for *P. heubneri* and *P. uninodis*. This isolate is being mass produced on rice in PNG and Fiji and tested in field trials for control of Taro beetle as part of an ACIAR/SPC project. Initial tests in PNG at 3 sites with doses ranging from 10g to 300g applied into the planting hole have increased the proportion of marketable corms from 33% to 65%. Research is still evaluating the most effective dose and an acceptable formulation. Also possible combinations with chemical pesticides are being studied.

Field population dynamics of egg parasitoids of the glassy-winged sharpshooter and smoke-tree sharpshooter in California

JG Morse, AK Al-Wahaibi
Department of Entomology, Univ. of California, Riverside, CA 92521 USA; joseph.morse@ucr.edu

The glassy-winged sharpshooter (GWSS), *Homalodisca coagulata* (Say) (Hemiptera: Cicadellidae), is under chemical management in California in the vicinity of Temecula, the Coachella Valley, the southern San Joaquin Valley, and Ventura Co. This insect is of concern not only because it vectors various strains of *Xylella fastidiosa* with potential to cause disease on a wide variety of crops (e.g., Pierce's disease on grapes) but also because control mandated to limit its spread in the state causes disruption of nursery shipments and movement of harvested citrus. The smoke-tree sharpshooter, *H. liturata* Ball, is native to California and has also been shown to vector *Xylella* diseases although apparently to a letter degree than the introduced *H. coagulata*. A two-year field study in the vicinities of Riverside and Desert Center, CA evaluated levels of egg parasitism on these two sharpshooter species across five fields containing a total of ten host plants. One of these fields was used by the California Deptartment of Food & Agriculture as a site for augmentative release of four exotic species/strains of parasitoids over the duration of this study. The temporal pattern of egg parasitism by eight species, six *Gonatocerus* (Hymenoptera: Mymaridae) and two *Ufens* (Hymenoptera: Trichogrammatidae) are discussed.

Potential biological control of invasive alien flatworms

AK Murchie
DARD (NI) & QUB, Newforge Lane, Belfast, BT9 5PX, U.K.; archie.murchie@dardni.gov.uk.

The British Isles have been invaded by antipodean terrestrial flatworms, termed locally the 'New Zealand flatworm' (*Arthurdendyus triangulatus*) and the 'Australian flatworm' (*Australoplana sanguinea*). Both species are earthworm predators and there is increasing evidence that *A. triangulatus* negatively affects earthworm populations, in particular anecic species of earthworm. Decline/alteration of earthworm populations could have damaging knock-on effects on soil fertility and other earthworm-feeding wildlife. However, control options are limited due to the flatworms' abundance and cryptic nature. An exclusion experiment was designed to investigate the impact of Carabidae on *A. triangulatus*. Barriered field plots, half of which were treated with insecticide, were sampled weekly for flatworms and carabids. In insecticide-treated plots, there were fewer carabids but more flatworms, compared to untreated controls. However, the difference between treatments was not large, suggesting that carabids moderate rather than control *A. triangulatus* populations. 'Classical' biological control is another option. A Tasmanian midge, *Planarivora insignis* (Mycetophilidae) is the only known parasitoid of terrestrial flatworms. Little is known about this midge beyond a single publication in 1965. Could this midge be used as a control agent for invasive flatworms?

Bollgard®II – Will it affect abundance of *Microplitis demolitor* in Australian cotton agroecosystems?

D Murray, R Annetts, P Gregg
Department of Primary Industries & Fisheries, PO Box 102, Toowoomba, QLD, 4350, Australia; dave.murray@dpi.qld.gov.au

The braconid *Microplitis demolitor* is the most important parasitoid of early instar *Helicoverpa* spp. in the cotton agroecosystem. Late first and second instar larvae are the preferred host stage for oviposition, with host death usually in the third or fourth instar. Feeding by parasitised larvae is greatly reduced, with diet consumption about 10% of that consumed by healthy larvae. In unsprayed non-Bt cotton, parasitism rates of second and third instar larvae often exceed 50% in the latter half of the growing season. *Microplitis demolitor* also transmits ascovirus when ovipositing which usually results in the death of the immature parasitoid in the ascovirus-affected host. Although routine insecticide use in conventional cotton can be disruptive to adults and immature stages of *M. demolitor*, the pupal case offers protection from most insecticides. Cotton is just one of many crop hosts that harbour *M. demolitor* in the farming system. Bt transgenic cotton, particularly Bollgard®II, results in extremely high mortality of larvae of *Helicoverpa* spp. It is not known to what extent the increased adoption of Bollgard®II will affect abundance of *M. demolitor* through reduced host availability in cotton.

Quantifying conservation biological control of *Bemisia tabaci* in the cotton system

SE Naranjo, PC Ellsworth
USDA-ARS, 4135 E. Broadway Rd., Phoenix, AZ , USA 85040; snaranjo@wcrl.ars.usda.gov

Multiple mortality forces act on insect populations. Estimating mortality caused by natural enemies within the context of other interacting mortality agents is important to understanding the contribution of biological control to pest suppression. Field studies examined the role of natural enemy conservation in cotton within the context of alternative management strategies for *Bemisia tabaci* based on selective and non-selective insecticides. *In situ* life tables were used to quantify and interpret the effects of natural enemies relative to other contemporaneous mortality factors acting on pest populations. Single applications of selective insecticides initially functioned by replacing some mortality from predation and parasitism, and contributing an immediate, and essential, level of irreplaceable mortality. However, because these selective materials did not disrupt natural enemies, parasitoids, and especially predators, were able to supply irreplaceable mortality that contributed to pest suppression for the remainder of the season. This extension in time also served to increase the cumulative chance of pest suppression by weather-related factors. In contrasted systems based on broad-spectrum insecticides, repeated applications were required for pest control. This study demonstrates the role of multiple mortality factors in managing *B. tabaci* and provides a mechanistic understanding of the important contribution of conservation biological control.

"The biology and characterisation of an ascovirus (Ascoviridae) from Australia"

IR Newton
School of Life Sciences, The University of Queensland, Brisbane, QLD, 4072, Australia;
i.newton@uq.edu.au

Ascoviruses (Ascoviridae) are a group of enveloped DNA viruses that cause a chronic and lethal disease in insects. Most of the described ascoviruses are hosted in the larval stage of the Noctuidae (Lepidoptera). Unpublished reports indicated that an ascovirus was found at high incidence (>50%) in populations of *Helicoverpa armigera* (Hübner) and *Helicoverpa punctigera* (Wallengren) in southeast Queensland, Australia. These pathogens were thought to be vectored by the braconid parasitoid wasp *Microplitis demolitor* (Wilkinson). I have formally identified and characterised this ascovirus by examining; the genetic relationship to other known ascoviruses (using RFLPs, Southern blot hybridisations and sequencing the polymerase gene), the host range of the virus and the histopathology. The Australian ascovirus was similar to the *Heliothis virescens* (Fabricius) ascovirus (HvAV) and the *Trichoplusia ni* (Hübner) ascovirus (TnAV) from the USA. To further understand the biology of the Australian ascovirus, I studied its transmission and interaction with hymenopteran parasitoids; I examined other "alternative" modes of transmission and its field prevalence in Australia. The Australian ascovirus appears to be an opportunistic pathogen; it may rely on multiple hosts, multiple vectors and multiple modes of transmission for dissemination and persistence in the field.

Choosy egg parasitoids: specificity of response of egg parasitoids to plant volatiles induced by egg deposition

M Hilker, R Mumm
Freie Universität Berlin, Institute of Biology, Haderslebener Str. 9, D-12163 Berlin, Germany; hilker@zedat.fu-berlin.de

Plants may respond to insect egg deposition by release of volatiles which attract egg parasitoids (1). Recently Scots pine (*Pinus sylvestris*) was shown to respond to egg deposition by the pine sawfly *Diprion pini*. Pine twigs with host eggs emit volatiles that attract the eulophid egg parasitoid *Chrysonotomyia ruforum,* a species specialized on diprionid eggs (2, 3). We tested whether this response is specific for the plant and herbivore species. *C. ruforum* shows a high specificity for oviposition-induced plant volatiles with respect both to the plant and herbivore species. Furthermore, the parasitoid´s response to these volatiles depends on its experience prior to the bioassay. While numerous generalist parasitoids are well-known to learn a wide range of volatiles when they had the opportunity to associate them positively with a host , the specialist *C. ruforum* was shown just to be able to learn specific volatile blends.

Patch use by egg parasitoids: theory, facts, and biological control

Y Hirose
349 Asano, Munakata 811-3415, Japan

This is a critical review of theoretical and empirical studies on patch use by egg parasitoids, determining if theory explains observed facts. It explores the possibility that egg parasitoids aggregate in host patches of high density or large size because classical patch-use theory predicts that foraging parasitoids should spend a relatively longer amount of time in high-quality patches, and the possibility that parasitoid aggregation results in density dependent parasitism. It stresses the fact that host age profoundly influences patch use by parasitoids of eggs laid in masses because host quality declines with host age; this occurs simultaneously in all hosts in a patch (i.e. egg mass). When parasitoid females discover low-quality host patches just before host hatching, they should leave the patches as soon as possible to search for another patch. The case of *Anagrus sophiae* (= *delicatus*) females that attack only a small fraction of hosts in an egg mass and leave high-quality patches still carrying apparently mature eggs (Cronin & Strong, 1993) seems to be exceptional among quasi-gregarious egg parasitoids. Characteristics of patch use by egg parasitoids are discussed in relation to their use in biological control.

Selecting arthropod biological control agents: improving agent selection to minimize non-target impacts and maximize target impacts

MS Hoddle

Department of Entomology, University of California, Riverside, CA 92507, U.S.A; mark.hoddle@ucr.edu

Non-target impacts and establishment of ineffective arthropod biological control agents targeting arthropod pests are receiving increased levels of research either through retrospective studies or via *a priori* evaluations before release to from quarantine. Glassy-winged sharpshooter, *Homalodisca coagulata*, an invasive xylophagous hemipteran in California, is the focus of a major classical biological control program with mymarid parasitoids that have been recruited from the pest's home range in the southeast U.S.A. Native sharpshooters potentially at risk from exotic parasitoids are being evaluated for susceptibility to attack as are native sharpshooters in French Polynesia, where *H. coagulata* established *circa* 1999. Laboratory studies assessing risk and parasitoid efficacy have indicated that screening parasitoids for potential efficacy is strongly influenced by parasitoid species and experimental conditions such as the complexity of the environment searched and relative host abundance provide. These different metrics for evaluating parasitoid efficacy can provide different answers as to which parasitoids will be most effective. Our work suggests that greater thought needs to be given to prevailing pest densities at the start of the biological project and how host-parasitoid dynamics will change as successful agents control the target pest making it less common. Lower pest densities because of successful biological control may affect which species or guilds of parasitoids come to dominate and regulate the system at low host densities compared to observations at the start of the program where pest numbers were higher.

Attractants for *Aleochara* spp. (Coleoptera: Staphylinidae), natural enemies of *Delia radicum* (Diptera: Anthomyiidae), in canola

K Riley, NJ Holliday, U Kuhlmann, LJ Donald
Dept Of Entomology, University of Manitoba, Winnipeg, Mb, Canada R3T 2N2;
Neil_Holliday@umanitoba.ca

Defatted mustard seed meal has been shown to attract *Aleochara* species in vegetable brassicas in Sweden, and crop damage was reduced in plots with this treatment (Ahlström-Olsson & Jonasson, I0BC/WPRS Bull. 1992; 15:171). In trials with mustard flour in Canada and with defatted mustard meal in Switzerland, pitfall traps in canola plots with mustard preparations spread at 20 g/m² did not catch higher numbers of *Aleochara bilineata* than did traps in untreated control plots. However, in the Swiss trial, *A. bipustulata* catches in traps in mustard meal plots were almost 2.5 times those in control plots. Parasitism of *Delia radicum* pupae by *A. bipustulata* was significantly higher in mustard meal plots than in control plots, but parasitism by *A. bilineata* was not affected by the treatment. In Y-tube olfactometer studies, *A. bipustulata* exhibited preference for mustard meal compared to a blank control, but *A. bilineata* showed no preference. We are conducting further olfactometer studies comparing mustard meal and mustard flour in the presence and absence of soil and of moisture. Additionally, we are comparing the chemical composition of volatiles from potential attractants using gas chromatograph mass spectrometry.

Influence of host density on the dispersal of a specialist parasitoid

CL Hsu, G Heimpel, DA Andow, R Venette
Dept. of Entomology, UMN, 219 Hodson Hall, 1980 Folwell Ave., St. Paul, MN 55108, USA; hsux0049@umn.edu

The use of genetically modified corn in the United States to control the European corn borer, *Ostrinia nubilalis*, is creating a dramatic shift in the spatial dispersion of hosts available to the specialist parasitoid *Macrocentrus grandii*. The persistence of this parasitoid in the Midwestern corn belt may be limited by its dispersal abilities, and its behavioral response to large regions of low host densities created by the widespread use of genetically modified corn. We marked parasitoids developing on *O. nubilalis* using foliar applications of rubidium chloride to 0.2 ha corn plots. Marked parasitoids were presented with transgenic (low host density) and nontransgenic (high host density) corn fields and their dispersal in the two types of fields was monitored using sticky traps. More than 10,000 parasitoids were captured in the first year and preliminary results show differences in the behavior of male and female *M. grandii* dispersing into transgenic corn fields. Parasitoids were captured throughout the 8 ha transgenic corn fields demonstrating that dispersal into low host density fields is possible at this scale. Rubidium levels in parasitoids collected from the 0.2 ha treated plots were 8 times higher than in unmarked parasitoids.

Biological control of *Bemisia tabaci* by the predators

J Huang, Y Jing, HW Luo, ZH Wang
College Of Plant Protection, Fujian Agriculture And Forestry University, Fuzhou 350002, P.R.China; jhuang@fjau.edu.cn

The sweetpotato whitefly, *Bemisia tabasi* (Gennadius), is a widespread pest of crops in the world, which recently seriously occurs in China, and damages the most economically significant crops of cotton, vegetables and ornamentals, showing a tendency of annual outbreaks with the trouble problem urgent to be solved in agricultural productions. The predatory enemies of *Bemisia tabasi* in China have some species of ladybeetles, thrips, aphids lions and predatory mites, of which the ladybeetles *Serangium japonicum* and *Delphastus catalinae* are active as the dominant species. Both the two species of ladybeetles have a good efficiency feeding on the different stages of *Bemisia tabaci*, especially preferring to the whitefly eggs. At the laboratory, *Delphastus catalinae* develops a generation by 17-22 days at 25-28°C, with the ladybeetble population increases 21.61 times more than that of the fore generation, and develops about 15 generations per year. The predatory quantity per day reaches up 1198 and 670 of whitefly eggs fed by a 4th instar larva and an adult female of *Delphastus catalinae* respectively. The mass rearing of ladybeetles carries out followed by the rearing process of host plant – host whitefly – ladybeetble.

The *Sirex* woodwasp control programme in South Africa

BP Hurley, MJ Wingfield
Forestry And Agricultural Biotechnology Institute (Fabi), University Of Pretoria, Pretoria, 0002, South Africa; Brett.Hurley@Fabi.Up.Ac.Za

The *Sirex* woodwasp, *Sirex noctilio*, was first detected in South Africa in the Tokai plantation, Cape Town in 1994. *Sirex noctilio*, together with its symbiotic fungus *Amylostereum areolatum*, inhabits and kills pine trees. Since its initial detection in South Africa, this exotic pest has spread rapidly and is causing increasing losses to the pine industry. Three biological control agents were introduced into South Africa soon after *S. noctilio* was first detected. These included the parasitic nematode, *Beddingia siricidicola*, which is considered to be the best biological control agent against the woodwasp. Unfortunately, the biocontrol agents have not spread together with *S. noctilio*. To address this problem, *B. siricidicola* has been re-introduced on a much larger scale and on a more continuous basis than was previously attempted. The aim here has been to ensure that the nematode becomes established and that it achieves sufficient control of the wasp in South African pine plantations. Studies are also underway to investigate possible differences in the life-cycle of *S. noctilio* in different climatic zones of South Africa. Furthermore, we are considering evidence to suggest that the wasp has been introduced into the country more than once.

Associative learning of plant chemicals by the egg-larval parasitoid, *Ascogaster reticulata* Watanabe (Hymenoptera: Braconidae)

Y Kainoh, K Shoji, M Satoh
Institute of Agriculture and Forestry, University of Tsukuba, Tsukuba, Ibaraki 305-8572, Japan; parasite@sakura.cc.tsukuba.ac.jp

We examined the learning response to authentic chemicals in *Ascogaster reticulata* Watanabe, an egg-larval parasitoid of the smaller tea tortrix, *Adoxophyes honmai* Yasuda (Lepidoptera: Tortricidae). After 3 times' conditionings of chemicals associated with the host egg mass, the strength of the learned response in a female was evaluated by the distance walked along the chemical cues with her characteristic antennating response in 9-cm Petri dish assays. We compared the learned response of females to 5 authentic chemicals, i.e., linalool, geraniol, methylsalicylate, *(Z)*-3-hexenol and benzyl alcohol. The order of learned responses was as follows: linalool = geraniol > methylsalicylate > *(Z)*-3-hexenol = benzyl alcohol. When the females were conditioned with geraniol, they responded to geraniol significantly longer in a choice between geraniol and linalool. The linalool-conditioned females positively chose linalool in the same choice situation, but not significant. Use of the mixtures of these chemicals in different ratio also had similar effect.

Augmentation of parasitoids by mass-hatching devices: a new biocontrol technique

P Kehrli, S Bacher
Ecology and Entomology Group, PO Box 84, Lincoln University, Canterbury, New Zealand;
kehrlip@lincoln.ac.nz

Augmentation can be an effective biocontrol strategy to increase the impact of antagonists. However, mass-reared beneficials are generally expensive and often poorly adapted to field conditions. The goal of this study was the development of a device, which selectively permits parasitoids to emerge out of pest-infested plant material. Plant material containing the host and its parasitoids can be collected and stored in large closed devices from which the generally smaller parasitoids can emerge through a selective tissue filter of appropriate mesh size. We used mass-hatching devices to augment populations of indigenous parasitoids of the invasive horse chestnut leafminer, *Cameraria ohridella* (Lepidoptera, Gracillariidae). Whereas more than 75 % of the 15'000 parasitoids passed the separator only 1 % of the 50'000 leafminers overcame the tissue filter. Furthermore, the set-up of mass-hatching devices in the city of Basel, Switzerland, significantly increased parasitism rates of *C. ohridella*. Mass-hatching devices may thus contribute to an integrated control strategy against *C. ohridella* in Europe. In general, mass-hatching devices are a promising new augmentative approach to control insect pests with a dormant stage in or on plant residues and should be considered as a supplementary, cost-effective biocontrol technique.

Molecular genetic investigation of local adaptation and incipient speciation in a tritrophic system

KM Kester, BL Brown
Dept. of Biology, Virginia Commonwealth University, 1000 W. Cary St., Richmond, VA, 23284-2012 USA; kmkester@vcu.edu

Seven polymorphic microsatellite loci were assayed in two groups of the insect parasitoid, *Cotesia congregata* (Say) [Hymenoptera: Braconidae]. One group originated from *Manduca sexta* L. and *Manduca quinquemaculata* (Haworth) on tomato and tobacco ("solanaceous group") and the other from *Ceratomia catalpae* (Boisduval) on catalpa ("catalpa group"). Allelic distributions differed significantly between the solanaceous and catalpa groups (Fisher's exact test $P = 0$ overall and for each locus). Across all loci, F_{ST} was < 0 for within-group comparisons and > 0.47 for between-group comparisons. Wasps from the solanaceous and catalpa groups were examined for mtDNA sequence variation to investigate their possible status as sibling species. One conserved mtDNA gene (16S) showed a single fixed nucleotide difference between the two groups. The results support the hypothesis that host plant association is a significant factor influencing population structure of *C. congregata*.

Selecting arthropod biological control agents against arthropod pests: how can the science be improved to decrease the risk of releasing ineffective agents?

KA Hoelmer, AA Kirk

USDA-ARS European Biological Control Laboratory, Campus International de Baillarguet, Montferrier 34980, France; khoelmer@ars-ebcl.org

From the practitioner's viewpoint, there are several principles that, if observed, will improve the chances for successful agent selection:

1) Involvement of morphological and/or molecular characterizations is needed from the inception of the project. When the native range/origin of a pest is unknown, this will help to identify significant differences in pest populations and may reveal their actual native range. Identification and characterization of the natural enemy geographic populations and possible host range differences is equally important.
2) Use of climate matching tools is a good starting point for locating climatically-adapted populations of natural enemies.
3) Native range studies should be conducted to evaluate the impact of exotic agents on the target pests.
4) Concurrent and parallel studies should be conducted in the potential release area to document gaps in native enemy activity or other ecological factors that contribute to high pest populations. This also means that a committed practitioner is in place in the receiving area.
5) Collection of natural enemies of species that are taxonomic relatives or ecological homologues of the target pest and which occur in the same or neighboring habitats may reveal field specificities.
6) Quarantine evaluations can provide a preliminary screening of potential effectiveness.
7) Field cage/semi field evaluations are desirable to validate the results of preliminary screenings under more realistic conditions.

These approaches will be discussed in relation to examples of recent projects.

Management of sucking pests in broadacre crops using *Beauveria bassiana* & *Metarhizium anisopliae*.

"K Knight, C Hauxwell, D Holdom"
Agency for Food and Fibre Sciences, Department of Primary Industries & Fisheries, Biopesticides Unit, 80 Meiers Road, Indooroopilly, Qld, 4068, Australia; kristen.knight@dpi.qld.gov.au

Biopesticides based on insect pathogens have been widely applied in an integrated pest management (IPM) strategy against *Helicoverpa* species in Australia, maintaining beneficial insect populations and minimising the development of resistance to chemical insecticides. As reliance on chemical control has reduced in cotton and grain crops, sucking pests such as mirids (*Creontiades* sp.) and green vegetable bug (*Nezara viridula*) are emerging as significant problems. Application of broad-spectrum insecticides against sucking pests threatens the successful IPM strategy by destabilising natural enemy populations and triggering outbreaks of *Helicoverpa sp,* however there are currently no selective insecticides registered for sucking pests. We have identified *Beauveria bassiana* and *Metarhizium anisopliae* isolates active against these pests. Field trials demonstrated control of mirids equal to that achieved with the chemical Dimethoate by four to six days after treatment for both isolates at 1×10^{13} spores/hectare. There was no significant impact on natural enemies in any of the field trials. Monitoring has indicated that sucking pest populations build up in pulse crops through the vegetative stage. We are modelling pest populations and developing a pest management strategy based on population management using biopesticides as an alternative to reactive knockdown using broad-spectrum chemical insecticides.

Red imported fire ant: benefit or detriment to conservation biological control in cotton?

AE Knutson, R Diaz, J Bernal
Texas A&M Research & Extension Center, 17360 Coit Road, Dallas, TX , USA. 75252; a-knutson@tamu.edu.

Predation of sentinel eggs of *Helicoverpa zea* and *Spodoptera exigua* (Noctuidae) was 1.5-2.0 and 4.1 times greater, respectively, in the presence of red imported fire ant, *Solenopsis invicta* (Formicidae), than when fire ants were excluded from 3-ha plots of cotton in central Texas in 2001-2002. Most (68%) of the observed predation events on beet armyworm eggs was due to *S. invicta*. Densities of cotton aphid, *Aphis gossypii*, were 5.5 times greater in the presence of fire ants compared to ant exclusion plots, although aphid densities did not reach economic levels. In additional field trials conducted in 2003, densities of cotton aphid were not significantly different between ant treatments and again did not exceed the economic threshold (50 aphids/leaf). Densities of *Hippodamia convergens* (Coccinellidae) adults and larvae were significantly greater in the ant exclusion treatment Red imported fire ants are intraguild predators in cotton. However, our results suggest that the overall impact of the red imported fire ant is beneficial to cotton pest management in Texas and efforts to enhance fire ant densities have the potential of increasing biological control of nocutid pests.

"Oral toxicity of *Photorhabdus* bacterial toxins against thrips species"

"LJM Gerritsen, WJ de Kogel"
Plant Research International, PO Box 16, 6700 AA Wageningen, The Netherlands, willemjan.dekogel@wur.nl

Photorhabdus and *Xenorhabdus* bacteria are symbiotic to entomopathogenic nematodes. These bacteria are released by nematodes after infection of insects. The oral toxicity of excretion products of several *Photorhabdus* and *Xenorhabdus* strains was tested on two thrips species: *Frankliniella occidentalis* and *Thrips tabaci*. Out of 46 *Photorhabdus* isolates and 6 *Xenorhabdus* isolates only 6 North American *P. temperata* isolates were toxic to the thrips species. After 7 days of inking from *P. temperata* supernatant a mortality of 90% was recorded and reproduction was inhibited. Thrips were also killed after feeding from leaves that were treated with the toxins. Possibilities of using *P. temperata* for the control of thrips will be discussed.

"Understanding target weed population dynamics can improve our ability to select effective agents against weeds"

D Kriticos
Forest Research, PB 3020, Rotorua, 3201 New Zealand; Darren.Kriticos@forestresearch.co.nz

Understanding the population dynamics of a weed and the role of environmental factors in influencing these dynamics can help us prioritise insect and pathogen guilds in terms of their likely efficacy in controlling target weeds. In order to be effective, an agent needs to inflict sufficient damage, on appropriate organs or lifestages, and do so in a timely manner. Modelling the population dynamics of a weed can indicate the likelihood of agents from different guilds being able to inflict these desirable damage patterns under the range of environmental conditions that are likely to be encountered in the introduced range. The most desirable agents are those that, when released from their own predators or parasitoids, would act upon the plant population in the manner that most amatically reduces the problems caused by the weed – characteristics that will vary from weed to weed. The characteristics of the most desirable agents can then be used to influence the suite of agents that are specifically targeted for searching, and to help prioritise them for importation and host-specificity testing. If agent establishment follows the lottery model, then prioritising agents that, should they establish, are most likely to be effective should improve our overall success rate.

Efficacy of nuclear polyhedrosis virus with azadirachtin on the mortality, feeding, biological, biochemical & histopathological profiles of *Helicoverpa armigera.*

"N Senthil Kumar"
P.G Department of Biotechnology, N.G.M College, Pollachi 642001,India; nskbiotech@rediffmail.com

The mortality of third instar larvae of *Helicoverpa armigera* larvae was observed in a dose dependent manner and the time to kill was significantly reduced in the combined treatment of Nuclear Polyheosis Virus (NPV) and Azadirachtin (AZA). The average leaf disc consumption of *H. armigera* larva fed with NPV (5 x 10^4 PIB/ml) treatment was 1.90 cm^2/larva and AZA treatment (4 μg/cm^2) was 0.63 cm^2/larva whereas it was significantly reduced to 0.21 cm^2/larva in the low dose combined treatment. Significant reduction in the larval and pupal weights, elongation of larval and pupal duration and a astic reduction in the adult longevity, fecundity and survivability were observed after the combined treatment. Reduced amounts of protein (35.8 mg/g), lipid (47.4 mg/g), carbohydrate (35.7 mg/g), amino acids (32.6 mg/g), DNA at 96 hrs post-treatment (82 μg/g) and RNA at 96 hrs post-treatment (2.4 μg/g) were observed after NPV and AZA treatment. These biochemical changes suggest that AZA did not affect the multiplication of NPV and further there is a synergistic interaction between NPV and azadirachtin. The combined treatment caused a severe necrosis of the midgut epithelial cells and loss of cell shape. The combined treatment of NPV and azadirachtin had much greater effect in relation to the pest management strategy.

Suitability of parasitized greenbugs (*Schizaphis graminum*) as food source for predatory Coccinellidae

M Lebusa, T Royer, K Giles.
Oklahoma State University, Stillwater, Ok 74078.

Laboratory studies were conducted to determine first, the stage of development at which the predatory coccinellidae, *Hippodamia convergens*, *Coccinella septempunctata* and C*oleomegilla maculata* are able to start feeding on the parasitized greenbugs "mummies" (*Schizaphis graminum*), and second to determine the nutritional effects of mummies on the growth, development and survival of *Coccinella septempunctata.* Lady beetles were collected from the field and fed unlimited amount of pea aphids (*Acyrthosiphon pisum*) until when they laid eggs. A batch of coccinellid larvae at each instar was fed fresh mummies on daily basis and observed. The preliminary results showed that *Hippodamia convergens* start feeding on mummies at the third instar, even though *Coccinella septempunctata* start feeding on mummies at the second instar, and each instar larva was able to molt to the next stage of development. Further results of the experiment show that *C.septempunctata* take long to develop and they survive through one molt when they are fed mummies. More results will be obtained at a later stage of the study. This study confirms that *Coccinella septempunctata* and *Hippodamia convergens* are able to feed on the parasitized greenbugs at both larval and adult stages of development.

"Isolation & characterization of novel insecticidal *cry1*-type genes from *Bacillus thuringiensis* strains"

"MS Li, JY Choi, JY Roh, HJ Shim, JN Kang, KS Boo, YH Je "
"School of Agricultural Biotechnology, College of Agriculture and Life Sciences, Seoul National University, San 56-1, Shinllimdong, Kwanakgu, Seoul, 151-742, Korea; mshli7125@hanmail.net"

"To identify new *cry1*-type insecticidal genes, 56 lepidopteran-specific *Bacillus thuringiensis* (Bt) strains were isolated from Korea. Universal oligonucleotide primers, K5un2 and K3un2, were designed and used to amplify all known *cry1*-type genes with PCR from 56 Bt isolates. The restriction fragment length polymorphism (RFLP) patterns of the PCR-amplified fragments revealed 7 distinct patterns, and a standard isolate was selected from each one of the RFLP groups. Through cloning and sequence analysis of the PCR-amplified fragments showing unique RFLP pattern, 7 novel *cry1*-type genes were identified. Bt K-1 and Bt 2385-1 strains were selected to isolate and characterize the active regions of the novel genes, and then 5 novel genes were cloned from them. To verify the activity against lepidopteran larvae, the novel genes were expressed using baculovirus expression vector system and the bioassay was performed to *Plutella xylostella* (Px) and *Spodoptera exigua* (Se). All novel *cry1*-type genes had high toxicities against Px larvae and, *cry1-44* and *cry1-5* had the highest toxicity against Px and Se larvae, respectively. Also, *cry1-1* and *cry1-5* had dual toxicities against Px and Se larvae. Finally, each novel gene must be a very useful resource for development of microbial insecticide and insect resistant plants.
"

"Bats feed on crop pests in California's Sacramento Valley"

RF Long
UC Cooperative Extension, 70 Cottonwood St. Woodland, CA 95695; rflong@ucdavis.edu

Food habits of Mexican free-tailed and Yuma bats were examined in the Sacramento Valley in California. Analyses of guano samples indicated that these two species of bats fed on moths, beetles, and plant bugs suggesting they might help control crop pests. Further studies in cotton, walnuts, pears, and alfalfa showed that bats forage extensively in these crops; however, their impact on biological pest control remains unclear. A colony of 150 bats will feed on more than a million insects a year. In addition, bats may protect crops by their echolocation calls alone. Many insects, including moths, are sensitive to bat calls and take evasive action when they detect bats by turning or diving to the ground, which may disrupt their mating and egg-laying behavior. Given the beneficial nature of bats, growers in California have been putting up bat houses to attract bats to their farms for pest control. Analysis of 175 bat houses in California showed that bats prefer houses that were attached to wooden barns, at least ten feet off the ground, that received morning sun and afternoon shade.

What hypervariable molecular markers tell us about parasitoid population structure & dynamics at both landscape & geographic scales

HD Loxdale, C Macdonald, DA Baker
Rothamsted Research, West Common, Harpenden, Hertfordshire, AL5 2JQ, UK; Hugh.Loxdale@bbsrc.ac.uk

We here discuss the use of polymorphic microsatellite markers to study natural populations of the hymenopterous primary parasitoid, *Diaeretiella rapae* (M'Intosh), a polyphagous parasite of crucifer and cereal aphids. Using five such markers, its population structure and dynamics was examined at the field and landscape scale when attacking cabbage aphid, *Brevicoryne brassicae* (L.) infesting oilseed rape, *Brassica napus* at two sites in southern Britain. Parasitoid samples were collected at different spatial scales ranging from individual racemes to field corners. The data were analysed using Bayesian and other statistics to provide new insights into parasitoid movement, persistence and breeding structure. In addition, the same markers were later used to study the genetic variability of *D. rapae* at four geographic sites (Western Australia, France, Morocco and Kazakhstan) reared on the Russian wheat aphid (RWA), *Diuraphis noxia* (Mordvilko). When compared with Old World populations, Australian parasitoids had low allele length and frequency variation, suggesting a significant founder effect. Marked genetic differentiation between populations was also apparent, potentially important for host utilization in this species when introduced to a new geographic area/s. Low genetic variation and gene flow in a founder population could limit evolutionary potential, including the ability to switch to novel introduced hosts, e.g. RWA.

"The density & diversity of parasitic Hymenoptera as bio-indicators of habitat disturbance in a cotton producing region"

"R Magallanes-Cedeño, JJ Ellington, A González-Hernández, G Díaz-López "
E Marcelin Lotes 5 y 7, Magisterial. Tapachula, Chiapas. México, C.P. 30770; ricardomagallanes@doctor.com

The presence and diversity of hymenopteran parasitoids were compared in cotton with sprays of chemical insecticide, and protected with a bioinsecticide in Huehuetán, Chiapas, México from September, 1999 to January, 2002. Parasitoids were collected weekly from phytophagous insects on upper, middle and lower leaves, squares, flowers and bolls, held in styrofoam cups, with a semi-transparent lid. During the last two years, parasitoids were also collected by vacuuming above the plant canopy. Chemical insecticide decreased both the incidence and diversity of parasitoids early in the first year; however, the guild of natural enemies reappeared and became more abundant and diverse in the chemical treatment. This was associated with the protection brought to the crop by chemical insecticide sprays which resulted in more productive plants, furnishing more refuge to parasitoids late in the season. However, when the crop was rainfed, and phytophagous insects did not cause significant plant damage, natural enemies were affected by the chemical insecticide. Over 300 morphospecies of hymenopteran parasitoids were collected during the experiment. The fact that parasitic Hymenoptera occur at the top of the arthropod food chain makes this group of insects particularly useful in evaluating factors which control and often simplify natural and man-made ecosystems.

The impact of predatory bugs on *Helicoverpa armigera* in Australian cotton crops

"S Mansfield"
CSIRO Entomology and the Australian Cotton Cooperative Research Centre, Australian Cotton Research Institute, Locked Bag 59, Narrabri, NSW 2390, Australia and Forest Research, Private Bag 3020, Rotorua, New Zealand; sarah.mansfield@forestresearch.co.nz

The bigeyed bug, *Geocoris lubra*, and the damsel bug, *Nabis kinbergii*, are two common insect predators in Australian cotton crops. These predators are known to feed on the lepidopteran pest, *Helicoverpa armigera*, however such predation is difficult to observe and quantify under natural conditions. The detection of specific protein markers in predator gut contents allows direct measurement of predation from field-collected individuals. Here, I outline the development of ELISA protocols to detect predation by these two species on *H. armigera* using a species-specific monoclonal antibody. Although prey-specific proteins were detectable for only short periods within the predators, positive examples of predation have been recorded. Adult and juvenile predators of both species were collected from commercial cotton farms in northern NSW during the 2001-02 and 2002-03 seasons. Approximately 12% of *G. lubra* and 24% of *N. kinbergii* tested positive for recent predation on *H. armigera*. Predation rates were similar in both seasons although the relative abundance of *H. armigera* was lower in 2001-02 than 2002-03. This suggests these insect predators can contribute to the suppression of *H. armigera* even when pest populations are low.

Viral pathogens for the control of painted apple moth *Teia anartoides* (Lepidoptera: Lymantriidae)

"NP Markwick, J Poulton, VK Ward, VL Young, Z Li, C Hauxwell, TR Glare"
HortResearch, Mt Albert Research Centre, Private Bag 92169, Auckland, New Zealand; nmarkwick@hortresearch.co.nz

The painted apple moth (PAM), *Teia anartoides* (Lepidoptera: Lymantriidae) is a native of Australia, where it is a horticultural pest. Recently, PAM was found in Auckland, New Zealand and poses a threat to horticulture, pine forests and native plants. An eradication campaign was mounted in the Auckland suburbs including aerial applications of the biopesticide Foray (based on *Bacillus thuringiensis*) and releasing sterile male moths. To supplement eradication, we have investigated the availability and potential of microbial insect pathogens to control PAM. Efforts to identify potential biological control agents have included evaluation of several nucleopolyheovirus (NPV) strains from related species (e.g. other lymantriids) and from commonly found forest or horticultural pest insects. Most were non-pathogenic or showed minor sub-lethal effects and one appeared to potentiate a virus present at low levels in PAM larvae. However, an NPV (*Oran*NPV), discovered in PAM in Australia in the 1960s, was highly virulent as were two NPV stains isolated from other lymantriid species (*Orygia pseudotsugata* and *O. leucostigma*). Finally, a cypovirus, isolated from PAM in New Zealand, was infective in bioassays. Preliminary sequence data suggests that this cypovirus is an undescribed member of the *Cypoviridae*. Host range testing of these viruses is underway.

"Occurrence & abundance of spiders in cotton ecosystem of Tamil Nadu, India"

"VG Mathirajan, A Regupathy"
Department of Entomology, Tamil Nadu Agricultural University, Coimbatore- 641 003, India; mathirajan@mailcity.com

Agricultural entomologists have acknowledged the importance of spider species as a major factor in regulating pest populations of crops. Despite their importance were highlighted in various ecosystems by several workers, the role they play in regulation of pest populations in cotton ecosystem has received scant attention in India and few workers have attempted on faunistic survey in recording the spider fauna in cotton ecosystem. A survey was conducted at major cotton growing areas of Tamil Nadu *viz.,* Attur, Bhavanisagar and Coimbatore during winter cotton 1998 (July- December) and at Kovilpatty and Srivilliputur during summer cotton 1999 (February – June). The survey yielded 21 species *viz., Araneus* sp., *Argiope catenulata* Doleschall, *A. minuta* Karsh, *Neoscona theisi* Walcknear, *Cyrptophora cicatrosa* Stoliczka, *C. viridanus* Cambridge, *Oxyopes javanus* Thorell, *O. rufisternum* Thorell, *Peucetia viridana* Stoliczka, *Plexippus paykulli* Audouin, *Tetragnatha javana* Thorell, *Thomisus cherapunjens* Tikader, *T. pugilis* Stoliczka, *Leucage decorata* Blackwall, *Gasterocantha citricola* Forskal, *Neoscona elliptica* Tikader, *Clubiona* nr. *assodes* Cambridge, *Lycosa pseudoannulata* Boes. et Str., *Pardosa* sp., *Bianor* sp. and *Salticus* sp. grouped under 16 genera belonging to eight families (Araneidae, Argiopidae, Clubionidae, Oxyopidae, Lycosidae, Salticiade, Tetragnathidae and Thomisidae).

Genetic differentiation of hymenopteran parasitoids: using AFLPs in fingerprinting studies

"R Medina, P Barbosa"
Department of Entomology, Plant Sciences Building, University of Maryland, College Park, MD, USA 20742

"The ecology of insect parasitoids is influenced by plants on which their hosts occur. Parasitoid fitness is affected by plant traits. Thus, adaptation to plant traits could promote significant phenotypic and genotypic differences among sympatric populations. We present data on phenotypic and genotypic differences of two parasitoids ovipositing on (*Plathypena scabra*) on alfalfa and soybean. We compare the developmental time, percent parasitism, and pupal weight of a generalist (*Cotesia marginiventris*) and in a specialist parasitoid (*Aleiodes nolophanae*) and use AFLPs to measure genotypic differences in parasitoids from alfalfa or soybeans. AFLPs have been widely used in biology. Genotypic differentiation among populations of several plant and animal species have been explored with AFLPs. Cluster analyses have been applied to visualize and test systematics, evolutionary and population ecology hypotheses. However, these comparisons are potentially flawed because there is no way of knowing whether the number of individuals and bands used to generate similarity matrices and cluster analyses are sufficient to validly represent the genome of field populations. There are no agreed upon criteria for determining the appropriate number of individuals and bands. We present a method for determining the number of individuals and bands to consider in representing genetic profiles of populations.[agm1]
"

Genetic differentiation of hymenopteran parasitoids

RF Medina, P Barbosa
4112 Plant Sciences Bldg. University of Maryland, College Park MD 20742 USA; rfmedina@umd.edu

The ecology of parasitoids is strongly influenced by the host plant. Parasitoid fitness is affected by a variety of plant traits. Thus, it is reasonable to assume that adaptation to plant traits could promote phenotypic and genotypic differences among populations of parasitoids. We present data on phenotypic and genotypic differences of two braconid parasitoids ovipositing on the same host on different host-plants. We compare the developmental time, percent parasitism, and adult weight of a generalist (*Cotesia marginiventris* (Cresson)) and of a specialist parasitoid (*Aleiodes nolophanae* (Ashmead)) of the green cloverworm and use AFLP data as a measure of genotypic differences in parasitoids emerging from hosts on alfalfa versus those reared from hosts on soybeans. AFLPs have been widely used in ecology to explore genetic differentiation among populations in several species and cluster analysis methods have been applied to visualize these differences and to test all sort of hypotheses. However, these analyses are potentially flawed because there is no agreed upon criteria for determining the appropriate number of individuals and bands for such representations to capture variation in the field. We present a method for determining the number of individuals to collect and number of bands to consider when studying genetic differentiation.

Habitat manipulation for insect pest management in Australian cotton cropping systems

"RK Mensah, RV Sequeira"
NSW Agriculture, Australian Cotton Research Institute, Locked Bag 1000, Narrabri, NSW 2390, Australia; robert.mensah@agric.nsw.gov.au

Adoption of within-field monocultures of cotton crops in Australia discriminate against and reduce the establishment and activity of natural enemies of pests because they lack ecological diversity. Increased habitat diversity in the cotton cropping systems has been achieved by planting refuge crops adjacent to cotton fields or as strips or centrally located blocks. The use of refuge crops in this way has enhanced (1) the conservation and establishment of natural enemies on cotton crops early in the cotton season to suppress pest populations and (2) the diversion of pests away from cotton onto the refuge crops resulting in the reduction of pest population. Interplanting cotton crops with refuge crops such as lucerne, the strips should be 8-12 metres wide and 300 metres apart and should run the whole length of the adjacent cotton field. The problem associated with the use of refuge crops for pest management in cotton is that natural enemies may not be inclined to move from the refuge crops to forage the adjacent cotton crops. The movement of the natural enemies can be improved by either applying a natural enemy food attractant to the cotton crops or by reducing the size of the strips planted to refuge crops. The criteria for the selection and management of the refuge crops as well as their deployment in IPM programs in cotton will be discussed.

"Selecting parasitoids for biological control introductions: codling moth as a case study"

NJ Mills
Insect Biology, Wellman Hall, University of California, Berkeley CA 94720-3112, USA; nmills@nature.berkeley.edu

The parasitoid assemblages of lepidopteran pests are more diverse and interactive than those of homopteran pests, posing a greater dilemma for the biological control practitioner in selecting candidates for introduction. How do we identify the single best candidate for introduction, or if more than one species is selected, how important is it that they show no direct interactions? The recent biological control program against codling moth in California will be used to illustrate both theoretical and practical aspects of parasitoid selection for introduction. From a theoretical perspective, the importance of pest refuges from parasitism, antagonistic interactions, and parasitoid aggregation will be emphasized. In contrast, from a practical perspective, the importance of ease of collection, rearing success, and risk will be considered. These contrasting perspectives provide an interesting example of parasitoid selection as both an art and a science.

RESPONSE OF *TRICHOGRAMMA PLATNERI* & *T. PRETIOSUM* TO PATCHES OF SINGLE & CLUSTERED HOST EGGS

NJ MILLS, U KUHLMANN
INSECT BIOLOGY, WELLMAN HALL, UNIVERSITY OF CALIFORNIA, BERKELEY CA 94720-3112, USA; NMILLS@NATURE.BERKELEY.EDU

COMMERCIALLY PRODUCED *TRICHOGRAMMA* SPECIES ARE WIDELY USED IN AUGMENTATIVE BIOLOGICAL CONTROL PROGRAMS. HERE WE TEST WHETHER TWO NORTH AMERICAN SPECIES *T. PLATNERI* AND *T. PRETIOSUM*, DIFFER IN THEIR RESPONSE TO AND EFFICIENCY OF USE OF SINGLE AND CLUSTERED HOST EGGS. THE OVIPOSITION BEHAVIOR OF INDIVIDUAL EXPERIENCED PARASITOID FEMALES WAS MONITORED CONTINUOUSLY IN PATCHES (3.5 X 3.5 CM CARD) WITH 16 SINGLE SPACED OR CLUSTERED EGGS OF *EPHESTIA KUEHNIELLA* AT 25°C FOR UP TO 1 H OR UNTIL THE FEMALE LEFT THE PATCH. THE OVIPOSITION BEHAVIOR OF EACH PARASITOID SPECIES IN EACH PATCH TYPE WAS SUMMARIZED AS GENERALIZED ETHOGRAMS, PATTERNS OF PATCH USE, TIME BUDGETS AND THE SEQUENCE OF SEX ALLOCATION. *T. PLATNERI* HAD A GREATER RATE OF OVIPOSITION IN PATCHES WITH SINGLE HOST EGGS, AND AN INDETERMINATE ALLOCATION OF SEXES IN PATCHES OF CLUSTERED HOST EGGS. IN CONTRAST, *T. PRETIOSUM* SHOWED BOTH A GREATER RATE OF OVIPOSITION AND A MORE EFFICIENT SEX ALLOCATION IN PATCHES OF CLUSTERED HOST EGGS. THE MORE EFFICIENT USE OF HOST EGG CLUSTERS BY *T. PRETIOSUM* THAN BY *T. PLATNERI* SUGGESTS THAT CLOSER ATTENTION SHOULD BE PAID TO MATCHING THE OVIPOSITION BEHAVIOR OF *TRICHOGRAMMA* SPECIES TO THE OVIPOSITION STRATEGY OF THE TARGET PEST.

Metarhizium anisopliae as a mycoinsecticide for taro beetles (*Papuana* spp.) in Papua New Guinea & other Pacific Islands.

"RJ Milner, R Masamdu"
"BioPesticide Consultant, 81 Birriwa Road, Bungendore, NSW, 2621, Australia; rmilner@alphalink.com.au"

Taro is an important root crop for Melanesian and Polynesian people. It is extensively cultivated in PNG as well as Solomon Islands, Fiji, and Vanuatu. The adults of several species of Taro beetle are naturally occuring pests in PNG and the Solomons and recent introductions into other countries such as Fiji. The larvae are detritus feeders and are not an economic problem. The adults burrow down through the soil and eat large holes in the developing corm resulting in the death of the plant or a non-marketable product. An isolate (FI-1452) of *Metarhizium anisopliae* found on *P. woodlarkiana* in PNG is virulent for that species as well as for *P. heubneri* and *P. uninodis*. This isolate is being mass produced on rice in PNG and Fiji and tested in field trials for control of Taro beetle as part of an ACIAR/SPC project. Initial tests in PNG at 3 sites with doses ranging from 10g to 300g applied into the planting hole have increased the proportion of marketable corms from 33% to 65%. Research is still evaluating the most effective dose and an acceptable formulation. Also possible combinations with chemical pesticides are being studied.

Field population dynamics of egg parasitoids of the glassy-winged sharpshooter and smoke-tree sharpshooter in California

"JG Morse, AK Al-Wahaibi"
Department of Entomology, Univ. of California, Riverside, CA 92521 USA; joseph.morse@ucr.edu

The glassy-winged sharpshooter (GWSS), *Homalodisca coagulata* (Say) (Hemiptera: Cicadellidae), is under chemical management in California in the vicinity of Temecula, the Coachella Valley, the southern San Joaquin Valley, and Ventura Co. This insect is of concern not only because it vectors various strains of *Xylella fastidiosa* with potential to cause disease on a wide variety of crops (e.g., Pierce's disease on grapes) but also because control mandated to limit its spread in the state causes disruption of nursery shipments and movement of harvested citrus. The smoke-tree sharpshooter, *H. liturata* Ball, is native to California and has also been shown to vector *Xylella* diseases although apparently to a letter degree than the introduced *H. coagulata*. A two-year field study in the vicinities of Riverside and Desert Center, CA evaluated levels of egg parasitism on these two sharpshooter species across five fields containing a total of ten host plants. One of these fields was used by the California Deptartment of Food & Agriculture as a site for augmentative release of four exotic species/strains of parasitoids over the duration of this study. The temporal pattern of egg parasitism by eight species, six *Gonatocerus* (Hymenoptera: Mymaridae) and two *Ufens* (Hymenoptera: Trichogrammatidae) are discussed.

Potential biological control of invasive alien flatworms

AK Murchie
DARD (NI) & QUB, Newforge Lane, Belfast, BT9 5PX, U.K; archie.murchie@dardni.gov.uk.

The British Isles have been invaded by antipodean terrestrial flatworms, termed locally the 'New Zealand flatworm' (*Arthurdendyus triangulatus*) and the 'Australian flatworm' (*Australoplana sanguinea*). Both species are earthworm predators and there is increasing evidence that *A. triangulatus* negatively affects earthworm populations, in particular anecic species of earthworm. Decline/alteration of earthworm populations could have damaging knock-on effects on soil fertility and other earthworm-feeding wildlife. However, control options are limited due to the flatworms' abundance and cryptic nature. An exclusion experiment was designed to investigate the impact of Carabidae on *A. triangulatus*. Barriered field plots, half of which were treated with insecticide, were sampled weekly for flatworms and carabids. In insecticide-treated plots, there were fewer carabids but more flatworms, compared to untreated controls. However, the difference between treatments was not large, suggesting that carabids moderate rather than control *A. triangulatus* populations. 'Classical' biological control is another option. A Tasmanian midge, *Planarivora insignis* (Mycetophilidae) is the only known parasitoid of terrestrial flatworms. Little is known about this midge beyond a single publication in 1965. Could this midge be used as a control agent for invasive flatworms?

Bollgard$^{®}$II – will it affect abundance of *Microplitis demolitor* in Australian cotton agroecosystems?

"D Murray, R Annetts, P Gregg"
Department of Primary Industries & Fisheries, PO Box 102, Toowoomba, QLD, 4350, Australia; dave.murray@dpi.qld.gov.au

The braconid *Microplitis demolitor* is the most important parasitoid of early instar *Helicoverpa* spp. in the cotton agroecosystem. Late first and second instar larvae are the preferred host stage for oviposition, with host death usually in the third or fourth instar. Feeding by parasitised larvae is greatly reduced, with diet consumption about 10% of that consumed by healthy larvae. In unsprayed non-Bt cotton, parasitism rates of second and third instar larvae often exceed 50% in the latter half of the growing season. *Microplitis demolitor* also transmits ascovirus when ovipositing which usually results in the death of the immature parasitoid in the ascovirus-affected host. Although routine insecticide use in conventional cotton can be disruptive to adults and immature stages of *M. demolitor*, the pupal case offers protection from most insecticides. Cotton is just one of many crop hosts that harbour *M. demolitor* in the farming system. Bt transgenic cotton, particularly Bollgard$^{®}$II, results in extremely high mortality of larvae of *Helicoverpa* spp. It is not known to what extent the increased adoption of Bollgard$^{®}$II will affect abundance of *M. demolitor* through reduced host availability in cotton.

"Quantifying conservation biological control of *Bemisia tabaci* in the cotton system"

"SE Naranjo, PC Ellsworth"
"USDA-ARS, 4135 E. Broadway Rd., Phoenix, AZ, USA 85040; snaranjo@wcrl.ars.usda.gov"

Multiple mortality forces act on insect populations. Estimating mortality caused by natural enemies within the context of other interacting mortality agents is important to understanding the contribution of biological control to pest suppression. Field studies examined the role of natural enemy conservation in cotton within the context of alternative management strategies for *Bemisia tabaci* based on selective and non-selective insecticides. *In situ* life tables were used to quantify and interpret the effects of natural enemies relative to other contemporaneous mortality factors acting on pest populations. Single applications of selective insecticides initially functioned by replacing some mortality from predation and parasitism, and contributing an immediate, and essential, level of irreplaceable mortality. However, because these selective materials did not disrupt natural enemies, parasitoids, and especially predators, were able to supply irreplaceable mortality that contributed to pest suppression for the remainder of the season. This extension in time also served to increase the cumulative chance of pest suppression by weather-related factors. In contrasted systems based on broad-spectrum insecticides, repeated applications were required for pest control. This study demonstrates the role of multiple mortality factors in managing *B. tabaci* and provides a mechanistic understanding of the important contribution of conservation biological control.

"The biology & characterisation of an ascovirus (Ascoviridae) from Australia"

IR Newton
School of Life Sciences, The University of Queensland, Brisbane, QLD, 4072, Australia, i.newton@uq.edu.au

Ascoviruses (Ascoviridae) are a group of enveloped DNA viruses that cause a chronic and lethal disease in insects. Most of the described ascoviruses are hosted in the larval stage of the Noctuidae (Lepidoptera). Unpublished reports indicated that an ascovirus was found at high incidence (>50%) in populations of *Helicoverpa armigera* (Hübner) and *Helicoverpa punctigera* (Wallengren) in southeast Queensland, Australia. These pathogens were thought to be vectored by the braconid parasitoid wasp *Microplitis demolitor* (Wilkinson). I have formally identified and characterised this ascovirus by examining; the genetic relationship to other known ascoviruses (using RFLPs, Southern blot hybridisations and sequencing the polymerase gene), the host range of the virus and the histopathology. The Australian ascovirus was similar to the *Heliothis virescens* (Fabricius) ascovirus (HvAV) and the *Trichoplusia ni* (Hübner) ascovirus (TnAV) from the USA. To further understand the biology of the Australian ascovirus, I studied its transmission and interaction with hymenopteran parasitoids; I examined other "alternative" modes of transmission and its field prevalence in Australia. The Australian ascovirus appears to be an opportunistic pathogen; it may rely on multiple hosts, multiple vectors and multiple modes of transmission for dissemination and persistence in the field.

Life history of *Euselasia bettina* and *E. chrysippe* (Lepidoptera: Lycaenidae: Riodininae) on *Miconia calvescens* (Melastomataceae) from Costa Rica

"K Nishida"
"Sistema de Estudios de Posgrado en Biología, Escuela de Biología, Universidad de Costa Rica, 2060 San José, Costa Rica; knishida@cariari.ucr.ac.cr"

The life history and early stages of *Euselasia bettina* (Hewitson, 1869) and *E. chrysippe* (Bates, 1866) on *Miconia calcvescens* Schrank & Mart. ex DC., are described and illustrated. The species possess six larval instars and the larvae are processionary throughout their development. The eggs are laid in clusters on the underside of leaves—the mean number of eggs in each cluster: *E. bettina* 89 (SD=9; range=82-99; n=3) and *E. chrysippe* 70 (SD=20; range=44-113; n=29). The larvae are gregarious foliage consumers that feed, rest, and molt synchronously. A speices of Aphelinidae was reared from eggs of these two species, and a species of *Calolydella* sp. tachinid fly was reared from late instar larvae of *E. chrysippe*. *M. calvescens* is currently registered as one of the threatening invasive weeds in Tahiti and in Hawaii, and these two *Euselasia* species are currently considered as one of the potential biological control agents (Miconia Project Hawaii-University of Costa Rica 2004). This information will be useful for the biological control workers and personnel responsible identifying insects in quarantine in Hawaii.

"Parasitoid complex of indigenous garden pea leafminer and its effective use for biological control of *Liriomyza* leafminers in vegetable greenhouses"

K Ohno, F Fukuhara, K Takamatsu, A Tokita
Laboratory of Applied Entomology, Faculty of Agriculture, University of Miyazaki, Gakuen Kibanadai Nishi 1-1, Miyazaki City, 889-2192, Japan;
ohnok@plant.miyazaki-u.ac.jp

The infestation rate of the garden pea leaves by *Chromatomyia horticola* gradually increased during the winter, while parasitoids activity was limited only in a warmer day because of low temperature. However, the parasitoid populations seemed to reach a high density with 90 to 100% total parasitism rate on the well-developed garden pea leafminer populations in late spring and early summer. Throughout 3 years survey, 21 parasitoid species were recorded from the garden pea leafminer, most of which are also parasitoids of the invasive *Liriomyza* leafminers. Among the parasitoids emerging from the garden pea leafminer, *Chrysocharis pentheus* and *Diglyphus isaea* were dominant larval parasitoids, while *Chrysocharis pubicornis* and *Dacnusa nipponica* were dominant pupal and larval pupal parasitoids, respectively. By introducing infested leaves into vegetable greenhouses, the farmer can expect emerged wasps to suppress *Liriomyza* leafminer populations. Changes in the infestation rate by *C. horticola* and its parasitoid complex emphasize the potential in the inoculative biological control of the invasive *Liriomyza* leafminers.

Introducing *Plutella xylostella* granulovirus for DBM control on cabbage through a farmer field school approach in Ghana

MY Osae, AJ Cherry, H Braimah, PK Entsie, D Djegui
"Biotechnology and Nuclear Agriculture Research Institute, Ghana Atomic Energy Commission, P. O. Box LG 80, Legon, Accra, Ghana; my-osae@excite.com "

A Kenyan isolate of *Plutella xylostella* granulovirus (*Plxy*GV) was introduced to Ghana for the control of Diamondback moth larvae using a farmer field school approach. Fifty farmers were given training in the use of *Plxy*GV, and in IPM. Field trials were established as part of the training to compare farmers' practice against a control and the use of *Plxy*GV in an IPM context. Density of *P. xylostella* larvae was not significantly different for the three treatments, but pupal density was approximately two times higher on farmer practice plots compared to the control and *Plxy*GV plots. Natural enemies were more abundant on control plots, followed by *Plxy*GV plots and then farmer practice plots. Control of *P. xylostella* larvae alone with *Plxy*GV increased mean cabbage head weight from 0.39 kg for the control to 0.51 kg for the *Plxy*GV treated plants. Mean price per head was US$ 0.2, US$ 0.3 and US$ 0.5 for control, *Plxy*GV treated and farmer practice plots respectively. Reduced phytosanitary intervention frequency on *Plxy*GV plots, reduced cost of control and effective conservation of natural enemies compensated for the relatively lower yields. *Plxy*GV is a safe, effective and environmentally friendly biological control agent and must be popularised in Ghana

Hirsutella thompsonii Fisher, a fungal pathogen of *Floracarus perrepae* Knihinicki and Boczek (Acarina: Eriophyidae)

SK Ozman-Sullivan, JA Goolsby
CRC for Tropical Plant Protection and Dept. of Zoology and Entomology, The University of Queensland, 4072, Brisbane, QLD, Australia; current address, Ondokuz Mayis University, Faculty of Agriculture, Department of Plant Protection, 55139, Samsun, Turkey; sozman@omu.edu.tr

The biology and phenology of *Floracarus perrepae* Knihinicki and Boczek, a potential biological control agent of *Lygodium microphyllum* (Cav.) R. Br., Old world climbing fern, was studied in Queensland, Australia from 2000-2002. *Hirsutella* spp. are well-known pathogens of mites and during the study, *Hirsutella thompsonii* Fisher was isolated from *F. perrepae*. The fungus was described and illustrated. Healthy mites are cream in colour but when infected darkened, became moribund and died. Hyphae of *H. thompsonii* filled the abdomen of *F. perrepae* and then protruded from the genital and anal openings and the legs. *Hirsutella thompsonii* caused significant mortality to all life stages of *F. perrepae* in the leaf rolls, causing natural epizootics in field populations.

The successful cross-species release of parthenogenetic *Stichotrema dallatorreaunum* onto New Britian Island, Papua New Guinea, as an IPM agent to suppress tettigoniid pests of oil palm

WW Page, RW Caudwell, J Kathirithamby
PNGOPRA, P.O. Box 97, Kimbe, WNBP 621, Papua New Guinea; bill.page@pngopra.org.pg

Stichotrema dallatorreanum parasitize *Segestidia novaeguineae* (sexava, Tettigoniidae) on mainland Papua New Guinea, but were not known on New Britain Island. Laboratory studies showed that *S. dallatorreanum* from Popondetta reproduce parthenogenetically and could parasitize sexava species found on New Britain (*Segestidia defoliaria* and *Segestes decoratus*). 8431 releases were made on the island during 2000-2002 in oil palm areas to help suppress sexava. Post-release monitoring produced few returns of the parasitoid. Only two recoveries were made in 2002 (near Kimbe and Bialla) and after July no parasitoids were found. In November 2003, a reservoir of the parasitoid was found in *S. defoliaria* near Bialla (>30% parasitization). It is suggested that, because of the severe 2002 dry season caused by El Nino, few hosts were available as sexava eggs were diapausing. In such dry seasons, *S. dallatorreanum* distribution could be reduced to areas with higher rainfall where sexava hatching continues. Similarly, after 1997, *S. dallatorreanum* were only found in wetter areas near Popondetta. To speed up the spread of the parasitoid, parasitized sexava are collected from Bialla and re-distributed into other oil palm areas. However after severe dry seasons *S. dallatorreanum* may have to be redistributed from areas where they have survived.

Performance of *Trichogramma* spp. viewing the biological control of *Spodoptera frugiperda*

JRP Parra, EB Beserra
Depto. Entomologia, Fitopatologia e Zool. Agrícola, ESALQ, USP, Caixa Postal 09, 13418-900, Piracicaba-SP, Brazil; jrpparra@esalq.usp.br

Under laboratory conditions, biological and ethologic aspects of *Trichogramma atopovirilia* and *T. pretiosum* were compared. Under field conditions, the egg-laying distribution of *S. frugiperda* varied according to the phenological stage of the corn. A higher amount of egg laying was collected at 4-6 and 8-10 leaf stages and regardless of the phenological stage of the corn, most egg laying had more than one layer, usually three, covered by scales. The natural parasitism was low and constant in all development stages of the corn and *T. pretiosum* was the most abundant among the collected species. The studies on strain selection showed a wide range regarding performance in *T. pretiosum* strains as to adequacy and preference to *S. frugiperda* eggs. Both *T. atopovirilia* and *T. pretiosum* had a good biological performance and were adapted to *S. frugiperda* eggs even after being reared on *A. kuehmiella* for several generations. The presence of scales on eggs laid by *S. frugiperda* decreased the number of parasitized eggs and affected the behavior of both species. The conclusion is that the parasitism of both species is affected by the physical barriers of *S. frugiperda*, which may lead to a decreased performance of the parasitoid in the field.

Biological suppression of diamondback moth, *Plutella xylostella* (Lepidoptera: Plutellidae) using a cross-infective nucleopolyheovirus of the greater wax moth, *Galleria mellonella*

R Parthasarathy, RJ Rabina
Department of Microbiology and Cell Biology, Indian Institute of Science, Bangalore-560 012 India; rrps@mcbl.iisc.ernet.in

A nucleopolyheovirus isolated from the greater wax moth, *Galleria mellonella* (GmNPV) was found to be cross infective to sixteen economically important lepidopteran insect pests, of which seven were confirmed by restriction endonuclease analysis (RENA) of viral DNA. Laboratory bioassays on serial passages of GmNPV five times through seven insect hosts revealed a astic reduction of LC_{50} to the third instar larvae of *Plutella xylostella*. Histopathological studies with GmNPV infected larval tissues of *P. xylostella* showed the rate of viral infection in fat bodies and hypodermis. Field evaluation of GmNPV @ $7.5x10^{13}$ POB/ha against *P. xylostella* on cauliflower indicated that GmNPV reduced larval population by 65.7 per cent, which was next to insecticide, indoxacarb (73.9 %), equivalent to *P. xylostella* granulovirus (65.8 %) and higher than Delfin (59.4 %). The yield of heads (t/ha) also confirmed the above order of efficacy. These studies showed 1) unequivocal confirmation of cross-infectivity of GmNPV to *P. xylostella* by RENA and histopathology 2) possibility of increasing the virulence of virus against targeted pest by serial passages through alternate hosts 3) efficacy of GmNPV against *P. xylostella* under field conditions. The scope of development of GmNPV as a bioinsecticide for ecofriendly management of *P. xylostella* in crucifer ecosystems is discussed.

Importation and establishment of *Bemisia tabaci* parasitoids in southwestern United States

CH Pickett, WJ Roltsch, KA Hoelmer, GS Simmons, J Gould, JA Goolsby, M Rose
CDFA, 3288 Meadowview Rd., Sacramento, CA 95832, U.S.A.; cpickett@cdfa.ca.gov

Bemisia tabaci Biotype B (Homoptera: Aleyrodidae) was first reported causing widespread, economically damaging outbreaks in field crops in southwestern United States in the early 1990's. Shortly thereafter, classical biological control became the centerpiece for a major pest management control program by the USDA and cooperating state agencies. Parasitoids were collected from *Bemisia tabaci* populations in subtropical regions throughout the world. Newly imported, screened natural enemies were released into a combination of urban properties and commercially grown crops infested with *B. tabaci*. Releases of parasitoids imported from overseas began in 1994 and ceased in 2000. Following controlled laboratory and field studies, and small scale field releases, 5 species of Aphelinidae were mass reared and released: *Eretmocerus mundus*, *Er. hayati*, *Er. emiratus*, *Er.* nr. *emiratus*, and *Encarsia sophia*. Differences in species establishment between regions in the United States suggests that pre-adaptation to climate was an important factor to successful colonization.

Using *Trichogramma* to control diamondback moth in cabbage: the influence of alternative host species and plant growth.

R Pluke, G Leibee
Urb. College Park, 1783 Calle Alcalá; San Juan; 00921, Puerto Rico; rpluke@ufl.edu

Diamondback moth (DBM) is possibly the most important insect pest in cruciferous crops and there is a global effort to find effective control strategies. Control is only tenuously achieved using insecticides and efforts have long been made to look for alternative control methods. There is interest in the use of the egg parasitoid *Trichogramma* to control DBM. Relatively little work has been done with egg parasitoids and DBM control. Both our laboratory and field studies showed that *Trichogramma* could definitely be an important component of an IPM control program of DBM. The *Trichogramma* species used in the study was shown to prefer the smaller DBM eggs to the larger eggs of the soybean looper, an alternative host species. Prior exposure to one or other of the host species' eggs did not affect this preference. The fieldwork showed that levels of parasitism greatly depended on the interactions of cabbage plant growth, ovipositional patterns of the host species and foraging behavior of the *Trichogramma*. This study highlights the fact that successful use of *Trichogramma* (and other biological control agents) depends on piecing together the pertinent interactions of host, host plant and parasitoid, ensuring correct and effective use of the biological control agent.

Bio-efficacy of *Heterorhabditis indicus* (RCR) along with three botanicals against *Helicoverpa armigera (Hub.)*

A Prabhuraj, BV Patil, Shivaleela Department of Entomology, College of Agriculture, Raichur – 584 101, Karnataka, India; prabhusha@rediffmail.com

Compatibility of locally isolated entomopathogenic nematode, *Heterorhabditis indicus* (RCR) in different concentrations of leaf extracts of *Prosopus juliflora, Vitex nigundo* and *Pongamia pinnata* and their bio-efficacy against *Helicoverpa armigera* (Hub.) was conducted under laboratory condition during 2002-03. In compatibility study, all botanicals tested were highly toxic to infective juveniles (IJs) at higher concentrations (10, 5 and 4 %) resulting in more than 80 % mortality after 48 h of exposure. As the concentration reduced, the nematode survivability increased. Lowest concentration of one percent resulted 34.83, 30.10 and 31.2 % nematode mortality in *P. juliflora, V. nigundo* and *P. pinnata*, respectively indicating the scope of integration. In bio-efficacy study, *H. indicus* at 50 IJs/larva in combination with 0.5 % of *P. juliflora* and *V. nigundo* recorded cent percent mortality in early third instar larvae after 48 h and was on par with inoculation of nematode alone at 150 IJs/larva. However, similar combination in *P. pinnata* resulted in only 65 % mortality. Sequential application of either *P. juliflora* or *V. nigundo* at 2.5 % followed by nematode at 50 IJs/larva was the next best option which resulted in 70% mortality. Similar trend was observed against late fourth instar larvae.

Movement of the predatory coccinellid, *Hippodamia convergens*, in a two-crop system

JR Prasifka, KM Heinz
Genetics Lab c/o Insectary, Iowa State University, Ames, IA 50011, USA; prasifka@iastate.edu

Complementary field studies were used to investigate predator movement between grain sorghum and cotton crops. Rubidium mark-capture experiments suggested that coccinellids, particularly *Hippodamia convergens* Guérin-Méneville, produced an overall pattern of predator movement from sorghum into cotton. Manipulations of aphid levels in field cages tested if prey abundance and crop phenology influenced movement of *H. convergens* into cotton. More beetles were collected on caged cotton during late stages of crop phenology or when relatively low cotton aphid densities were present. *H. convergens* carbon isotope ratios were used to assess adult feeding after colonizing cotton and whether prey consumed in sorghum contributed to egg production in cotton. When cotton aphids were absent, *H. convergens* adults stayed in cotton, did not produce eggs and consumed few prey. With cotton aphids present, *H. convergens* isotope ratios changed from prey consumed in cotton, and isotope ratios of egg masses indicated prey consumed in grain sorghum contributed very little to egg production in cotton. An area-wide pattern analysis also suggested the abundance of grain sorghum and uncultivated areas positively influenced cotton predator abundance, as did prey levels and cotton planting dates.

"Management of insect pests of cole crops through utilization of biotic agents in northwestern Himalayas, India"

D Raj, N Devi, RS Chandel
Department of Entomology, CSK Himachal Pradesh Agricultural University, Palampur-176 062, India

The studies were conducted for three consecutive years in three districts of ecological safe hill state where pesticidal applications have recently started picking up on vegetables. In view of giving pesticide free cabbage, cauliflower and broccoli, field releases of biotic agents viz., *Trichogramma chilonis* and *Trichogramma bactrae* @ 75000/ha against lepidopterous pests were made at all the locations in three districts *viz.,* Kangra, Mandi and Una during cropping seasons in 1998,1999 and 2000.*Bacillus thuringiensis* was also applied @ 2.5 g/litre of water.*Diaeretiella rapae* was released @ 50000/ha against aphids.There was considerable reduction in the population of *Pieris brassicae* and *Plusia orichalcea* when Bt sprays were given along with parasitoid release. However, good control of *Plutella xylostella* and *Helicoverpa armigera* was achieved even without Bt spray with the releases of *T. bactrae* and *T. chilonis*. Bt sprays further added to achieve better control. The population of aphids generally remained low. But the releases of *D. rapae* led to more decline in aphid population

Insecticide use pattern and locational specific performance of *Cotesia plutellae* Kurdjumov in parasitization of *Plutella xylostella* L. larvae

U Shankar, UK Bar, SVS Raju
Department of Entomology And Agricultural Zoology, Institute of Agricultural Sciences, Banaras Hindu University, Varanasi-221005, India; svsraju_bhu@yahoo.com

Insecticide use pattern and parasitism of diamondback moth (DBM), *Plutella xylostella* L. by *Cotesia plutellae* Kurdjumov was surveyed under field conditions in North East Plain regions of India. Farmers used only the insecticides to combat DBM and the insecticide use pattern against DBM during the two years of study revealed that organophosphates were the most commonly used insecticides (30.99 % and 44.87 %) followed by synthetic pyrethroids (30.99 % and 23.08 %), chlorinated hydrocarbons (22.53 % and 15.38 %), carbamate compounds (14.08 % and 12.82 %) and botanicals (01.41 % and 03.85 %) during the first and second years of the experimental periods, respectively. Among various chemicals, cypermethrin was most extensively used (26.76 % and 21.79 %) followed by cartap hydrochloride (14.08 % and 12.82 %), endosulfan (12.68 % and 11.54 %), quinalphos (11.27 % and 07.69 %) and dimethoate (05.63 % and 12.82 %) during the two years of experimentation on cauliflower. The *C. plutellae* pupae, the only abundant larval parasitoid of DBM in this region were collected from these different locations having varying insecticide pressure. The killing efficiency (K-value) and the longevity of the female parasitoid collected from the areas of higher insecticide input was more (0.805 and 0.790) than those collected from the areas receiving less insecticides (0.706 and 0.577) during both the years of study.

Coenosia humilis an important predatory muscid of *Liriomyza huidobrensis* attacking potatoes in Indonesia

A Rauf, Harwanto, P Ridland
Bogor Agricultural University (IPB), Bogor 16680, Indonesia; aunu@indo.net.id

Field and laboratory studies were conducted on potatoes in Pangalengan, West Java to (a) determine the abundance of the predatory fly *Coenosia humilis* Meigen (Diptera: Muscidae) and the potato leafminer fly *Liriomyza huidobrensis* (Blanchard) (Diptera: Agromyzidae). (b) study the behaviour of the predator and (c) evaluate effects of insecticide application on both flies. Our research revealed that the abundance of *C. humilis* and *L. huidobrensis* both peaked 56 days after planting of the potato crop. Yellow sticky trap catches showed that adults of *C. humilis* and *L. huidobrensis* were both more active during morning and afternoon than in the middle of the day. In the field, some 113 *C. humilis* flies were collected with prey sticking on their mouth parts. Laboratory examination indicated that the prey consisted of small sized insects such as Diptera and Homoptera, with the highest proportion (68%) being agromyzid flies. In the laboratory, each predator consumed an average of 23.5 *L. huidobrensis* flies in 24 hours or about one fly per hour. Under field conditions, predation rate might be lower. However, since the predators were abundant in potato fields in Pangalengan, *C. humilis* might be expected to make a significant contribution in suppressing leafminer fly population. Insecticide applications as practiced by farmers significantly suppressed the predator and at the same time promoted the leafminer population.

Antioxidants increase the efficacy of commercial baculovirus biopesticides against *Helicoverpa* sp. in cotton

AF Reeson, C Hauxwell
Agency for Food and Fibre Sciences, Department of Primary Industries & Fisheries, Biopesticides Unit, 80 Meiers Road, Indooroopilly, Qld, 4068, Australia; anew.reeson@dpi.qld.gov.au

Commercial biopesticides based on nucleopolyheoviruses (NPVs) are widely used to control *Helicoverpa* sp. in eastern Australia. While results are generally good, the virus is less effective on cotton than on other crops. One hypothesis for this is that the surface of the cotton leaf is hostile to baculoviruses, resulting in rapid loss of persistence. Another hypothesis is that constituents of cotton foliage interfere with the infection process in the insect midgut. Hoover *et al* suggested that this is due to oxidation by free radicals generated during consumption of the leaf, and might be modified by applying antioxidants such as mannitol with the virus. We tested this hypothesis in the field by applying NPV with mannitol, which resulted in a 50-75% increase in insect mortality. Laboratory experiments indicated that mannitol is not a feeding stimulant, nor did it activate the virus directly, which supports the hypothesis that the increase in mortality is due to interactions of mannitol with the cotton plant chemistry. Mannitol might serve as a useful additive to NPV products. However, it is relatively expensive and would significantly increase costs to growers. We tested alternative compounds that delivered similar increases in efficacy at reduced cost.

"Beating around the bush in Australia: native vegetation resources for beneficial insects"

IC Rencken, L Silberbauer, N Reid, P Gregg
Ecosystems Management, University of New England, Armidale, NSW, 2351, Australia; irencken@metz.une.edu.au

"A range of beneficial insects species occur within the cotton agroecosystems in Australia, but farming systems do not always encourage their survival. Recent changes in cotton farming systems and an increased awareness of the value of pest control services provided by generalist predators have led to increased enthusiasm for maintaining populations of beneficial insects on farm. Some efforts have been made to plant winter wheat, sorghum and lucerne to increase in-situ populations of beneficial insects. Little attention, however, has been given to the existing non-crop vegetation (native trees, grasses and shrubs and introduced weeds) surrounding cotton fields and the role it may play in supporting populations of beneficial insects. The aim of this study is to investigate the spatial and seasonal fluxes of populations of several species of generalist insect species within the surrounding non-crop vegetation, thus learning more about potential habitats for beneficial insects within the cotton agroecosystem and finding ways to preserve and incorporate these habitats within existing cotton farms.
"

Biotechnology and maize pests: historical farmer perceptions and adoption of transgenic maize in integrated production

"ME Rice"

Department of Entomology, 103 Insectary, Iowa State University, Ames, IA 50011, USA;
merice@iastate.edu

Ostrinia nubilalis (Crambidae), *Diabrotica virgifera* and *Diabrotica barberi* (Chrysomelidae) are primary maize pests in the United States. Transgenic maize expressing a *Bacillus thuringiensis* (Bt) protein for *O. nubilalis* control was commercialized in 1996. Farmers (n=7,427) that planted Bt maize were surveyed (1996-1998). Farmers planting Bt maize increased acreage from 10.5% (1996) to 40.7% (1998) and decreased insecticide use from 13.2% (1996) to 26.0% (1998). The primary reason for planting Bt maize was to eliminate insect-caused yield loss. Most farmers believed Bt maize yields were similar to or greater than non-Bt hybrids and that *O. nubilalis* previously caused greater yield loss than suspected in non-Bt maize. A second survey (2001) evaluated farmer (n=1,313) perceptions prior to commercialization of transgenic Bt maize designed to control *Diabrotica* spp. Most farmers (75.2%) used crop rotation to control *Diabrotica* larvae. However, 33-39% of farmers in two major maize states used insecticides in rotated maize. Perceived benefits of *Diabrotica*-control maize were less insecticide in the environment (68.5%) and less insecticide exposure (69.9%). Concerns were selling the grain (59.3%) and higher technology fees (54.8%). These surveys provide an historical foundation on transgenic Bt maize use, initial farmer perceptions regarding performance, and attitudes regarding pest control.

Genetic, molecular, and analytical tools for refining classical biological control

GK Roderick, RA Hufbauer
Division of Insect Biology, University of California, Berkeley CA 94720-3112; roderick@berkeley.edu

The field of population biology has fully embraced the use of novel genetic and molecular tools and accompanying analytical approaches to understand both population dynamics and micro-evolutionary change. Here, we attempt to demonstrate how classical biological control can benefit from many of these approaches, and in particular, to address the charge that "biological control is not yet a predictive science." First, we examine the following processes: agent selection/prioritization, diagnostics and identification, quarantine, efficacy, and target specificity. For each we point to studies in the basic literature that have used successfully molecular, genetic, and analytical approaches to address similar issues. Second, we argue that classical biological control may be more predictive than recognized, especially when biological control is considered as replicated semi-natural field experiments. In this light, the field has much to offer as a test bed for theories in both ecology and evolutionary biology. Lessons from biological control can even help inform researchers and policy makers about the risks of both invasive organisms and genetically modified organisms.

Impact of insect-resistant transgenic crops on entomophagous arthropods and how to assess these effects

J Romeis, M Meissle, F Bigler

"Agroscope FAL Reckenholz, Reckenholzstr. 191, 8046 Zurich, Switzerland; joerg.romeis@fal.admin.ch"

"One of the primary concerns related to the adoption of insect-resistant transgenic plants is their potential impact on non-target organisms. This includes entomophagous arthropods which play an important role in natural pest regulation. Despite the fact that regulatory bodies require information on the potential risk of releasing transgenic plants in the environment, to date, no specific protocols have been designed for assessing the risks that insect-resistant transgenic crops pose for these beneficial organisms. Here a framework for risk assessment is proposed to evaluate the effects of insect-resistant plants on entomophagous arthropods. Using maize expressing the *cry1Ab* gene derived from *Bacillus thuringiensis* (*Bt*) as an example, we illustrate the steps necessary for assessing the risks for larvae of the green lacewing, *Chrysoperla carnea*. Based on the information available we conclude that the *Bt*-transgenic maize poses a negligible risk for this important predator. The results are presented in the context of other laboratory studies on the impact of *Bt*-transgenic crops on entomophagous arthropods.
"

Bt-transgenic cotton and insect natural enemies: compatibility or irreconcilable differences?

JR Ruberson, JB Torres
Department of Entomology, University of Georgia, Tifton, GA 31794 USA; ruberson@tifton.uga.edu

Transgenic insecticidal plants confront herbivores and their natural enemies with a potent bottom-up force. Targeted herbivores are directly and severely affected by the transgene product, whereas nontargeted herbivores may experience direct or indirect consequences from reduced competition or modified pest management practices. Our studies focused on effects of Bt-cotton on population dynamics of predators in fields in southern Georgia, USA. We examined a suite of foliage-dwelling and epigeal predators in cotton fields (paired Bt- and non-Bt cotton fields). We found no differences in abundance or diversity of predators over 2 years. We also assayed selected species of field-collected heteropteran predators for presence of Bt protein. Most predators contained no detectable levels of Bt; some nabids did. We also examined direct and indirect effects of Bt-cotton on the predator *Geocoris punctipes* by rearing bugs on Bt- and non-Bt cotton with two prey: 1) eggs of *Helicoverpa zea*; and 2) 1-2 day-old larvae of *Spodoptera exigua*. Predator development, size, fecundity, and longevity were affected by prey type, but no plant effect was observed, indicating that Bt-cotton does not adversely affect this omnivore directly or indirectly. To date we have found no detrimental effect on predator populations in the cotton agroecosystems.

"Genetic polymorphism in prey preference of a polyphagous predatory arthropod"

I Lesna, MW Sabelis
Section Population Biology, Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Kruislaan 320, 1098 Sm Amsterdam, The Netherlands; sabelis@science.uva.nl

Arthropod predators usually feed on a variety of prey types. At one extreme, populations consist of an ensemble of specialists and at the other they are composed of indiscriminate generalists. In between these extremes populations may be composed of generalist predators with learned or genetically fixed prey preferences. Whether mono- or polymorphism will evolve depends on various factors, such as the cost of flexibility for the generalist, the variability in supply of various prey species and the degree to which the population is homogeneously mixed with respect to mating. Here, we report on experimental evidence for genetic variation in a local population of the haplo-diploid predatory mite, *Hypoaspis aculeifer*, collected from *c.* 0.25 m^2 sandy soil in a lily field. Using two species of astigmatic mites as prey (*Rhizoglyphus robini* and *Tyrophagus putrescentiae*) two-way selection for prey preference during four generations yielded lines with preference for one or the other prey. Cross-breeding in both directions resulted in hybrid females with intermediate preferences and the choices found in females from F1xParent backcrosses were best explained by assuming monogenic inheritance without dominance. We also demonstrate that this genetic polymorphism can be maintained by heterozygote advantage and disassortative mating.

Oligidic diet on the biology of a reduviid predator *Rhynocoris marginatus* (Fab.) (Heteroptera: Reduviidae)

'Sahayaraj, K, Sujatha, S''

Crop Protection Research center, Department of Zoology, St. Xavier’s College, Playamkottai – 627 002, Tamil Nadu, India; ttn_ksraj@sahcarnet.in

Rhynocoris marginatus (Fab.) (Heteroptera : Reduviidae) belongs to Harpactorinae a sub family of Reduviidae. It has been reported to predating upon more than 20 insect pests belongs to various orders. However, mass production technique is not available for this promising biological control agent. In this work we tried to record the biology of this reduviid on beef liver based oligidic diet (OD). It revealed that all the life stages of *Rhynocoris marginatus* preferred to feed the oligidic diet, but the preference varied depends upon the nymphal stage. For instance, first nymphal instar highly preferred the OD (74.5%) followed by fourth nymphal instar (70.35%). Oligidic diet prolongs the nymphal developmental period from 44.21 days (reared on factitious host *Corcyra cephalonica* Stainton) to 123.0 days. Similarly oligidic diet reduced the survival rate and weight gain. The weights of the adult *Rhynocoris marginatus* were 68.33 and 107.0 grams when reared on oligidic diet and *C. cephalonica*. Oigidic diet also alters the sex ratio (0.75 and 0.58 for OD and *C. cephalonica,* respectively). Oligidic diet reared *Rhynocoris marginatus* do not laid any eggs during its adult stage. We propose to alter the adult diets for the successful mass production of this reduviid.

Microbial control of the red palm weevil *Rhynchophorus ferrugineus* (Oliv.) in Egypt

H Salama, S Moawed
National Research Centre, Tahrir street, Dokki , Cairo

**"The disastrous invasion of the red palm weevil *Rhynchophorus ferrugineus* results in great losses of palm trees ever encountered in Arab Gulf countries and is entitled as the palm tree acquired immune deficiency syndrome (AIDS). The female is a strong flyer and lays its eggs in wounds around the trunk of palm trees. The insect development from hatched larvae to adult is completed entirely inside the trunk of the tree causing damage by feeding on tissue that may ultimately lead to death of tree. In this microhabitat, the conditions are more favourable than the outer atmospheric conditions. The cytoplasmic polyheosis virus was isolated from the larvae, identified and its symptomatology was considered. Based on laboratory studies, large scale field experiments were conducted to investigate its pathogenicity when injected inside the trunk of the infested trees at a concentration of 100×10^6 polyhedra / ml at the rate of 200 ml / tree . After 3 – 4 weeks, complete recovery of infested trees occurred . The mirosporidia *Vairimorpha ephstiae* showed also to be highly potent when injected at a concentration of 100×10^6 spore / ml at the rate of 200 ml / tree . A complete recovery of the trees was obtained within 4 weeks. Combination of both agents led to high synergism Both agents or their combination may be recommended for control of this curculionid insect pest most efficiently .

Mass rearing methods for *Metaphycus bartletti* and *M. luteolus*, biological control agents of mediterranean black scale and soft brown scale

L. Salehi, JA Altmann
Dept. of Plant Protection, Faculty of Agriculture, The Univ. of Guilan, Rasht, Iran; salehi@guilan.ac.ir;

Mass rearing techniques of the mediterranean black scale, *Saissetia oleae* and soft brown scale, *Coccus hesperidum* , hosts for parasitoids *Metaphycus bartletti* and *M. luteolus* were tested under laboratoyry conditions at 24.4±2°C, 55±5% RH and L:D 14:10 in Biological Services in Loxton, South Australia. Black nightshade, *Solanum nigrum* was among the best plants with more than 76 and 80% crawlers establishment for black scale and soft brown scale, respectively. Second and third instars nymphs were transferred to butternut pumpkins, *Cucurbita moschata* for adult scales reproduction. The mean of one generation of black scale and soft brown scale was completed in 73.9±1.8 days and 44.4±2.4 days, respectively. The best black scale stage for *M. bartletti* production were 3rd and 4th instars and for *M. luteolus* were 2nd and 3rd instars. Both female parasitoids did not attack 1st instar and mature adult scales. Female *M. bartletti* parasitised proportionally more hosts as host density increased meanwhile, low percentage of parasitism by female *M. luteolus* was estimated by increasing number of soft brown scale. Results indicated that parasitized scales could be stored in the refrigerator at 10°C at least to 8 weeks without any effect on adult parasitoids.

The use of rubidium as a marker to assess the dispersal of the parasitoid, *Dolichogenidea tasmanica* (Hymenoptera: Braconidae) in vineyards

SL Scarratt, SD Wratten
National Centre for Advanced Bio-Protection Technologies, PO Box 84, Lincoln University, Canterbury, New Zealand; scarrats@lincoln.ac.nz

Dispersal of the parasitoid, *Dolichogenidea tasmanica* (Cameron) (Hymenoptera: Braconidae) which parasitises larvae of the lightbrown apple moth, *Epiphyas postvittana* Walker (Lepidoptera: Tortricidae) was studied from flowering buckwheat, *Fagopyrum esculentum* Moench plants in a vineyard in New Zealand. Four sequential foliar applications of rubidium chloride (RbCl) were applied to single strips of buckwheat, sown in the centre of each of five vineyard blocks. Yellow sticky traps were placed in each block at distances of 0, 2, 5 and 15 vine rows from the buckwheat to collect adult *D. tasmanica.* Buckwheat plant tissue samples were taken following the application of RbCl to ascertain whether the plants had been marked. Results showed that the number of *D. tasmanica* marked with rubidium decreased linearly from the buckwheat. Also, the number of *D. tasmanica* caught was significantly higher at distances of 0, 2 and 5 vine rows from the buckwheat. The buckwheat plant tissue was marked with rubidium and these levels declined after the initial application of rubidium. These results suggest that *D. tasmanica* fed on the buckwheat plants and then moved at least a distance of 10 meters from the plants within the seven-day sampling period.

Landscape and on-farm dispersal of *Diadegma semiclausum*: a key parasitoid of the diamondback moth, *Plutella xylostella*

NA Schellhorn, L Maratos, J Bellati
South Australian Research & Development Institute, GPO Box # 397, ADELAIDE, SA, 5001, Australia; Nancy@saugov.sa.gov.au.

On-farm refuges can be effective for conservation biological control if beneficial insects move from the refuge to the crop in greater numbers than the pests. We conducted experiments to monitor on-farm and property-property dispersal of the parasitoid, *Diadegma semiclausum* (Hellén) (Hymenoptera: Ichneumonidae). We sprayed a resin-based fluorescent dye on the refuge crop to mark the resident insect populations and monitor their dispersal before and after the refuge was cultivated. Before cultivation of the refuge, 5% of marked *D. semiclausum* had dispersed as far as 60m. After cultivation, 7% had dispersed as far as 212m (the furthest distance sampled), while greater than 85% of *P. xylostella* (L.) (Lepidoptera: Plutellidae) moths moved to the adjacent broccoli. Within a crop, dispersal of marked *D. semiclausum* was slightly aggregated before cultivation, but randomly distributed after cultivation. Among farms, at the scale of the landscape, 10-17% of *D. semiclausum* moved between properties greater than 1.2 km apart, and they were highly aggregated in brassica crops. *D. semiclausum*, and *P. xylostella* were highly associated at the landscape scale. Our results suggest that on-farm refuges provide a source of *D. semiclausum* that move into adjacent plantings, and between properties.

The establishment and utilisation of *Trichogramma pretiosum* Riley against *Helicoverpa* spp. in Australian cotton farmscapes

BCG Scholz, NRR Parker
Department of Primary Industries and Fisheries, P.O. Box 102, Toowoomba Qld. 4350; brad.scholz@dpi.qld.gov.au

Trichogramma pretiosum is a New World species of egg parasitoid that has been evaluated and utilised as a biological control agent of *Helicoverpa* and *Heliothis* pest species throughout the world. It was released in the Ord River irrigation area of Western Australia, and on the Darling Downs region of south-east Queensland, during the 1970's. The species became established in the Ord River region, but was not recorded during extensive sampling of *Helicoverpa* eggs on the Darling Downs from 1985-1995. Releases of *T. pretiosum* recommenced on the Darling Downs in 1995, and the species has since become widespread and abundant in cotton farming systems. *T. pretiosum* now accounts for 97% of all egg parasitoids reared from *Helicoverpa* eggs in cotton on the Darling Downs, and has caused high levels of egg parasitism (80-100%) from mid-January to April for the past six years. The introduction of *B.t.* cotton, and greater use of selective insecticides, are thought to have benefited *T. pretiosum* by reducing the number of disruptive broad-spectrum chemicals used to manage cotton pests. The diversity of cropping on the Downs, and the continuity of hosts that this favours, is also believed to assist the growth of *T. pretiosum* populations.

"Enhancing juvenile mortality of *Helicoverpa* spp. (Lepidoptera: Noctuidae) in chickpea/cotton cropping systems"

RV Sequeira, AD Moore, AJ Shields, J Blacklock
Queensland Department of Primary Industries, Locked Bag 6, Emerald, Qld. 4720; Richard.Sequeira@dpi.qld.gov.au

This presentation is a summary of research aimed at finding non-chemically dependent ways of minimising the survival of *Helicoverpa armigera* and *H. punctigera* in chickpea (*Cicer arietinum*). Chickpea is highly attractive to *Helicoverpa* in all its phenological stages. Field assessments of egg distribution patterns reveal marked changes in the oviposition behaviour of *Helicoverpa* spp. in chickpea plots with and without contaminant plants of other species. Comparisons of mean egg densities on contaminant plants and the surrounding chickpea crop indicate that moths lay most of their eggs on the contaminants. Characteristics of this "aggregative" egg distribution phenomenon are described in relation to crop phenology within contaminated crops. Life table assessments indicate that > 80% of eggs laid on the contaminants do not survive to the larval stage. Our results suggest that contaminant plants in chickpea plots serve as *Helicoverpa* sinks. We propose that differential host plant apparency is a plausible explanation for the aggregative oviposition response to and the resultant sink effect of contaminants in chickpea. A strategy of deliberate contamination of chickpea crops with other plant species merits further investigation as a cultural pest management strategy for *Helicoverpa* spp. Implications of *Helicoverpa* management in chickpea for cotton pest management are discussed.

"Influence of radiation on parasitoid - host interaction between *Steinernema glaseri* and *Spodoptera litura* (Fab.) vis-à-vis other biorational pest control measures"

"RK Seth, TK Barik, S Chauhan, R Joshi"
Department of Zoology, University of Delhi, Delhi 110 007, India; rkseth@del2.vsnl.net.in

"Bioinfectivity of entomopathogenic nematodes (EPNs) was evaluated on radio-sterilized host, followed by assessment on perpetuating bioefficacy of EPNs derived from irradiated hosts, up to ensuing two generations, to ensure safe transport and viable augmentation of this bio-control agent. Further, the interaction of EPNs was studied with radiation-induced F_1 sterility in *S. litura.*, by evaluating the infective behaviour of normal infective juveniles (IJs) on F_1 sterile insects, and viability of F_1 IJs derived from F_1 sterile host, in order to understand the feasibility of using EPNs with F_1 sterility technique for pest control. Behaviour of EPNs from radio-sterilized hosts in relation to host treated with moulting hormone (MH)-agonist was studied. Both the sterilizing and lethal doses of MH-agonist, appeared to be compatible for integrated application with bioinfective EPNs. Also, the effect of low dose ionizing radiation on EPNs bio-efficacy was studied towards host in different regimens, in order to explore radiation hormesis. Low dose range (1.5-2.5Gy) could induce faster morbidity and mortality in host by irradiated EPNs, with their slightly enhanced harvesting, when irradiated IJs were bioassayed one week post-irradiation. Potential role of radiation as a tool in pursuing compatible utilization of these EPNs with biological based tactics is discussed.
"

Novel methods of entomopathogenic nematode application

DI Shapiro-Ilan, EE Lewis
USDA-ARS, 21 Dunbar, Rd. Byron, GA, 31008, USA; dshapiro@saa.ars.usda.gov

Entomopathogenic nematodes are generally applied for insect control in aqueous suspension using various sprayers or irrigations systems. Novel methods of application can reduce costs and improve efficacy of pest suppression. Some novel methods of application include baits or slow-release bags. Another alternative is application of nematodes in their infected hosts. Applications of nematodes in infected hosts can result in significant pest suppression under field conditions. Our research has addressed the following questions: 1) Are there any advantages to applying nematodes in infected hosts Vs aqueous application? 2) Is it feasible to apply infected hosts from a technical standpoint? Our laboratory experiments suggest advantages of greater dispersal, infectivity, and survival in nematodes applied in infected hosts compared with aqueous application. In greenhouse studies, superior efficacy was observed in suppression of *Diaprepes abbreviatus* and *Otiorhynchus sulcatus* when nematodes were applied in infected hosts. Further, our studies indicate it is feasible to store and package nematode infected hosts for commercial application. Fragile cadavers such as *Galleria mellonella* can be coated with formulations to facilitate storage and application. Alternatively, hard-bodied insects (such as *Tenebrio molitor*) can be ideal hosts because they are naturally resistant to rupturing or sticking together.

Molecular characterisation of the whitetop collar gall weevil, *Ceutorhynchus assimilis,* opens the door to its use as a biological control agent

MC Bon, B Fumanal, JF Martin, R Sobhian, JP Lumaret, AW Sheppard
CSIRO European Laboratory, Campus International de Baillarguet, 34980 Montferrier Le Lez, France ; andy.sheppard@csiro-europe.org

Molecular phylogenetic studies have increasing relevance in biological control for (a) subspecific genetic characterisation of the target to trace origins or relatedness to non-targets, (b) the subsequent design of host test lists for risk analysis, and (c) subspecific genetic identifiers of agents to allow monitoring following release. A recent exciting development has used of molecular techniques to create biocontrol opportunities for potential agents previously confounded by taxonomic ambiguities or complex subspecific host specificity variation. In this paper we overview one such study that mapped population level mitochondrial haplotypic variation of the collar gall weevil, *Ceutorhynchus assimilis* (a natural enemy of the white-top, *Lepidium aba*, an exotic invasive weed across 3 continents) to differences in host specificity. Literature and field records suggested the weevil had a relatively broad host range within the Brassicaceae. The biogeographical distribution and field host range of 4 morphologically indistinguishable clades of the weevil were defined from geographically widespread collections. Only the target weed supported complete larval development in one of these clades. A parallel origin-tracing study evaluating the genetic structure of *Lepidium aba* in its native range can now be used to assess the non-target risks from inferred insect-plant evolutionary patterns.

Economics of transgenic management programs: what are the global implications of IPM community acceptance?

LP Gianessi, CS Silvers
904 SW 9th Terrace, Ft Lauderdale, FL 33315 USA; cressidasilvers@hotmail.com

US growers are planting 80 million acres with transgenic crops because the crops are the most cost-effective means for control of certain pests. The transgenic crops are less expensive and/or more efficacious in controlling the pests than are conventional crops. US growers are gaining $1.5 billion in annual net income from planting transgenic maize, soybeans, cotton, canola, squash and papaya. Transgenic crops in development in the US for pest management could add another $1.0 billion to annual net income. Potential economic gains of planting transgenic crops are also very high in the European Union. Transgenic herbicide-tolerant oilseed rape, maize, rice, wheat and sugarbeet are projected to improve EU farm net income by $561 million while fungal resistant potato and insect resistant maize would provide approximately $1.2 billion in net benefits. When transgenic crops are used to manage pests, one result is a reduction in the use of chemical pesticides. In the US, transgenic insect-resistant maize and cotton substitute for 2.6 and 1.9 million pounds of insecticides. In the EU, a fungal-resistant potato would eliminate the need for 7.5 million kilograms of fungicides.

How can understanding target pest and agent population dynamics improve our ability to select effective agents against arthropod pests?

P Stiling, T Cornelissen
Department of Biology, University of South Florida, 4202 East Fowler Avenue, Tampa, FL 33620, USA; pstiling@tampabay.rr.com

First we reviewed the contents of several entomological/biocontrol journals to see where biocontrol research is focused and in what directions researchers think it is headed. Second, we used meta-analysis to look at pest densities in the presence and absence of biological control agents. Various biological features of both pest and natural enemy were coded in the analysis to help us understand which biological features are important in reducing pest densities and thus increasing the likelihood of selecting effective biocontrol agents.

"Evaluation of *Beauveria bassiana* for control of household ants"

JL Stimac, SB Alves, RM Pereira, LA Wood, K Durbin
Department Of Entomology & Nematology, University Of Florida, Natural Area drive, Po Box 110620, Gainesville, Florida, Usa, jls@ifas.ufl.edu

"Efficacy of the entomopathogenic fungus, *Beauveria bassiana*, was evaluated for household ants in indoor environments. Efficacy was determined by exposure of ants to baits or baited traps. Five ant species (fire ant, carpenter ant, pharaoh ant, crazy ant and ghost ant) were exposed to Fungus biological bait (*B. bassiana*) or chemical bait from commercial products (Combat, Max, Raid) for 3 days. Also, fire ants were continuously exposed for 90 days to fungal bait powder in plastic traps. Efficacy was characterized by cumulative percent mortality. At 28 days after initial exposure to baits, mean cumulative mortality of ants ranged from 26%-100%. No bait gave the highest mortality for all ant species but Max was the most efficacious for 4 species, Fungus and Combat for 3 species and Raid was not best for any species. Fungus had the highest weighted sum score for all ant species tested. Death was delayed when fungal powder bait was placed in plastic traps and ants had to search to find bait. When fire ants foraged bait in traps, mortality did not reach 90% until 70 days of continuous exposure.
"

Potential benefit of the fire ant – cotton aphid mutualism for cotton plant fitness

JD Styrsky, MD Eubanks
301 Funchess Hall, Dept. of Entomology and Plant Pathology, Auburn University, Auburn, AL, 36849, USA; styrsjd@auburn.edu

Ants commonly form mutualistic associations with honeydew-producing homopterans in which homopterans gain protection from predators and parasitoids in return for producing a food resource (honeydew) for ants. The cost to plant fitness of this mutualism can be substantial and represents a real threat to yield in agricultural systems. Plants may benefit from the mutualism, however, if the attraction of ants onto plants increases ant suppression of other, non-homopteran herbivores. Red imported fire ants (*Solenopsis invicta*), an abundant introduced predator, engage in a mutualism with cotton aphids (*Aphis gossypii*), an important pest of cotton, throughout the southeastern United States. We hypothesize that low to moderate densities of cotton aphids indirectly benefit cotton yield by attracting fire ants onto plants resulting in increased suppression of caterpillar herbivory. Results from field experiments are consistent with our hypothesis: fire ant abundance on plants increased significantly with cotton aphid abundance, resulting in decreased plant damage by caterpillars and increased square and boll number. Our results highlight the potential indirect benefit of homopteran pests in biological control, but we argue that the benefit is conditional. We develop a heuristic model that predicts that the benefit of the fire ant-cotton aphid mutualism varies with the intensity of caterpillar herbivory.

Diversity of parasitoid fauna of *Liriomyza* Spp. (Diptera: Agromyzidae) on vegetable crops in Bali and Lombok

W Supartha, PM Ridland
"Department of Plant Pests and Diseases, Faculty of Agriculture, Udayana University Denpasar, Bali – Indonesia; iw_supartha@hotmail.com "

The detailed surveys for parasitoids of leafminers in Bali and Lombok were conducted from June 2001 until October 2003. There were 14 parasitoids associated with *Liriomyza* spp. on vegetable crops in Bali and Lombok. Among the 14 species, there were 6 species of Eulopidae indicated high parasitization levels namely *Neochrysocharis* sp., *Hemiptarsenus varicornis* Girault. *Opius* sp., *Asecodes deluchii* (Boucek), *Pnigalio* sp. and *Quaastichus* sp. The four first of them, have special characters in the field. *H. Varicornis* has high parasitization level and disperse at all locations in Bali and Lombok. Meanwhile, *Opius* sp. has high abundant population with high parasitization level at high land (especially in Baturiti, Tabanan and Pancasari, Buleleng, Bali). *A. deluchii* and *Neochrysocharis* are more specific at low land and middle altitude. The average of parasitization levels of the four parasitoids was 19.6 percent (for *Neochrysocharis*), 17.8 percent (for *H. varicornis*), 6.4 percent (for *Opius* sp.), and 6.5 percent (for *A. deluchii*) respectively. In Bali, the *Opius* sp. was mostly observed on potato crops at the high land areas, while *Neochrysocharis* sp. and *A. deluchii* were more observed on bean crops especially yard-long bean at lowland areas. *H. varicornis* was found on all host plants in mostly crop locations and altitudes in Bali and Lombok. Meanwhile, *Neochrysocharis* sp which was found in Lombok more observed on beans in lowland.

Detection of prey DNA within generalist predators: tales of beetles and spiders

WOC Symondson
Cardiff School of Biosciences, Cardiff University, PO Box 915, Cardiff CF10 3TL, UK;
Symondson@Cardiff.ac.uk

The most accurate method for determining the diets of generalist predators in the field has, until recently, involved the relatively difficult and expensive development of prey-specific monoclonal antibodies. We report here our rapid progress developing and applying prey-specific primers to amplify and detect the DNA of a range of different species of molluscs, annelid worms, aphids, Diptera, Collembola, Lepidoptera, aphids and nematodes within the guts of spiders and both carabid and coccinellid beetles. New techniques are reported that allow large numbers of field samples (predators) to be rapidly and simultaneously screened for a broad range of prey targets. Applications of this technology to the testing of important ecological hypotheses will be described, including areas such as the effects of biodiversity on biological control, prey selection, the importance of detritivores as alternative prey, classification of predators into guilds by determination factors such as when predation occurred, and infiltration of native food webs by alien species.

"Coevolution between *Wolbachia* and *Trichogramma* under local mate competition"

Y Tagami, K Miura, Y Suzuki
Hiroshima University, 739-8528 Higashi-hiroshima, Japan; tagamiy@affrc.go.jp

Local strains infected with parthenogenesis-inducing *Wolbachia* have been found in gregarious egg parasitoid wasps, *Trichogramma kaykai* and *T. dendrolimi*. In case of *T. kaykai*, the embryonic mortality of infected individuals is much higher than that of *Wolbachia*-free ones. In contrast, *Wolbachia* infection does not significantly affect the mortality in *T. dendrolimi*. To explain the difference in the interaction between *Wolbachia* and *Trichogramma*, we developed a lattice model in which the positive effect of fertilization on the immature survival rate and the effect of female-biased sex ratios under local mate competition are incorporated. Simulation results revealed that the sex ratio has a prominent effect on the successful invasion of *Wolbachia*-infected wasps into a population. If mating occurs randomly and the sex ratio is not biased in *Trichogramma*, infected wasps can easily invade even though the immature mortality of infected wasps is high. However, if the sex ratio is extremely female-biased, then infected wasps hardly establish in a population unless the mortality cost is negligible. On these bases we discuss the coevolution between *Wolbachia* and *Trichogramma*.

"How many natural enemy species should we introduce for classical biological control?"

M Takagi
Institute of Biological Control, Faculty of Agriculture, Kyushu University, Fukuoka 812-8581, Japan; mtakagi@grt.kyushu-u.ac.jp

I will review the history of three cases of classical and one conservative biological control of fruit tree pests in Japan to consider the scientific approach for the selection of natural enemies in biological control. The first case is biological control of the red wax scale, *Ceroplastes rubens*, a citrus pest by *Anicetus beneficus*. The second one is that of the chestnut gall wasp, *Doryocosmus kuriphilus* by *Torymus sinensis*. The third one is that of the arrowhead scale, *Unaspis yanonensis*, a citrus pest by two parasitoids, *Aphytis yanonensis* and *Coccobius fulvus*. All those pests and natural enemies were introduced from China into Japan, and the first tow cases were single species introductions and another was multiple species introduction. The last case is conservative biological control of the Japanese mealybug, *Planococcus kraunhiae*, a persimmon pest by two native parasitoids, *Anagyrus fujikona* and *Allotropa subclavata*. It was suggested that disordered introduction of all of the natural enemies availablewas was not appropriate. However, it may not be wise to persist with single species introductions. Careful study on host-parasitoid systems may be important for making introduction decisions.

"Parasitoids invasions on the leafminer *Lithocolletis Sp.* (Lepidoptera: Gracillariidae) on *Pongamia* sp. (Leguminosae) trees in Delhi, India."

V Thareja, M Hayat
Reader, Zoology, Miranda House, University Of Delhi, Delhi-110007, India; mhvt@rediffmail.com

"The field study of parasitoid fauna on the leafminer host *Lithocolletis sp.* already sampled on *Pongamia sp.*, widely grown medicinal tree, has been carried out for two years (2002-04). The two phases focused during the study are:
Quantitative sampling covering random collection of a series of mines, twice a week, to determine the degree of parasitization & phenology particularly the seasonal variation of the parasitoid.
Parasitized larvae of *Lithocolletis sp.*/pupae of the parasitoids reared to eclosion to identify the species of parasitoids.
Studies reveal that the parasitoid complex includes ten species. The dominant species are *Ageniaspis fulvicornis* (Encyrtidae) and *Pholetesor sp.*(Braconidae), co-dominated by *Closterocerus insignis* (Eulophidae). *A. fulvicornis* is a larval endoparasitoid, polyembryonic, most likely as primary/secondary and a koinobiont with peak parasitization in December 2002. *Pholetesor sp.* is larval endoparasitoid, solitary, presumably primary and a koinobiont with peak parasitization in November 2002. *C. insignis* is a larval ectoparasitoid, solitary, likely as primary and a koinobiont with peak parasitization in October 2002. Thus there are seasonal variations. The percentage parasitisim of *Pholetesor sp.* and *C. insignis* declines in 2003 whereas *A. fulvicornis* is not significantly affected. Varied species richness of the parasitoid in different habitat indicates that some of the parasitoids are possibly niche specific than just host specific.
"

"Dispersion and host searching capacity in *Trichogramma*: attributes that influence their success as natural enemies"

LJ Thomson, BJ Rundle, UM Kolliker-Ott, AA Hoffmann
CESAR: Centre for Environmental Stress and Adaptation Research, Biological Sciences Building 2, La Trobe University, Plenty Road, Bundoora, Victoria 3086, Australia; L.Thomson@Latrobe.edu.au

"The ability of adults to find hosts – host searching behaviour - plays a key role in the success of an egg parasitoid such as Trichogramma. Environmental and genetic factors will both contribute to phenotypic variation in the searching behaviour of Trichogramma. Environmental factors include the size and type of the rearing host egg, which in turn can influence parasitoid body size and parasitoid wing shape, as well as the thermal environment experienced by immatures and adults. Increased size and changes in some shape parameters are associated with increased field fitness as measured by success in locating hosts. Genetic variation in traits influencing foraging ability such as walking speed and the ability to prospect over large areas per unit time will influence searching success, but given the low heritability demonstrated for these traits, it is not clear if genetic factors make a major contribution to phenotypic variation. This in turn raises the value of screening strains for laboratory traits as a way of predicting field success.
"

An egg host unit: what is it and what does it involve.

SB Vinson
"Department of Entomology, Texas A&M University, College Station, TX. 77843-2475, USA; bvinson@tamu.edu"

Parasitoids that use eggs as a host must locate and recognize the appropriate host egg. This involves a number of factors. These factors will be discussed and the factors that are important to the parasitoid make-up what will be described as a egg host unit.

Effects of modern pesticides on the predator *Chrysoperla carnea* **and the parasitoids** *Psyttalia concolor* **and** *Hyposoter didymator***. a comparison of laboratory results**

P Medina, J Morales, A Huerta, N Nelson, E Abdallahi, A Adán, F Budia, P Del Estal, G Contreras, E Viñuela
Protección De Cultivos. E.T.S.I. Agrónomos. Polytechnic University Of Maid. 28040-Maid. Spain; evinuela@pvb.etsia.upm.es

The use of beneficial arthropods has become wide-spread in IPM programs, but pesticides still play a key role in managing many pests. Accordingly, an essential step for their joint use is to determine the impact of pesticides on the beneficial of interest. Pymetrozine (Plenum®), Natural pyrethrins+PBO (Pelitre Hort®), Triflumuron (Alsystin®), Fipronil (Regente®) and Imidacloprid (Confidor®) were tested at the maximum recommended rate in Spain (300, 80, 150, 30, 150 mg a.i./l) in residual, topical and ingestion treatments. Pupae of the enemies were not affected by any pesticide, and effects on adults were dependent on the species and the route of exposure. Pymetrozine and triflumuron were generally, the safest for the enemies, and fipronil and imidacloprid the more harmful. Pyrethrins were harmful to adults of every enemy by residual contact or topical application and much less toxic when adults fed the insecticide.

100 YEARS OF BIOLOGICAL CONTROL IN QUEENSLAND

C Walton
Pest Management Strategy, Queensland Department of Natural Resources, Mines and Energy, GPO BOX 2454, Brisbane Qld, 4001;
craig.walton@nrm.qld.gov.au

"Biological control programs have been carried on weeds in Queensland since the unsuccessful introduction of a cochineal beetle (*Dactylopius ceylonicus*) to control prickly pears (*Opuntia* sp.) in 1903. The subsequent successful control of a number of prickly pears in the 1920-30's set the tone for the use of this technique, both in Australia and across the globe. Not only have imported biological control agents been responsible for significantly reducing the impacts of many of Queensland's most serious weeds but the use of biological control has also entered the culture as an acceptable and desirable option for the management of weed species, if not at times overrated. Biological control programs are currently being questioned, however, after the recent off-target impacts of a biological control agent imported to control lantana (*Lantana camara*) started to attack to commonly grown garden plants and due to costs. Historical assessments of weed impacts and analyses from recent cost: benefit studies will be presented to demonstrate the significant contribution that the science of biological control has provided to Queensland.
"

Selecting agents for biological control of fruit-infesting Tephritidae

M Trostle, RA Wharton, WA Overholt, RH Messing, J Sivinski
Department of Entomology, Texas A&M University, College Station, TX, USA 77843; rawbaw2@tamu.edu

Members of the family Tephritidae are among the most economically important pests of fruits worldwide. Several species, primarily in the genera *Ceratitis* and *Bactrocera*, have been accidentally introduced to several parts of the world, where they have become established. Biological control can be an important tool in IPM programs targeting these pests in areas where they are adventive. Selection of natural enemies for biological control involves initial discovery and acquisition of biological information essential for successful culturing of potential agents, but also must address such issues as host specificity and non-target impacts. We discuss the problems associated with selection of natural enemies of tephritids in a classical biological control setting involving foreign exploration in subsaharan Africa. The primary focus is on Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann), but we also discuss other species of *Ceratitis* and *Bactrocera* found in the Afrotropical Region.

The distribution of spider families in cotton around Australia.

MEA Whitehouse
CSIRO Cotton Research Institute, Locked Bag 59, Narrabri NSW 2390, Australia;
Mary.Whitehouse@csiro.au

"The aim of Integrated Pest Management (IPM) is to manage pest infestations in agricultural systems by using natural enemies and more selective products. The most abundant group of predators in agricultural systems are spiders, a group which has been largely overlooked in the management of pests in cotton. In this study I identified the spider communities associated with cotton in seven different locations around Australia. I established whether these communities were structurally identical (that is, whether they consist of the same guilds represented by different species); and whether the community structure changed over the course of a year. I found that spider communities were not structurally identical at different locations around Australia. In the south they were dominated throughout the year by the stalkers, Oxyopidae, while in the north they were dominated throughout the year by the foliage runners, Cycloctenidae. In more central latitudes there was a succession of different spider families dominating the community throughout the season. The dominance of different families and guilds at different sites, and the fact that some sites experience a dominance succession while others don't, have ramifications for the implementation of IPM practices at the different sites.
"

The use of the gregarious egg parasitoid *Tetrastichus coeruleus*, **a biological control agent on the aspargus beetle (***Crioceris asparagi***).**

S Wielaard, JJM van Alphen
PO Box 9516, NL-2300 RA Leiden, The Netherlands; wielaard@rulsfb.leidenuniv.nl

The asparagus beetle, *Crioceris asparagi,* causes economical damage in asparagus crops in the Netherlands. Pesticides are used to control this beetle. The parasitoid *Tetrastichus coeruleus* is its natural enemy and is able to keep beetle populations at low densities in the wild and in US asparagus crops. We are trying to set up a mass rearing of this biocontrol agent to make it available to asparagus growers. Knowledge of diapause induction and termination is essential for this goal. Last instar larvae of *T. coeruleus* diapause in a cocoon, made in the soil by the host larva. In spring, development is resumed and after pupation adults emerge. By rearing the parasitoids under different circumstances, we tested which factors are responsible for diapause induction and determined the sensible period. Light conditions during the larval development determine the percentage of larvae entering diapause. Under light conditions that resemble those of the asparagus season (16L:8D) roughly a third of the larvae enters diapause. When light conditions are 12L:12D, 75-100% enters diapause. Larvae in diapause are stored at 4°C. Diapause is terminated after 60-100 days. Diapausing larvae can be stored for at least 200 days. Storing reduces time and costs of production and facilitates distribution.

"Integration of transgenic cotton with IPM – opportunities and challenges"

LJ Wilson, GP Fitt, B Pyke
CSIRO Plant Industry, Locked Bag 59, Narrabri, NSW, 2390, Australia; lewis.wilson@csiro.au

The introduction of Bt-cotton in 1996 created new opportunities and challenges for IPM in Australia. In this first commercial season, Bt-cotton crops were grown (Ingardâ Cry1Ac) with area capped at 10% of the industry. Bt-cotton reduced the need to control *Helicoverpa*, enhancing the opportunity to conserve beneficials. Bt cotton provided cotton producers a low risk starting point to experiment with IPM. The availability of Bt-cotton, increasing availability of more selective insecticides and a co-ordinated extension effort, provided the impetus for increased adoption of IPM practices by growers. Pesticide reductions of over 70% a.i. have been documented. In 2003, Bt-cotton area increased to a cap of 40% including Bollgard II (Cry1Ac & Cry2Ab), which will totally replace Ingard in 2004 with further reductions in insecticide use expected. Continued effectiveness of Bt cotton requires effective resistance management and close attention to secondary pests (aphids, mites, whitefly). The prevalence of sucking pests (mirids, aphids, jassids) has increased in transgenic crops, because these pests were formerly controlled by applications targeting *Helicoverpa*. Products for controlling mirids mostly disrupt beneficials increasing risks of secondary pests. The challenge for Australian cotton is to develop tools to selectively manage sucking pests without disrupting IPM systems in the transgenics.

Importance of short-term dispersal, or trivial movement of augmentative biological control agents

MG Wright, MP Hoffman
Department of Plant and Environmental Protection Sciences, University of Hawai'i at Mānoa, Honolulu, HI 96822, USA; markwrig@hawaii.edu

This paper examines the importance of short-term, trivial movement of augmentative biological control agents in agricultural systems. Effective, rapid dispersal within release sites is essential for effective augmentative biological control, both in terms of determining optimal release rates and positions within crops, and in ensuring that the natural enemies that are released are able to rapidly locate and attack the target pests. Many *Trichogramma* species have been considered for augmentative control programs, and in many cases, extremely limited dispersal after release has been a limiting factor in the effectiveness of these programs. However, in other cases, such as *Trichogramma ostriniae*, dispersal within fields over relatively large distances is rapid. The implication for augmentative releases of *T. ostriniae* in corn is that low numbers of release points are required for inoculation of large areas. In other species, dispersal is slower, the wasps may be less efficient and the result is a less effective augmentative agent. We compare dispersal ability in a range of species which may be used in augmentative release programs in this paper, and show how an understanding of trivial movement is essential for planning of economically viable programs.

Effect of prey density on leaving tendency of *Orius sauteri* attacking *Thrips palmi* on an eggplant leaf

E Yano, N Jiang, L Hemerik, M Mochizuki, T Mitsunaga, T Shimoda
3-1-1, Kannondai, Tsukuba, Ibaraki, 305-8666, Japan; yano@affrc.go.jp

Orius sauteri is a predator with a wide range of prey species. Since 1998 this species is in use as biological control agent of thrips. In this study its searching efficiency, its time allocation on a leaf, its leaving tendency and the attack of prey items are investigated in detail. About 78% of the encountered prey items were eaten. During 86% of the time searching for prey was concentrated on the lower leaf side where prey can be found. Patch residence times for empty leaves were different from those on leaves with thrips larvae, independent of the specific density. Walking activity was not affected by thrips density, and walking took place during 64% of the total patch time. The patch leaving tendency of *O. sauteri* after predation was analyzed by the proportional hazards model (Cox, 1972). The leaving tendency was affected by the presence of prey items irrespective of the specific density. If prey were present the leaving tendency decreased by 0.327, resulting in larger giving up times than when no prey items were present. The time since patch entry increased the leaving tendency, making sure that not much time is wasted on patches where encounters with prey items are scarce.

Bacterial microflora community associated with *Costelytra zealandica* (Coleoptera: Scarabaeidae) defined by DGGE profiles of 16S rRNA genotypes

HY Zhang, TA Jackson
Biocontrol Technologies, AgResearch, Canterbury Agricultural and Science Centre, P.O. Box 60, Lincoln, New Zealand; hongyu.zhang@mail.hzau.edu.cn.

The bacterial microflora community associated with the digestive tract of *Costelytra zealandica* (Coleoptera: Scarabaeidae) was examined by using Denaturing Gradient Gel Electrophoresis (DGGE) of PCR-amplified 16S rDNA gene fragments and sequencing. Gel analysis indicated presence of a wide range of bacteria, with many species being non-culturable. The bacterial community in the midgut was highly variable and affected by environment and diet. The bacterial community of the hindgut was more diverse and less disturbed by external factors. The predominant bands on the DGGE gels of the hindgut samples were sequenced and identified as non-culturable, fermenting bacteria of the Clostridiales, Betaproteobacteria, Deltaproteobacteria and the CFB phylum. The most common genotypes were affiliated with novel Clostridiales. These novel Clostridiales species were present in the hindgut of all isolations in all larval instars suggesting a symbiotic relationship. The bacteria could not be located in egg samples collected from reproductive tissues indicating some form of horizontal transmission. The role of putative bacterial symbionts of *C. zealandica* will be discussed.

Screening of entomopathogenic fungi against the aphids, *Myzus persicae* and *Macrosiphum euphorbiae.*

S Aemprapa, M Thungrabeab
Academic Development and Service Center, Rajamongkol Institute of Technology, Thanyaburi, Pathumtanee, 12110. Thailand; entolpth@yahoo.com

The screening of entomopathogenic fungi, 17 isolates of *Metarhizium* spp., 7 isolates of *Paecilomyces* spp. and 3 isolates of *Hirsutella citriformis* against the aphids had performed in Lampang Agricultural Research and Training Centre, Lampang, Thailand. The efficacy test has done by spraying suspension of 10^8 spore per ml. of fungus in completely randomized design experiments on *Myzus persicae* and *Macrosiphum euphorbiae* . Then the number of the dead aphids which have covered by fungus was recorded and calculated percent mortality by Abbott's formula. The results showed that the mortality percentage of *Myzus persicae* was from 0 to 89.47 % and *Macrosiphum euphorbiae* was from 0% to 100 %. The fungi which killed aphids from 50% up were selected and checked virulent level by calculating the LC_{50} using Factorial in completely randomized design experiments. Factorial A was fungal isolate and factorial B was 5 levels of spore concentration. The results showed that the number of the aphids killed by fungi were correlated with the spore concentration while the percent and duration of mortality depended on the fungal virulence and aphid species. The highest and lowest LC_{50} of fungi on *Myzus persicae* and *Macrosiphum euphorbiae* showed significantly different. There was 1 isolates showed very high effect on *Myzus persicae* and *Macrosiphum euphorbiae.* Its LC_{50} was 1.95×10^4 and 2.24×10^6 spore/ml respectively.

Assessment of *Trichogramma embryophagum* (Hymenoptera:Trichogrammatidae) against *Sesamia* (Lepidoptera: Noctuidae)

A Agamirkarimi
College of Agricultural of Aboureyhan,Tehran university, Iran; mkarimi@ut.ac.ir

The role of *Trichogramma embryphagum* (Hymenoptera:Trichogrammatidae) (reared on *Heliothis zea* Boddie eggs) as parasitoid of the sugarcane and corn stem borers *Sesamia cretica* Led. And *S.nonagrioides botonephaga* T.&B.,was assessed under laboratory and greenhouse condition .Data on seven biological parameters are presented.The laboratory results showed that *T.embroypham* reared on *H.zea* eggs parasitized 50% of *S.critica* gggs,compared to 58.5% of *S.nonagrioides* eggs.percentages of emergence (87%), female progeny (71%),deform females (2.5%), and development time (8.9d) in *T.embroypham* reared from *S. cretica* gggs did not differ significantly from those reared on *H.zea* eggs (93%,69%,3.2%,2d and 8.5d respectively).However,*T.embroypham* females reared form *S.cretica* eggs had greater body length (39mm) than females reared on *H.zea* (0.33mm). in the greenhouse conditions, *T.*embroypham parasitized an average of 56.4% of the *S.cretica* eggs masses were distributed on the corn plants).about 21.6% of the eggs were dessicated,probably due to puncturing by the parasitoid,compared with 4.1% in the control,where egg masses were distributed on the plants without release of *Trichogramma*.Results showed the potential for use *Trichgramma* to control corn stalk borers in a field IPM program.

Survey of capability of egg parasitic wasp *Trichogramma embryophagum* to control *Ostrinia nubilalis*, in Tehran area at 1999-2001

A Agamirkarimi
College of Agricultural of Aboureyhan,Tehran University,Iran; mkarimi@ut.ac.ir

The researchon this subject was based on inundative release at farm of Agricultural Faculty biological research in Rehran(Varamin area).Before and after releasing the Trichogramma amount of parasitoid and percentage of damage have been calculated as well as the rate of parasitism in control areas(Varamin)in different month of the years 1999-2001.Rearing of *Trichogramma* was done on host egg of *Ephestia kouhniella*. During September of 1999 the highest percentage of parasitism was about 90% while in 2001 it was 82%. In toghdar farm after 7times releasing the highest rate of parasitism had been 87.5%during August 1999.

Mass rearing of the egg parasitoids, *Trichogramma evanescens* & *T. oleae* (Hym: Trichogrammatidae)

HF Alrubeai, SH AL-Tai, ZA AL-Gahrbawi, AH Salman
Ministry of Science and Technology, IPM center, P.O. Box 765 Baghdad, Iraq.

This study was conducted using the egg parasitoids, *Trichogramma evanescens* and *T. oleae* to evaluate its egg preference of the factitious host, *Ephestia calidella* and *E.cautella* and to investigate the influence of temperatures of 14, 22, 25, 28, 30, 33 and 35°C, 60± 5% RH and 16 hr light / day on some biological characteristies of both parasitoids populations. The results indicated that host egg preference of two *T. evanescens* races depend on the type of host egg that the parasite generations reared on it. The highest total fecundity was 117 eggs / female at 25°C for *T. oleae*. The estimated optimal temperature for fecundity was around 24°C and 19°C, for *T. evanescens* and *T. oleae*. respectively. The results showed a slight differences in adult emergence for both parasitoids species at different temperatures tested, expect at 35°C, where no emergence occurred. Results also indicted the presence of variable effects of temperatures on developmental periods of the parasitoids. The relation between temperature and development duration of both species was calculated, where the minimum and maximum developmental of *T. evanescens* were around 9 and 37°C and for *T. oleae*. were 9 and 38°C, respectively.

Mass rearing & efficiency study of *Eocanthecona Furcellata* (Wolff) (Hemiptera: Pentatomidae) for control of lepidopterus insect pests of asparagus in Thailand

O Kern-asa, W Amornsak and W Suasa-ard
National Biological Control Research Center (NBCRC), Kasetsart University/National Research Council of Thailand, P.O.Box 9-52, Jatujak, Bangkok 10900,Thailand; agrwis@ku.ac.th

Mass rearing of predatory pentatomid, *Eocanthecona furcellata* (Wolff) (Hemiptera: Pentatomidae) was conducted at the NBCRC-Central Reginal Center, Kampaengsaen, Nakhon Pathom, Thailand. Many species of insect larvae were provived as preys of *E. furcellata* for mass rearing. *Spodoptera litura* F. (Lepidoptera: Noctuidae) was considered as the most easily available preys for mass-rearing of *E. furcellata*. Approximately 350 third-instar nymphs of *E. furcellata* were released in 0.5 acre in asparagus field at NBCRC-CRC for investigation on predatory efficiency. The result showed that the population of lepidopterus insect pests were reduced more than 69 percent in 48 hours after *E. furcellata* were released. About 500 of third-instar nymphs of *E. furcellata* were released in two locations of farmer asparagus fields at Kampaengsan district. Three weeks after released *E. furcellata* showed efficiency of control over the population of *S. litura* and *Spodoptera exigua* (HÜbner) (Lepidoptera: Noctuidae) in asparagus field.

Host stage preference and development of *Allotropa citri* Muesebeck (Hymenoptera: Platygastridae) on *Pseudococcus cryptus* Hempel (Homoptera: Pseudococcidae)

T Arai
Department of Apple Research, 92-24 Nabeyashiki, Shimokuriyagawa, Morioka, Iwate 020-0123, Japan; gaityuu@affrc.go.jp

Allotropa citri could parasitize all the developmental stages of *Pseudococcus cryptus*. In the experimental condition, however, no difference was observed in the percentage parasitism between the first and the second instar hosts, but the parasitism of the third instar and adult female hosts was lower than that of the first and second instars combined. No difference was observed in the developmental duration of this parasitoid between the first and the second instar hosts. Therefore, the first and second instar nymphs of *P. cryptus* were considered suitable host stages for *A. citri*. The developmental duration of this parasitoid at 20 and 25 °C under a short day photoperiod of 8L16D was not different from that under a long day photoperiod of 16L8D. Therefore, it is considered that *A. citri* could parasitize *P. cryptus* under a short day photoperiod as well as under a long day photoperiod if the temperature is maintained over 20 °C.

Biological control of the Mediterranean fruit fly in Israel

Y Argov, Y Gazit
The Israel Cohen Institute for Biological Control, Plant Production and Marketing Board - Citrus Division, P.O. Box 80, BET-DAGAN, 50250, Israel; yael@jaffa.co.il

Our objective: to use biological control to decrease populations of the Mediterranean Fruit Fly *Ceratitis capitata* (Medfly). The worldwide tendency is to reduce chemical control and to switch to environmentally friendly control methods. In Israel today, the control of Medfly is still based on organophosphates (mostly malathion - bait applications). Small fruit gardens and neglected groves are considered as major sources of infestation. Effective biological control may reduce the Medfly populations there therefore decreasing the infestation rate of commercial groves, requiring less chemical sprays. Furthermore, biological control is the major complement to the Sterile Insect Technique (SIT). Before the beginning of this study, three Braconid species were found on Medfly in Israel: the pupal parasitoid *Dirhinus giffardii*; and the larval - pupal parasitoids *Aganaspis daci* and *Psyttalia concolor* (complex). Since 2002, we have imported four other Braconid species: the egg – pupal parasitoids *Fopius arisanus* and *F. ceratitivorus*; the larval - pupal parasitoids *Psyttalia concolor* (complex); and *Diachasmimorpha krausii*. We have cultured each on Medfly and have begun to study some aspects of their biology. We have started to release them all over the country and are monitoring recovery by fruit sampling.

Fatty acid composition of eggs of two host species of *Trichogramma* & relationships with cold tolerance

MRF Avanci, LA Foerster, AK Doetzer, G Sassaki, LM de Souza
PO Box 19020, Curitiba, Parana, 81531-990, Brazil; avanci@bio.ufpr.br

Fatty acid composition of insect eggs is closely related to the cold tolerance. In this work, the proportions of fatty acid in eggs of two noctuid species were compared, one active during summer, *Anticarsia gemmatalis*, and the other found during winter in Southern Brazil, *Mythimna sequax*. Eggs were obtained from laboratory rearing, stored in liquid nitrogen during 30 days and exposed to *Trichogramma pretiosum* at 21ºC. In another essay, eggs were parasitized at 21ºC and the parasitoids were stored in the pupal stage at 4ºC during 20, 30, 45 or 60 days. Parasitism on *M. sequax* and *A. gemmatalis* eggs after maintenance in liquid nitrogen were respectively 55.3% and 29.2%. The host did not influence on the parasitoid survival after pupae storage at 4ºC during 20 and 30 days, and the emergence ranged from 75.4% to 100.0%. After 45 and 60 days storage, parasitoids developing on *M. sequax* showed emergence (90.0% and 77.0%) higher than the one obtained on *A. gemmatalis* (38.3% and 13.0%). *M. sequax* eggs contain higher concentration of palmitic, stearic, oleic and linoleic acids, in relation to *A. gemmatalis*, so that the winter host contains higher nutritive resource and shows higher cold resistance of the cell membrane.

Biological control efficacy of entomopathogenic nematode, *Steinernema carpocapsae* against lepidopterous insects of Chinese cabbage under greenhouse and open field conditions in Korea

SD Bae, HJ Kim, JS Park[1], HJ Cho, ST Park
Yeongnam Agr. Res. Inst., RDA, Milyang 627-130, Republic of Korea; baesdo@rda.go.kr

Control efficacy of entomopathogenic nematode, *Steinernema carpocapsae* (SC) Weiser, was evaluated on the larvae of tobacco cutworm (TC), *Spodoptera litura* Fabricius, beet armyworm (BA), *Spodoptera exigua* Hubner, and cabbage webworm (CW), *Hellula undalis* Fabricius of Chinese cabbage at different spraying times under greenhouse and open field conditions in Milyang, south-eastern part of Korea. During late July to early October, control efficacy of SC against TC was in the range of 57 to 93% and 39 to 90% at greenhouse and open field, respectively. Likewise, during late August to early October control efficacy of SC against BA showed 51 to 94% and 42 to 90% between greenhouse and open field, respectively. On the other hand, control efficacy of SC against CW was in the range of 58% to 30% at greenhouse during middle September to early October. Accordingly, SC was very effective to control both TC and BA although their control efficacies were significantly depending upon air temperature while was not effective in the control of CW. Therefore, SC was considered as promising biological control agent against TC and BA during middle summer to middle fall seasons in Korea.

Potential use of *Trichogramma* as a tool in cotton IPM in Mato Grosso, Brazil.

CS Bastos, FA Suinaga, DEB Araújo, VL Menezes, AJS Lira.
Rua São Paulo, no. 790, Primavera do Leste, MT, Brazil, 78850-000; cristina@cnpa.embrapa.br

Considering, the spread use of *Trichogramma* in IPM programs all over the world, the objective of this study was to test the parasitism efficiency of *Trichogramma* when used to control Lepidoptera-pests of cotton and its potential to be used as a tool in cotton IPM of MT, Brazil. Two plots of one hectare each (management using *Trichogramma* and conventional management) were set up in Primavera do Leste, Campo Verde and Novo São Joaquim County, state of Mato Grosso, Brazil. From week zero (before parasitoid release) on, it was released 100,000 wasps/ha/week on the plots managed with *Trichogramma*. Both plots were evaluated every time that the parasitoids were released until harvest and the insect-pests densities, the number of non-parasitized and parasitized eggs of the cotton leafworm and of the tobacco budworm, as well as the number of parasitoids and predators were recorded. The results showed that a greater number of predators and parasitoids were found in the plots that were managed with *Trichogramma* than in the plots that were managed without *Trichogramma*. Both plots showed high rates of parasitism, achieving 100% in some points of evaluation.

Who should avoid intraguild predation: the predator or its parasitoid prey?

E. Bilu, M Coll
Department of Entomology, The Hebrew University of Jerusalem, P.O. Box 12 Rehovot 76100, Israel; Binyamin@agri.huji.ac.il

Predators may feed on both herbivores and their endoparasitoids. Such intraguild predation (IGP) is often asymmetrical, imposing strong selection pressure on the parasitoid, the IG prey in the system. If so, we hypothesize that the IG prey should evolve strategies to minimize IGP. Female parasitoids may change foraging site, behavior or both in the presence of their IG predators, thus reducing their risk of predation. The study system consisted of an IG predator, *Coccinella undecimpunctata*, a parasitoid IG prey, *Aphidius colemani,* and their aphid prey/host. The parasitoid preferentially parasitized hosts on which it was reared, regardless of the presence of the predator. Confronting a predator, *A. colemani* did not leave the host plant, even when predator-free plants were available nearby. Yet lower parasitism rates occurred in the presence of predators. *C. undecimpunctata* larvae fed on parasitized aphids showed decreased prey consumption and increased handling time with increasing parasitoid age. Larvae reared on mummies rather than aphids developed more slowly and had lower pupal and adult weights. Contrary to expectations, results show that (I) the IG prey in the system does not avoid predation although it experiences significant reduction in reproductive output; and (II) the IG predator is adversely affected by feeding on IG prey.

Analysis of molecular adaptation of nucleopolyhedrovirus genes

RL Harrison, BC Bonning
Department of Entomology, Iowa State University, 418 Science II, Ames, IA 50011 USA, bbonning@iastate.edu

Genes in which nonsynonymous substitutions are fixed at a higher rate than synonymous substitutions are said to have undergone molecular adaptation, or positive selection. The primary selection pressure on a virus results from virus-host interaction. Hence, analysis of selection pressures on virus genes can potentially identify genes involved in species-specific virulence. To identify baculovirus genes that have undergone positive selection, a maximum likelihood approach was used to analyze selection pressures acting on genes of nucleopolyhedroviruses (NPVs) that have different host ranges within Lepidoptera. Alignments of 84 group I NPV genes were fitted to models of codon substitution that allow for varying selection intensity among codon sites. Evidence for positive selection was found for nine genes: *ac38*, *ac66*, *arif-1*, *lef-7*, *lef-10*, *lef-12*, *odv-e18*, *odv-e56*, and *vp80*. NPV genes that have undergone positive selection may modulate the ability of different NPVs to replicate efficiently in cells (*lef-7*, *lef-10*, *lef-12*) or to establish primary infection of the midgut (*odv-e18*, *odv-e56*) of different host species. Analysis of the baculovirus DNA helicase gene (*dnahel*) with a method that allows selection pressure parameters to vary among lineages suggests that positive selection may have occurred in *dnahel* within a clade containing BmNPV.

Differential response of a generalist egg parasitoid to alternative host species with different physical features

RRR Brotodjojo, GH Walter
Dept. of Zoology and Entomology, University of Queensland, Qld 4072, Australia; s4022963@student.uq.edu.au

Trichogramma pretiosum Riley is a generalist parasitoid that attacks many insect pests, mostly lepidopterans. However, parasitism rates vary substantially across host species. We investigated whether natal host species and age of adult wasp (<24 h and 2 days old since eclosion) affects the oviposition preference and parasitism rates of *T. pretiosum* on *Helicoverpa armigera* Hub. and *Spodoptera litura* Fab. When a choice was given, regardless of natal host and adult age, the female wasps responded differently to the eggs of the two species. However, when female wasps had no choice, they responded to both host species in much the same way. When given a choice of egg species, the productivity of *T. pretiosum* was significantly higher on *H. armigera* eggs, but they showed equal productivity when there was no such choice.

Control of spiralling whitefly *Leccanoideus floccissimus* Martin et al. (Hemiptera: Aleyrodidae) & *Aleurodicus dispersus* Russell (Hemiptera: Aleyrodidae) by entomopathogenic fungus

SA Padilla, E Hernandez, A Carnero, C. Fernandez
Dpto. Protección Vegetal del I.C.I.A., Apdo. 60, 38200 La Laguna-Tenerife, Spain

The incidence of spiralling whiteflies *A. dispersus* and *L. floccissiumus* is one of biggest problems affecting ornamental crops and gardens in the Canary Islands. Several trials with different species of enthomopathogenic fungi for controlling these species of whiteflies have been performed under laboratory conditions. Results from these tests showed *Lecanicillium lecanii* and *Metarhizium anisophliae* as the most efficient species controlling *L. floccissimus*. Furthermore, a new bioinsecticide based on blastospores of the fungus *Paecilomyces fumosoroseus* (FuturEco S.L., Spain) was also evaluated. Preliminary tests with this bioinsecticide showed high efficacy against both species of spiralling whiteflies.

Mass production & utilization of the predatory stink bug, *Eocanthecona furcellata* **(Wolff) (Hemiptera: Pentatomidae)**

C-P Chang
Miaoli District Agricultural Research And Extension Station, Council Of Agriculture, Miaoli, 363,Taiwan, Bug01@Mdais.Gov.Tw

The richness of the species of stink bug, Pentatomidae, is clearly proved by the existence of over 5,000 species recorded in the world. Besides , the predatory stink bug , *Eocanthecona furcellata* (Wolff) , plays an important role in ecosystem. This predatory stink bug is a predatory insect that can be commonly found on horticultural plants preying on various Lepidopterous insect pests in Taiwan. The predatory stink bug can attack many important pests such as *Pieris rapae crucivora,Spodoptera litura, Plutella xylostella* , *Spodoptera exigua et al.* in Taiwan. It will also attack other Lepidoptera , Cleoptera on vegetables , fruits , ornaments and many other crops grown outdoors , in gardens , in greenhouses and other areas. The predatory capacity and predatory response of the stink bug to various prey were measured and it was taken as an important data for releasing the natural enemy to control the pests in the field. The study was conducted for assessment of efficacy and profit for control of *Pieris rapae crucivora* and assessing the profit of control measure to release this natural enemy. The basic biology , mass production, utilization of *Eocanthecona furcellata* (Wolff) were established and would be discussed in this report.

Cultivation media for *Bacillus thuringiensis* subsp. *israelensis* Phrae strain, from waste of agro-industry

L Chowanadisai, N Methawanitphong, M Riyaparn, M Kongmee
Biological Control Section, National Institute of Health, Department of Medical Sciences, Tiwanond Road, Nonthaburi 11000, Thailand,
laojana@dmsc.moph.go.th

Bacillus thuringiensis subsp. *israelensis* Phrae strain was proved to exhibit larvicidal activity against *Aedes aegypti*, vector carried dengue haemorrhagic fever. Juice in brown coconut or as called coconut milk, available in the coconut meat industry was therefore selected for the present study. Preliminary study indicated that among 8 kinds of media, cell mass from peptone glucose salt medium was 1.9709 g/l while those of plain coconut milk was 1.0128 g/l. The 18 recipes of coconut milk-based media (CM1-CM18) were then developed. It was indicated that the CM13, CM10 and CM11 recipes gave 1.7152, 1.6076 and 1.5955 g/l of cell mass, respectively. While the CM14, CM17 and CM15 recipes were the group of low cost. Considering on the amount of cell mass, cost and complication of the formula, the CM13 and CM17 recipes were subject to determine the larvicidal activity of the cell cultivated from both recipes in term of potency. The potency of candidate cells cultivated from CM13 and CM17 recipes were 908 and 10,657 ITU/mg, respectively. However, cell mass from CM13 recipe was 1.8 times higher than CM17 recipe while the cost was also106 times higher but potency of the cell from CM17 recipe was 11.7 times higher than those of CM13.

Mass-producing weed biocontrol agents through 'farming'

R De Clerck-Floate, J Moyer, B Van Hezewijk, B Stewart, D Brooke
Agriculture and Agri-Food Canada, Lethbridge Research Centre, P.O. Box 3000, Lethbridge, Alberta,T1J 4B1, Canada; Floate@agr.gc.ca

The recent success of the European root weevil, *Mogulones cruciger* Hbst. (Coleoptera: Curculionidae), as a biocontrol agent for the rangeland weed, houndstongue (*Cynoglossum officinale* L.) in British Columbia, Canada, has created a large demand for the weevil among ranchers and land managers. Numbers of the weevil sufficient to meet this demand cannot be easily collected from field sites, and mass-production of the agent in the laboratory is expensive and constrained by availability of host plant material. Hence, we have initiated a project to mass-produce the agent that involves growing houndstongue as a crop in an agricultural setting, releasing the weevil into the crop, and after two developmental generations, harvesting the progeny for distribution. Experiments are currently underway to develop agronomic methods of cropping houndstongue, which include seeding time, depth and spacing, fertilizer and mulch treatments, and methods of controlling houndstongue diseases and other competing weeds. Insect responses to the different agronomic treatments also are being investigated with the goal of maximizing insect production. It is anticipated that this method of mass-production could be adopted by ranchers and land managers to produce sufficient weevils to meet local demand, and through modification, could be used to produce other biocontrol agents.

Temperature-dependent development of *Anagyrus pseudococci* on the vine mealybug

KM Daane, VM Walton, RD Malakar-Kuenen
Center for Biological Control, Division of Insect Biology, University of California, Berkeley, CA, 94720, USA, daane@uckac.edu

The influence of temperature on *Anagyrus pseudococci* (Girault) development and overwintering was investigated to improve biological control of the vine mealybug, *Planococcus ficus* (Signoret), in California vineyards. We tested eight constant temperatures and show *A. pseudococci* completed development (egg to adult eclosion) between 14 and 34ºC. Development times ranged from 79.1 ± 1.0 days (14ºC) to 10.2 ± 0.3 days (34ºC). We determined optimal, maximum and minimum development temperatures as 24.7, 36.0 and 11.4ºC, respectively. The thermal constant is 231.9 degree-days. We compared these laboratory-derived temperature relationships with field activity of *A. pseudococci*. The parasitoid was reared from field-collected mealybugs between May and October. Laboratory-derived temperature-dependent development suggests there are seven to eight *A. pseudococci* generations during this period, two generations to each vine mealybug generation. Overwintering studies show that, regardless of when vine mealybugs were exposed to *A. pseudococci* (October 2001 to March 2002), emergence was concentrated over a 15 day period in early May. Results suggest that cues other than temperature are used to synchronize overwintered *A. pseudococci* adult emergence with field availability of vine mealybug. Results are discussed with respect to insectary rearing and augmentation of *A. pseudococci*.

Predation of *Alabama argillacea* (Lepidoptera: Noctuidae) by nymphs & adults of *Podisus nigrispinus* (Hemiptera: Pentatomidae) under different caterpillars densities & ages of cotton plants

SA De Bortoli, JE de M. Oliveira
FCAV-UNESP, Depto. de Fitossanidade, Via de Acesso Prof. Paulo Donato Castellane s/no., 14870.000, Jaboaticabal, São Paulo, Brasil;
bortoli@fcav.unesp.br

The predation rate of fifth instar nymphs and females of *Podisus nigrispinus* (Hemiptera: Pentatomidae) was evaluated at lower and higher threshold control levels for *Alabama argillacea* (Lepidoptera: Noctuidae) larvae, in three ages of cotton plants (20, 40 and 60 days). Five cotton plants were caged in field with one and three *A. argillacea* larvae per plant and one nymph or one female of this predator. Nymphs and adults of *P. nigrispinus* preyed higher number of larvae preyed with higher density of larvae and smaller leaf area in young cotton plants. Nymphs and adults this predator restrained plant defoliation bellow threshold control levels at both infestation levels and plant ages of 20 and 40 days, compared that of plants without this predator and on plants with 60 days. *P. nigrispinus* weight gain was affected when maintained in plants at more advanced development stages, in both tested densities of *A. argillacea* larvae.

Cold storage of egg parasitoids of soybean pentatomids as a method for large-scale production in biological control programs

LA Foerster, AK Doetzer, G Sassaki, LM de Souza
PO Box 19020, Curitiba, Parana 81531-990, Brazil; foerster@bio.ufpr.br

Hibernation is a common adaptation used by insects to overwinter in temperate and subtropical regions. Previous studies in natural conditions showed that *Trissolcus basalis* and *Telenomus podisi* hibernate as adults in Southern Brazil, so that storage in this stage can be an adequate procedure in the large-scale production of these species. In this work, adults of *T. basalis* and *T. podisi* kept during the immature stages at 25ºC were stored at 18ºC. Longevity of the hibernating parasitoids and fecundity after 180 days were evaluated. Alterations in the fatty acid composition of the parasitoids were measured. Mean longevity of stored females was 332.5 and 225.9 days, for *T. basalis* and *T. podisi* respectively, while non-hibernating females lived for 74.5 and 56.3 days. Storage of *T. basalis* did not influence its reproductive capacity; however, for *T. podisi*, fecundity decreased ca. 50% after hibernation. For *T. podisi*, content of pentadecanoic, palmitic and stearic acids decreased after storage, while the content of palmitoleic and oleic acids was higher in hibernating parasitoids. For *T. basalis*, storage did not influence the fatty acid composition, and it is concluded that this species can be stored during winter and released during the soybean season in Southern Brazil.

Storage of pentatomids eggs in liquid nitrogen for the production of parasitoids in laboratory

AK. Doetzer, LA Foerster, F Siquiera, LCF de Castro
PO Box 19020, Curitiba, Paraná, 81531-990, Brazil; doetzer@bio.ufpr.br

The egg parasitoids *Trissolcus basalis* and *Telenomus podisi* are commonly found on soybean pentatomids. Storage of the host eggs in liquid nitrogen could be used to increase the efficiency of the rearing of these species in laboratory and their field release. This work was conducted in order to determine which host species are suitable to parasitism after storage of the eggs during six months in liquid nitrogen. Parasitism by *T. basalis* was evaluated on *Nezara viridula*, *Acrosternum pengue* and *Edessa meditabunda,* while for *T. podisi*, the parasitism was investigated on *Euschistus heros*, *Piezodorus guildinii*, *Dichelops furcatus* and *Podisus nigrispinus*. Among all species evaluated, *N. viridula*, *A. pengue*, *P. guildinii* and *D. furcatus* were suitable to parasitism after storage and the rates of emergence on these species ranged from 61.8 to 94.5%. On the other hand, *T. basalis* did not parasitize eggs of *E. meditabunda* after storage and the emergence of *T. podisi* on stored eggs of *E. heros* and *P. nigrispinus* decreased in comparison to the control. It is concluded that eggs of four pentatomid species can be stored in liquid nitrogen and used in the large-scale production of *T. basalis* and *T. podisi*.

Maximising the efficacy of a coccinellid predator in a biocontrol setting (*Cryptolaemus montrouzieri*)

M Finlay-Doney, GH Walter
Department of Zoology & Entomology University of Queensland, St Lucia Brisbane 4072. m.finlay-doney@zen.uq.edu.au

Coccinellids are utilised in biocontrol programs throughout the world, and they are commonly accepted as 'voracious' predators of mealybugs and scales. One such organism is the native Australian ladybeetle *Cryptolaemus montrouzieri*. It is frequently released against the citrus mealybug (*Plannococcus citri*) both in Australia and overseas. The success of field releases has proved erratic. We conducted field studies, over two years, comparing the success of different life stages in controlling mealybug infestations in custard apple orchards. The results suggest that the release of early instar larvae is more efficacious than releases of either adult beetles or eggs. This field data is presented in conjunction with three laboratory experiments. The first experiment investigates the importance of intraspecific predation for eggs and first instar larvae. The remaining two examine the survival and searching capacity of second instar *Cryptolaemus* when they do not hatch in direct contact with a food source. These results are used to make recommendations for the improved manipulation of *Cryptolaemus* in a field environment.

Effect of the entomopathogenic fungus, *Paecilomyces fumosoroseus* to the green peach aphid, *Myzus persicae*.

S Futagami, H Hiromori, M Hatsukade
Department of Applied Entomology, Faculty of Agriculture, Shizuoka University, Ohya 836, Shizuoka 422-8529, Japan; t0330015@ipc.shizuoka.ac.jp

Green peach aphid, *Myzus persicae* (GPA) infests many vegetables, including crucifer. GPA has high fecundity and grows to a large population. Usually, chemical insecticides are used to control GPA, but may cause many problems. So, it is necessary to produce other ways to control GPA, and we estimated the control effect of *Paecilomyces fumosoroseus* to GPA. We isolated the entomopathogenic fungus, *P. fumosoroseus* (strain SPf-1) from soil that indicates high virulence to GPA. In laboratory conditions, SPf-1 cause high mortality and make lots of conidia on the cadaver of GPA. SPf-1 still showed high virulence even when the concentration was reduced. Generally, entomopathogenic fungi are suitable and virulent at 20~25°C. However in Japan, GPA infest much at early spring to late autumn when the temperature is relatively low, than high temperature at summer. To determine the usefulness of entomophatogenic fungi, researches at low temperature is necessary. In this study, we estimated the efficacy of SPf-1 to low temperature conditions, and efficacy at field environment. Furthermore, to enhance the fungal virulence, and gain stability effect under greenhouse environment, bioassays using soybean oil were conducted.

Indigenous insect parasites attack the introduced pine weevil, *Pissodes nemorensis,* in South Africa

S Gebeyehu, MJ Wingfield
Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria 0002, South Africa; solomon.gebeyehu@fabi.up.ac.za

The deodar weevil, *Pissodes nemorensis,* is an important exotic pest of pines in South Africa. It was accidentally introduced into this country from North America and was first detected in 1942. Currently, *P. nemorensis* is distributed throughout the pine growing regions of South Africa where it causes significant damage, particularly to stressed trees. Two natural enemies have been found feeding on *P. nemorensis* in the field. These include a species of *Pycnetron* (Hymenoptera: Pteromalidae) and a species of *Gobertina* (Diptera: Stratiomyidae). Neither of these parasites has previously been reported to feed on *P. nemorensis* in its native range. We, therefore, believe that they are most likely native to South Africa and that they have adapted the capacity to feed on an exotic pest species. We are currently studying the taxonomy, biology and the efficiency of parasitism of these parasites. We are also considering mass-rearing techniques on artificial media, with the aim of promoting biological control of *P. nemorensis* in South Africa.

Yeast symbionts of natural enemies: green lacewings, *Chrysoperla* spp., & the brownbanded cockroach parasitoid *Comperia merceti*

CM Gibson, MS Hunter
University of Arizona, Dept. of Entomology, 410 Forbes Building, Tucson, Arizona, U.S.A. 85721-0036; cgibson@ag.arizona.edu

Despite much recent interest in invertebrate-bacterial symbioses, fungal associations with insects have received relatively little attention. Even though some yeast-infected insects are economically important natural enemies, we know little about the contributions of these symbionts in natural populations, or whether symbiotic relationships are compromised during insectary-rearing, with subsequent decreases in biocontrol efficacy. Here we present research characterising symbioses between yeasts and two types of natural enemies. The yeast symbionts of green lacewings, *Metschnikowia sp.* and *Candida spp.*, were previously thought to provide missing amino acids from adult lacewings' primarily carbohydrate diet. Our data suggest that the yeasts themselves require some minimum quality diet before providing nutrients to adult lacewings. In addition, we present evidence that the yeasts in green lacewings are vertically transmitted; a novel finding that has important implications for the nature of the lacewing-yeast relationship. In a second system, we are examining the role of the vertically transmitted intercellular yeast symbionts in *Comperia merceti*, a specialist egg parasitoid of brownbanded cockroaches. These wasps have the potential to substantially suppress brownbanded cockroach populations in enclosed building settings.

Evaluation of an candidate agent, *Floracarus perrepae* (Eriophyidae) & selection of the best adapted genotype for biological control of old world climbing fern: an invasive weed in Florida, USA

JA Goolsby, AS Bourne, PJ DeBarro, TP Freeman, DM Hartley, JR Makinson, SK Ozman-Sullivan, RW Pemberton, JWH Trueman, AD Wright, R Zonneveld
United States Dept. of Agriculture, Agricultural Research Service, Australian Biological Control Laboratory, 120 Meiers Rd. Indooroopilly, Queensland Australia 4068; john.goolsby@csiro.au

Surveys for biological control agents *Lygodium microphyllum*, an invasive fern in Florida, USA were conducted in the its native range which includes Australia, Asia and Oceania. Twenty-two herbivores were documented including an eriophyid mite, *Floracarus perrepae* Knihinicki & Boczek. Molecular tools were used to match the origin of the invasive Florida fern with populations in the native range and the population from Cape York, Queensland was found to be an exact match for two chloroplast DNA sequences. Field studies of *F. perrepae* in Queensland found that the mite was active year round peaking during periods of ample soil moisture. Predator mites and a pathogen had significant impacts on *F. perrepae* populations, but heavy plant damage was still observed. Pre-release field impact studies revealed that *F. perrepae* caused more than 50% reduction in biomass of *L. microphyllum* over a two-year period. Several genotypes of *F. perrepae* were identified from the native range using CO1 and D2 genes. Each of these populations were screened for their acceptance of the invasive Florida genotype of the fern and the Cape York genotype performed best. Host-range tests have shown that *F. perrepae* is specific to *L. microphyllum,* and therefore its release in Florida is recommended.

Establishment & dispersal of phorid flies, *Pseudacteon* spp. (Diptera: Phoridae) in Alabama for control of imported fire ants, S*olenopsis* spp. (Hymenoptera: Formicidae)

LC Graham, VE Bertagnolli
301 Funchess Hall, Auburn, AL 36849, USA; fgraham@acesag.auburn.edu

Two species of *Pseudacteon* have been released in Alabama on the imported fire ant. *Pseudacteon tricuspis* is established in five populations of the red imported fire ant, *Solenopsis invicta,* in the southern two-thirds of the state and *P. curvatus* is established in four populations of the hybrid fire ant, *S. invicta* x *Solenopsis richteri*, in the northern third of the state. Establishment and dispersal of the flies from release sites is documented. Fire ant populations are monitored at release sites and control sites. Biological data are collected on the behavior of both species of phorid flies.

Attractiveness of flowering plants in the urban landscape to beneficial Syrphidae & Hymenoptera

GG Hamilton, JH Lashomb, JM Patt, D Matadha
Department of Entomology, 93 Lipman Drive, Rutgers University, New Brunswick, NJ 09801, USA

Studies have shown that the size and shape of flowers influences the types of hymenopteran natural enemies that can forage successfully in those flowers. In this study, we examined this phenomenon over a three year period to see if a similar effect could be found with beneficial insects attracted to flowers used in urban landscapes. To do so, common annual and perennial flowering plants were sampled once a week between May and September in two different locations during 2000, 2001 and 2002. In addition, flower shape and size was evaluated and correlated with attractiveness to different species. Differences in the type and abundance of the species attracted to different flower species as they relate to floral dimensions are discussed.

Biological control of tephritid fruit flies: a novel technique for efficient mass production & field delivery of the egg parasitoid, *Fopius arisanus.*

EJ Harris, RC Bautista, RI Vargas, EB Jang
U. S. Pacific Basin Agricultural Research Center, USDA-ARS, 2727 Woodlawn Drive Honolulu, HI, P. O. Box 4459, Hilo, HI 96720 USA;
eharris@pbarc.ars.usda.gov

The introduction and establishment in Hawaii of tephritid fruit flies, *Bactrocera cucurbitae, Ceratitis capitata, B. dorsalis* and *B. latifrons* causes direct damage to vegetable and fruit crops and high cost for exporting fresh produce to domestic and export customers due to quarantine treatments. To reduce the need for pesticide use, several species of natural enemies have been introduced into Hawaii to suppress tephritid fruit fly populations. The most successful of these was the egg-larval parasitoid, *F. arisanus*, parasitizing its preferred host *B. dorsalis.* Recently, we made a breakthrough in the development of a cyclindrical cage for mass producing *F. arisanus* in the laboratory and releasing it in the field. We have produced over 100,000 *F. arisanus* per week from 6 cyclindrical cages. With this tool we can mass produce (50,00-70,00) *F. arisanus* for hand carrying this parasitoid to a release site in sufficient numbers to conduct 1) rearing and colonization studies using, as host, a laboratory colony of *Bactrocera* or *Ceratitis* fruit flies; and 2) release two batches (4,000-6,000 each) of *F. arisanus* in the field at sites where fruit flies are infesting preferred hosts to rear this egg parasitoid on wild tephritid fruit flies.

Flower strip management closed to vegetable crops to enhance aphid biological control

F Francis, P Colignon, E Haubruge
Department Of Pure And Applied Zoology, Gembloux Agricultural University, B-5030 Gembloux, Belgium; haubruge.e@fsagx.ac.be

Introduction of herbaceous strip and set-asides closed to openfields was demonstrated to be of great interest on the entomological diversity and abundance. Whether "agro-environmental measures » are developed for several years in Belgium, flower strip seed mixture need to be improved to attract entomophagous beneficials and enhance biological control of aphids such as in vegetable crops. Plant composition of herbaceous strip was adapted by the introduction of wild plant species to attract pest predators. Four wild plant species were selected for their attractivity and the flowering period (*Chrysanthemum segetum* L., *Agrostemma githago* L., *Papaver rhoeas* L. and *Centaurea cyanus* L.). Two seed mixtures were tested in two vegetable crops, namely green pea and broad bean, and compared to conventional seed mixture of Fabaceae and Poaceae species. In 2002, more than 4000 *Syrphidae* were trapped on 14 weeks of observations. Eighteen genera and 31 species were identified, five genera constituted 89 % of the trapped individuals. Mean density of hoverflies in conventional herbaceous strip were significantly lower than the ones from both adapted herbaceous strip mixtures including the wild flowering species. In 2003, more than 2500 syrphids belonging to 15 genera and 24 species were trapped. More than 87% of them belonged to 5 genera. Yellow traps in both adapted flower strip mixtures contained significantly higher hoverfly density than in the conventional herbaceous strip mixture. Association of *C. segetum* and *A. githago* was found to be the more interesting wild species to be introduced in to attract aphidophagous hoverfly species. Flower strip closed to vegetable openfields was shown to be an efficient way to increase the aphid predator populations leading to more efficient natural biological control of insect pests such as aphids.

Functional Response of *Menochilus sexmaculata* **(Fabricius) predating on** *Macrosiphoniella sanborni* **(Gillete)**

J Duan, X He, R Zhang
Institute of Entomology, Life Science School of Zhongshan University, Guangzhou 510275, P.R.China, ls@zsu.edu.cn

The functional response of *Menochilus sexmaculata* (Fabricius) predating on old *Macrosiphoniella sanborni* (Gillete) nymphs fitted the model of Holling II type well. However, the predation was affected by temperature, vessel space and prey density. In the same temperature treatment, the higher of the prey density was, the more of predation number was found and the lower of finding area was observed. In the range of 15°C - 25°C, the predation ratio was the highest at 25°C, the average number of predation was 95 capita in one day, and the highest was 392.1 capita. The relationship between predation number and temperature was fitted with quadratic regression equation. Intraspecific interference was found in the experiment. The predation number of *M. sexmaculata* decreased with the increasing of its density. The relationship between predation ration (E) and natural enemies density (P) was described by equation of $E = 0.9003P - 0.9816$. Searching constant (Q) is 0.9003, and disturbing coefficient (m) is 0.9817.

Plant & habitat composition influence foraging behaviour of the parasitoid *Diadegma semiclausum* **(Hellén)**

T Bukovinsky, R Gols, L Hemerik, LEM Vet
Wageningen University, Biometris, P.O.Box 100, 6700 AC Wageningen, The Netherlands; Lia.Hemerik@wur.nl

The foraging behaviour of *Diadegma semiclausum* was studied in semi-field set-ups of different plant composition. The set-up consisted of a group of plants surrounding one or two target Brussels sprout plant infested by *Plutella xylostella* caterpillars. The surrounding plants were either malting barley or white mustard interspersed with sprouts, whereas the control consisted of sprout plants alone. We analysed factors influencing the arrival and leaving tendencies of the parasitoid *Diadegma semiclausum* in these set-ups. Barley and mustard decreased the arrival tendencies of parasitoids to the first target plant. The second target plant was located with the same efficiency in the different set-ups. Females in the mustard set-up tended to spend more time on target plants over successive visits. In all set-ups the total number of hosts encountered was approximately the same. However, in the mustard set-up parasitoids had to search longer to encounter hosts. Parasitoids had lower leaving tendencies from the mustard than from the other set-ups. The number of visits to target plants increased the leaving tendencies. Thus, plant species composition of habitats influence time allocation and foraging efficiency of parasitoids. Implications of these effects on host-parasitoid interactions and efficiency of biological control are discussed.

Host specific inhibition of immune reaction by entomopathogenic fungus *Nomuraea rileyi*

H Hiromori, D Yaginuma, M Hatsukade
Laboratory of Applied Entomology, Faculty of Agriculture, Shizuoka University, Ohya 836, Shizuoka 422-8529, Japan, ahhirom@ipc.shizuoka.ac.jp

The entomopathogenic fungi such as *Nomuraea rileyi* generally inhibit their host immune reaction. To convince the inhibition of host immune reaction by *N. rileyi* (Strain SdNr-1: isolated from *Spodoptera depravata*), hemocytes and its phagocytosis in the hemolymph of three spices of Noctuidae (*S. depravata, S. litura* and *Mythimna separata*) were observed after conidial injection of *N. rileyi*. The number of plasmatocytes and granular cells were decreased after injection of SdNr-1 to *S. depravata* compared with other lepidopteran larva. In the hemolymph of *S. depravata*, the phagocytosis and encapsulation by these hemocytes to FITC labeled conidia was inhibited by injection of *N. rileyi*. The phenoloxidase activity of hemolymph of *S. depravata* was reduced after injection of *N. rileyi* compared with other two spices. These results indicated the SdNr-1 had highly pathogenicity to *S. depravata* and the pathogenicity was caused by the effective inhibition of immune reaction of *S. depravata*.

Ichneumon promissorius - a pupal parasitoid of *Helicoverpa armigera*

JE Hopkinson, MP Zalucki, DAH Murray
Department of Primary Industries & Fisheries, PO Box 102 Toowoomba QLD 4350 Australia; Jamie.Hopkinson@dpi.qld.gov.au

Ichneumon promissorius parasitises many noctuids including the pest species *Helicoverpa armigera, Helicoverpa punctigera, Mythimna convecta, Persectania ewingii* and *Spodoptera exempta*, although parasitism rates are generally low. *Ichneumon promissorius* is found predominately in south-eastern Australia and in the south west of Western Australia as well as New Zealand and islands in the south Pacific. Development takes around 18 days at 30°C, with males emerging a day before females. Fecundity of females is variable ranging from 45 to 120 eggs. Lifespan for males is 27 days; lifespan of females is variable and linked to oviposition and mated status. In an experiment with four diet treatments, male lifespan was longest (45 days) when caged on cotton plants, compared to males restricted to water only (10 days). Female lifespan displayed a similar trend with wasps living longer on cotton plants (60 days) and least with water only (27 days). Fecundity was influenced by diet; the wasps fed on honey and water had the highest fecundity (140 eggs) while wasps fed water had a lower fecundity (90 eggs). These results are discussed in relation to the impact of this pupal parasitoid on pest species abundance.

UV mutants tolerant to pesticides from strains of the entomopathogenic fungus, *Nomuraea rileyi*

HJ Lin, LC Tang, HC Lu, RF Hou
Department Of Entomology, National Chung Hsing University, Taichung 402, Taiwan, Rhou@Dragon.Nchu.Edu.Tw

Nine strains of the entomopathogenic fungus, *Nomuraea rileyi*, were isolated from different localities in Taiwan. Two strains, designated TC and WF, were tolerant to higher temperatures and more virulent to the common cutworm, *Spodoptera litura*, and were selected to induce mutation by UV to increase virulence and tolerance to pesticides. After two-step irradiation with UV (254 nm), 55 mutants were obtained from various colonies. These mutants were assayed for virulence and tolerance to pesticides. Only six of them exhibited better virulence than the wild type against *S. litura*. Among 17 pesticides tested, only maneb, mancozeb, and copper oxychloride + mancozeb showed inhibitory effect on colony growth. Further screening of the virulent UV mutants against these three chemicals revealed that only two mutants, TC-168 and WF-245, possessed some tolerance against fungicides. However, TC-168 was not virulent to *S. litura*. Therefore, further UV irradiation of mutants and continuous screenings of strains need to be undertaken.

Complete sequence & organization of rRNA genes of *Nosema spodopterae* in Taiwan

S-J Tsai, W-F Huang, C-F Lo, C-H Wang
Department of Entomology, National Taiwan University, Taipei 106, Taiwan; wfhuang@ntu.edu.tw

"The rRNA gene organization of *Nosema spodopterae* displays a similar pattern to *Nosema* type species, *N. bombycis*, that is 5'-LSUrRNA (2,497 bp)-ITS (185 bp)-SSUrRNA (1,232 bp)-IGS (277 bp)-5S rRNA (114 bp)-3'. Compared to the organization of eukaryotic rRNA genes, the *N. spodopterae* rRNA genes display a reversed position of LSUrRNA and SSUrRNA in the operon, and believed it to be an important characteristic of the *Nosema* species. The secondary structures of SSUrRNA , LSUrRNA and 5SrRNA are constructed. This investigation demonstrates several *Nosema*-specific features of secondary structure.
"

Nucleotide sequence of 3'-end of *Homalodisca Coagulata Virus-1* **new virus from the glassy-winged sharpshooter,** *Homalodisca coagulata* **(Say) (Hemiptera: Cicadellidae)**

WB Hunter, PM Dang, JX Chaparro
USDA, ARS, U.S. Horticultural Research Lab, 2001 South Rock Rd., Ft. Pierce, FL 34945, Tel: 772-462-5898; Whunter@ushrl.ars.usda.gov

Nucleotide sequence was determined for the 3'-end of a new virus isolated from the glassy-winged sharpshooter, GWSS, *Homalodisca coagulata* (Say) (Hemiptera: Cicadellidae). The virus, named *Homalodisca coagulata virus* 1 (HCV-1), was isolated from adult and 5th instar nymphs. We have cloned and sequenced a 3200 bp cDNA representing the 3' -end of the HCV genome. Sequence analysis revealed that the 3' ORF encodes the putative capsid protein subunits. Deduced amino acid sequence and cleavage sites of HCV-1 showed similarities with the coat proteins of virus capsids of the insect-infecting Picorna-like viruses, within the Family *Dicistroviridae*. These are insect infecting, positive sense, single-stranded RNA viruses of 9-10 kb in size. The ssRNA Picorna-like viruses are a rapidly growing group. We propose that HCV-1 is a new member forming an independent species within the *Cripavirus* genus in the *Dicistroviridae.*

Conservation biological control of aphids in the potato field

K Ito
National Agricultural Research Center for Hokkaido Region, 1 Hitsujigaoka, Sapporo, Hokkaido 062-8555, Japan; kymt@affrc.go.jp

In the production of potato in Hokkaido, Northern Japan, aphids are the most serious pest insects due to their direct sucking damage as well as their transmission of plant viruses. Therefore, farmers usually apply insecticides 3 – 4 times on average. However, the reduction of agricultural chemicals to promote 'environmentally conscious agriculture' has been recommended in recent years. Therefore, the effect of not-applying insecticides was examined in the field for 5 years. Healthy seed tubers were used to minimize the virus diseases. The results showed that there was no outbreak of aphids observed due to suppression by indigenous natural enemies (ex. *Harmonia axyridis, Coccinella septempunctata* and *Orius* spp.); e.g. density of *Aphis gossypii*, the most harmful aphid causing direct damage, did not exceed 10 insects per compound leaf, and there were no other insect pests conspicuous. Consequently, both the tuber yield and the starch value were comparable to those in the insecticide-treated plot. These results suggest that the potato cultivation without application of insecticides has the potential to be realized.

Management of potato tuber moth *Phthorimaea operculella* (Zeller) by *Chelonus blackburni* Cameron

P Jasrotia, D Raj
Department Of Entomology, Chaudhary Sarwan Kumar Himachal Pradesh Agricultral University, Palampur-176 062, Himachal Pradesh, India, poonams99@rediffmail.com

The potato tuber moth, *Phthorimaea operculella* (Zeller) is the most ubiquitous pest of potato both in fields and country stores worldwide. So big is the menace of this pest that in areas where it remains unchecked, the losses in stores may go up 70 per cent Insecticidal control although being the most common method of pest control is recently been discouraged considering its adverse ecological impacts. Biological means of controlling the pest population have recently gained grounds keeping in view their long-term implication in suppressing pest population without any ill-effects on ecological balance. Amongst the various biocontrol agents used against potato, the egg-larval parasitoid, *Chelonus blackburni* Cameron has specific place to refer because of its being uniparental, parthenogenetic and having a fairly wide host range. In this perspective, the present investigation entitled "Management of potato tuber moth *Phthorimaea operculella* (Zeller) by *Chelonus blackburni* Cameron" was carried out in spring crop season (January-June) of 2001 and 2002 at Entomological Research Farm, CSKHPKV, Palampur and at farmer's field at Nagrota Bagwan. The studied revealed that PTM can be managed effectively in fields by integrating releases of *C. blackburni* @ 50,000 female adults/ha with either *Bt* @0.5% and GV @ 250 LE/ha and deltamethrin @0.005% (each treatment at weekly interval). However, under storage conditions at Palampur and Nagrota Bagwan, *C. blackburni* @ 10 adults/kg of potatoes was equally effective as GV@ 2LE/kg or *Bt* @0.5% or *Ageratum* powder @ 2cm layer.

Entomopathogenic nematodes in hydrogel formulations for pest control

M Jaworska, D Ropek
Department of Agricultural Environment Protection, University of Agriculture, Cracow, Poland, Mickiewicz Ave., 21, 31-120 Cracow, Poland;
rrmjawor@cyf-kr.edu.pl

Entomopathogenic nematodes (EN) isolated from insects are considered as natural pesticides. In Poland they were investigated as agents controlling *Hoplocampa testudinea* Klug., *Delia brassicae* Bauche, *Sitona* sp. and other pests. EN are also used for protection of mushrooms in the farms from flies. The effectiveness of EN in the field depends on moisture and temperature factors. Polyacrylamide is a promising hydrogel for nematodes formulation. It improves water retention of porous soils and prevents moisture deficiency to plants. In this study applicability of polyacrylamide in preparation of *S. carpocapsae* formulation was determined. Nematodes survived in good condition in those hydrogels at 5 ^{0}C and 10 ^{0}C for 4 weeks and their pathogenicity did not decrease. Pathogenicity of *S. carpocapsae* was also investigated in pot experiments. Nematodes suspended in hydrogels were more effective against test pests at lower soil moisture than those applied in water.

Bioinsecticide assessment of plants against fall armyworm, *Spodoptera frugiperda* (Lepidoptera: Noctuidae), in Morelos state, Mexico.

R Figueroa, R García, C Luna, ME Valdés, L Aldana, A Jiménez-Pérez
"CEPROBI-IPN. PO. Box 24, Yautepec, 62731, Morelos, Mexico; Rfigueroa@ipn.mx"

Corn, *Zea mays*, is an important food source for Latinamerican countries. Farmers control the fall armyworm (FAW) by spraying pesticides but pollution, kill of non-target species and insect resistance threats the environment and its sustainability. In 1997, we initiated a screening program aimed to find cheap, reliable and environmental-friendly natural products to control FAW. Bioinsecticide activity was evaluated at laboratory and greenhouse conditions. Plant powder was supplemented to artificial diet and larval size, weight, survival and adult emergence was recorded. More than 120 spp in > 10 families has been assessed by the program. Powder of the Caricaceae, *Carica papaya*; the Fabaceae, *Pithecellobium dulce* and *Prosopis juliflora* had bioinsecticide activity. Powder (15%, w/w) and acetonic extract (5-20%, w/v) of *C. papaya* seeds var. mamey produced 100% FAW mortality at laboratory conditions. Brake down of this acetic extract revealed that fractions 16-17 and 45 produced > 50% mortality. Aqueous extracts (5-20%, w/v) of seeds of four *C. papaya* varieties (Mamey, Maradol, Hawaian, Cera chichona) had bioinsecticide activity under greenhouse conditions. However, > 50 % corn's damage reduction was obtained with 20% aqueous extract of var. Mamey. Our results suggest that *C. papaya* seeds contain more than one molecule with bioinsecticide activity.

Scale insects & mealybugs in European greenhouses with notes on biological control

JP Kaas
Bio Pre Geerweg, 65 2461 TT Langeraar, the Netherlands; Biopre.nl@hetnet.nl

An overview is presented of settled species and occasional intercepts of hard scale (Diaspididae), soft scale (Coccidae) and mealybugs (Pseudococcidae) in N.W. European greenhouse cultures and interiorscapes. Remarks are made on biological control practices. Approximately 40 hard scale species have been encountered in greenhouses in the area. These include common and polyphagous species as *Aspidiotus nerii, Pinnaspis strachanii and P. buxii*; rare polyphagous species, settled in specific greenhouse situations; *Aulacaspis pentagona* and *Ichnaspis longirostris* and specialist species as *Furchadiaspis zamiae* (on Cycadeae), *Diaspis bromeliae, Gymnaspis achmaeae* (on Bromeliaceae), *Diaspis echinocacti* (on Cactaceae). Sometimes highly unusual species are encountered, e.g *Selenaspidius* and *Targionia* (both tentative id.) (on Aizoaceae) as small settled populations. Also *Fiorinia coronata* was intercepted. Soft scale insects are least species rich with *Saissetia coffea* and *Coccus hesperidum* regularly encountered. Less abundant are *Saissetia oleae, Coccus viridis,* and *Protopulvinaria pyriformis.* Most common mealybugs are *Planococcus citri*, followed by *Pseudococcus viburni* and *Pseudococcus longispinus*. Also *Spilococcus cactearum, Chorizococcus brevicruris* and *Rhizoecus* spp are found. Rarer intercepts are *Chaetococcus bambusae, Ferrisia virgata, Dysmicoccus brevipes and Trionymus* sp.

Potential for biological control of *Tamarix* spp. in the United States

AE Knutson, CJ DeLoach, RI Carruthers, J Tracey, D Bean, T Dudley, D Eberts, D Kazmer, J Knight, L Milbrath, D. Thompson.
Texas A&M Research & Extension Center, 17360 Coit Road, Dallas, TX , USA. 75252; a-knutson@tamu.edu

Saltcedars (*Tamarix* spp.) are exotic and invasive shrubs and small trees which have degraded riparian ecosystems in the western U.S. High water consumption by extensive monotypic stands of saltcedar is of special concern among water resource managers in the arid southwestern U.S.   A leaf beetle, *Diorhabda elongata* (Chrysomelidae) is the first agent approved for release in the U.S. for biological control of *Tamarix.* Field releases of beetles from Fukang, China and Chilik, Kazakistan have defoliated 95-98% of the Tamarix within a radius of 300 to 750 m (28 to 177 ha) within 3 years after releases at 5 sites north of the 38th parallel in the western U.S. Beetles from these regions failed to overwinter south of the 38th parallel as they prematurely enter diapuase in early summer in response to short day length. Collections of *D. elongata* from Crete and Tunisia are adapted to the shorter day lengths south of the 38th parallel and overwintered in Texas and New Mexico in 2003 and 2004.

The predatory role of earwig, *Labidura riparia* **japonica (Dermaptera) to the lepidopteran pests of golf course**

K Kawanishi, H Hiromori, M Hatsukade
Department of Applied Entomology, Faculty of Agriculture, Shizuoka University, Ohya 836, Shizuoka 422-8529, Japan; t0330003@ipc.shizuoka.ac.jp

There are many turfgrass insect pests in the golf courses in Japan, especially lepidopteran pests are numerous. These pests were generally controlled using chemical insecticides. Amount of insecticides treated to golf courses resulted environmental and other problems (exp. insecticidal resistance or pollution of ground water). New control strategy such as biological control, is needed to instead of chemical insecticides. In this study, we researched occurrence and behavior of the earwig (*Labidura riparia* japonica) in the Japanese golf course and estimated the predatory role to lepidopteran pests (bluegrass webworm: *Pediasia teterrullus*, lawn cutworm: *Spodoptera depravata*). A large number of *L. riparia* inhabited in the golf course, especially around bunker and fairway areas and were actived from early spring to late autumn. We observed *L. riparia* preyed upon the adult and larvae of lepidopteran pest. *L. riparia* could move long distance during one night. In the laboratory condition, adult and larvae of *L. riparia* have high ability as predator to lepidopteran pests. From these results, *L. riparia* plays important role as a biological control agent to lepidopteran pests on the golf course.

Biological control of ambermarked birch leafminer (*Profenusa thomsoni*) in Alaska

C MacQuarrie, D Langor, E Holsten, J Spence, D Williams, S Digweed
5320 122 Street, Edmonton, Alberta, Canada, T6H 3S5; dlangor@nrcan.gc.ca

Ambermarked birch leafminer (*Profenusa thomsoni*) can be a significant pest of birch (*Betula* sp.) in North America but can be controlled by the parasitoid, *Lathrolestes luteolator*. *P thomsoni* was introduced into Anchorage, Alaska USA in the late 1990's and now causes significant aesthetic damage to urban birch. While not lethal, repeated severe *P. thomsoni* damage can weaken trees, allowing establishment of fatal pests or diseases. A joint project between the United States and Canadian Forest Services was initiated in 2002 to bring *L. luteolator* from Canada to suppress *P. thomsoni* populations in Alaska in a classical biological control program. In 2003, work in Alaska established the range and phenology of *P. thomsoni* in the state and work in Canada located populations of *L. luteolator* in the Northwest Territories (NWT). Parasitized larvae were collected near Ft Smith NWT, brought to Edmonton, Alberta and overwintered. In 2004 caged and open releases are planned for the Anchorage area.

In vivo study of nucleopolyhedrovirus in *Spodoptera litura*

WH Lau, AS Sajap, N Abdul-Samad
Department of Plant Protection, Faculty of Agriculture, Universiti Putra Malaysia, 43400 UPM Serdang, Selangor, Malaysia; lauweih@putra.upm.edu.my

A virus, which posses certain features in common with nucleopolyhedrovirus, has been isolated from the diseased larvae of *Spodoptera litura*. The virus was propagated in the larvae of *S. litura* and specimens were collected after 0, 3, 6, 9, 12, 15, 18, 24, 48, 72, 96, 120 and 144-h postinoculation (p.i.) for histopathology study using electron microscope. The virus replicated in the nucleus, where the packaging of nucleocapsids and formation of polyhedra occurred, and the nuclei swelled due to overloading with polyhedrae. Abnormal feature of polyhedrae appeared among normal polyhedrae during the formation of mature virus.

Leafroller (Lepidoptera: Tortricidae) species & their parasitoids on fruit crops & shelter in Hawke's Bay, New Zealand

PL Lo, JTS Walker
HortResearch, Hawke's Bay Research Centre, Private Bag 1401, Havelock North, New Zealand; plo@hortresearch.co.nz

Leafrollers and their parasitoids were collected from apple, grape and boysenberry crops, and shelter plants in Hawke's Bay, New Zealand. Sixteen properties were visited monthly from November or December until April or May, between 1996-99. Leafroller larvae and pupae were reared to determine their species, or if they were parasitised. The introduced *Epiphyas postvittana* comprised over 80% of leafrollers at nine sites, whereas two native species (*Ctenopseustis obliquana* and *Planotortrix octo*) dominated on six properties. The leafroller species composition changed at one site during the study, and at another property compared with samples collected 12 years earlier. In both cases, *E. postvittana* replaced native leafrollers. Leafrollers were generally most abundant in March, but numbers varied considerably amongst sites and between years at the same site. Parasitoids from seven genera in four families (Hymenoptera: Bethylidae, Braconidae, Ichneumonidae; Diptera: Tachinidae) were reared. The relative abundance of the most common parasitoid, *Dolichogenidea* spp., was positively correlated with that of *E. postvittana*. Sites where native leafrollers were more common had more of the tachinid fly *Trigonospila brevifacies*. The percentage of leafrollers emerging as adults declined from over 60% in December to about 30% in April, as parasitism increased from approximately 10% to 50% respectively. Overall, 48% of leafrollers collected from crops were parasitised compared with 14% for larvae from shelter.

Potential for improved biological control of *Helicoverpa* in Victoria

KB MacGregor
Department of Primary Industries PIRVic, Knoxfield Centre, 621 Burwood Highway, Knoxfield, Private Bag 15, Ferntree Gully Delivery Centre, Victoria 3156; kylie.macgregor@dpi.vic.gov.au

Two species of the noctuid genus *Helicoverpa* (=*Heliothis*) are considered to be major economic pests of agriculture within Australia. *H. armigera* has an eastern coastal and northern tropical distribution, while *H. punctigera* is the more abundant and widespread species, occurring throughout the mainland. Control still relies predominantly on chemical insecticides, however insecticide resistance is becoming increasingly problematic, along with the environmental and human health concerns associated with pesticide use. Research into the control of *Helicoverpa* is now focusing on integrated management strategies. This study will address important questions of whether the biological control of *Helicoverpa* in Victoria can be improved, and whether new or established natural enemies can be successfully integrated into an overall IPM Strategy. Of particular importance to the study are the larval parasitoids *Microplitis demolitor* and *Cotesia kazak*. *M. demolitor* is an important native parasitoid, while *C. kazak* is an exotic parasitoid responsible for significant reductions in *Helicoverpa* populations in New Zealand. These species are favoured candidates for biological control in Victoria because they both parasitise early larval instars, killing the host before it completes more than 10% of its' total feeding capacity. The feasibility of using these parasitoids in biological control programs will be investigated.

Virulence & persistence of *Beauveria bassiana* for control of Fuller's rose weevil larvae & conidial persistence in kiwifruit orchard soil

CV Mander, TA Jackson, RB Chapman
AgResearch, PO Box 60, Lincoln 8152, New Zealand; manderc@lincoln.ac.nz

Fuller's rose weevil (FRW), *Naupactus cervinus*, has recently become a pest of kiwifruit in New Zealand because export fruit infested with FRW eggs do not meet Japanese quarantine standards. Biological control of FRW is sought as the use of chemical pesticides is restricted on kiwifruit. Eleven strains of the entomopathogenic fungus *Beauveria bassiana* and three strains of *Metarhizium anisopliae* were tested for virulence towards FRW larvae, with the greatest activity shown by strains of *B. bassiana*. The persistence of conidia in orchard soil was also assessed. Persistence was highly variable with some strains falling to background levels after one month. Other strains showed greater persistence and possible recycling, with a greater number of conidia detected after one month than the original application concentration. The implications of variation in virulence and persistence in terms of potential biocontrol of FRW are discussed.

Biological control of fruit-tree borer, ***Maroga melanostigma*** **(Wallengren) (Lepidoptera: Oecophoridae), in prune trees**

SP Marte, WG Thwaite, RN Spooner-Hart
NSW Agriculture, PO Box 51, Young, NSW, 2594, Australia; susan.marte@agric.nsw.gov.au

Maroga melanostigma is an Australian native pest in many species of trees. It is of particular economic importance in prune (*Prunus domestica*) trees in which borer activity reduces productivity and can eventually kill the tree. Young, New South Wales, the second largest prune-growing district in Australia, is where trees are most seriously affected by *M. melanostigma*. Only physical control of the pest is available, which entails using wire to infiltrate borer tunnels to pierce the larva. This is time-consuming and impractical. Minimal insecticide use on prunes in this area offers good prospects for biological control. Life cycle studies are in progress in three orchards in the Young district, up to 60 km apart. Experimental techniques include: field cages filled with detached borer-infested limbs; supplemental light-trapping to detect adult emergence; determination of oviposition by caging adults on prune limbs; and challenging young trees with early instar larvae. Eggs of *Helicoverpa* sp. have been used in the prune orchards to determine background populations of predatory insects, including *Trichogramma* spp. Biological control options favour the use of *Trichogramma* spp. following successful use of *T.* nr *brassicae* (formerly nr *invelae)* against *M. melanostigma* on a pecan farm in northern NSW.

Association of insect pathogens with the crop of *Myrmeleon bore* larvae

K Matsuda, K Ito, K Nakashima, H Nishiwaki, K Komai
Graduate School of Agriculture, Kinki University, 3327-204 Nakamachi, Nara 631-8505, Japan; kmatsuda@nara.kidnai.ac.jp

Fluid-feeding carnivorous insects inject their regurgitant into prey for extra-digestion. We have found that the color of insects predated by the pit-building antlion *Myrmeleon bore* changes to dark brown, a symptom resembling that of insects infected by pathogens. Since the mandibles are linked to the crop, it was postulated that insect pathogens in the crop move into prey along with the regurginant, causing such a death symptom. Thus, microorganisms were isolated from the crop of the antlion and tested for their pathogenicity in the larvae of *Spodoptera litura* by oral application as well as by injection. Some bacteria isolated killed the cutworms with darkening of the body color when injected. In addition, several *Bacillus* species as well as "injection-active" pathogens showed pathogenicity in the larvae when applied orally using artificial diets. Interestingly, a bacterial species isolated from the antlions was more pathogenic than its type cultures. All these results suggest that crop-associated pathogens are likely to utilize the prey-capturing behavior of antlions to increase the chance for their infection in compatible insects.

Host attributes influencing host range in *Encarsia formosa* Gahan

BC McNeil
CSIRO Entomology, 120 Meiers Road, Long Pocket, Qld, 4068, Australia; bradley.mcneil@csiro.au

Whiteflies (Hemiptera: Aleyrodidae) are a diverse group of insects occurring on most plant families. Adults are free living whereas the immature stages are sessile and occur on leaves. Immature whiteflies display a diverse range of cuticular architecture including colour variation, the production of various forms of wax, stacking of exuviae, presence or absence of spines, and differences in profile. The evolutionary reason behind this architecture is unknown, but these attributes may provide a barrier to predators and parasitoids. Prior studies indicate that for certain members of the parasitoid genus *Encarsia*, there is a strong correlation between polyphagy (>6 hosts) and the host cuticle being pale in colour. As not all pale-bodied nymphs are parasitised by these polyphagous species, other attributes may be influencing host acceptance. Current studies are focussing on the role of exuvial stacking and presence of flocculent wax in the whiteflies *Lipaleyrodes atriplex* and *L. euphorbiae*, respectively. Manipulation experiments will further determine whether these attributes have an effect on oviposition and foraging behaviour.

Genetic variation in the *Cotesia flavipes* complex of parasitic wasps: towards the effective biological control of stemborer pests in Australia

KA Muirhead, AD Austin, MN Sallam, SC Donnellan
Centre for Evolutionary Biology & Biodiversity, School of Earth & Environmental Science DP 418, The University of Adelaide, SA, 5005; katherine.muirhead@adelaide.edu.au

The *Cotesia flavipes* species complex of parasitic wasps are economically important worldwide for the biological control of lepidopteran stemborer species associated with gramineous crops. The complex, characterised in part by a dorsoventrally flattened body, currently comprises three species: *C. flavipes* Cameron, *C. sesamiae* (Cameron) and *C. chilonis* (Matsumura), which are morphologically similar. The absence of clear diagnostic characters to separate the species and inaccurate identification have confounded past efforts to assess the impact of specific introductions. Moreover, small- and large-scale geographic populations have exhibited differences in host/habitat preference and host range. Founder effects, drift, inbreeding and adaptation to new environments can occur during the introduction and establishment of biological control agents and may promote the genetic divergence of populations. Molecular markers are being developed to characterise genetic variation and phylogenetic relationships among these and other species and among worldwide populations of *C. flavipes*, and correlate these with host and/or habitat preference. The status of *C. flavipes*-like species in Australia will be determined for the preparedness of stemborer incursion into Australia. Genetic differentiation between populations may have potentially important implications for host utilisation and thus, the diagnosis of appropriate strains for biological control against specific host species.

Life history parameters of *Palexorista zonata* (Diptera: Tachinidae): host acceptance & suitability of three lepidopteran species

R Brzezowski, S Nakamura, T Yoshida
JIRCAS, 1-1 Owashi, Tsukuba, 305-8686, Japan; s.nakamura@affrc.go.jp

Biology of *Palexorista zonata*, one of important natural enemies of *Helicoverpa armigera* in Kenya was studied. Larvae of *H. armigera* collected from Nairobi University Kabete campus were reared in the laboratory. Emerging *P. zonata* flies were used to initiate a laboratory colony. Flies mated easily in captivity and oviposited on introduced caterpillars. Host larvae were then kept individually in containers provided with artificial diet. Their development and parasitization were observed daily. Larvae of three lepidopteran species were used as hosts: *H. armigera* along with two species of stemborers, *Sesamia calamistis* and *Chilo partellus*. The two latter species were introduced in order to assess their suitability for easy-maintenance of *P. zonata* colony. Records obtained during colony rearing as well as separate experimental sets explain some aspects of *P. zonata* biology, such as average clutch size, egg hatching time, duration of larval development, and the effect of superparasitism. Stemborer species could be used in *P. zonata* rearing, however their efficiency in terms of fly's body size and the number of puparia supported by one host were lower than that of *H. armigera*.

Oviposition preference of the tachinid fly, *Exorista japonica* (Diptera: Tachinidae): can female flies recognize suitable host instars?

S Nakamura
Jircas, 1-1 Owashi, Tsukuba, 305-8686, Japan; s.nakamura@affrc.go.jp

The oviposition preference of the tachinid fly, *Exorista japonica* for 5th and last instar larvae of *Mythimna separata* (Lepidoptera: Noctuidae) was investigated at different host encounter rates in the laboratory. Egg retention of host-deprived females under the conditions of low host encounter rates was also examined. *E. japonica* laying unincubated macrotype eggs directly onto host cuticles, cannot usually parasitize on soon-to moult hosts as day-1 5th instar larvae of *M. separata.* Females conditioned with either host instar larva until 24h before the experiment, were provided with a pair of those host instar larvae simultaneously. The same female was examined with a pair of the hosts for 5 times at the time interval of 1 min (shortly after the previous oviposition). The females oviposited on the conditioned instar larva at first, but tended to prefer last instar to 5th instar larva. The eggs that were retained in the uterus hatched earlier than the other eggs on hosts, and successfully parasitized on day-1 5th instar larvae. The results show that the females have oviposition preference and retained eggs increase probability for parasitization at low host encounter rates.

Seasonal occurrence of parasitoids attacking *Helicoverpa armigera* (Lepidoptera: Noctuidae) in Kenya

R Brzezowski, S Nakamura, T Yoshida
Jircas, 1-1 Owashi, Tsukuba, 305-8686, Japan; s.nakamura@affrc.go.jp

Helicoverpa armigera Hubner, a serious pest of important crops in Kenya, is attacked by various natural enemies, including several species of tachinid flies. Weekly collections of *H. armigera* larvae were initiated in order to obtain information on the pest and its parasitoids occurrence throughout the year. Larvae were collected from a pigeon-pea (*Cajanus cajan*) field, maintained for the purpose, located in the Nairobi University Kabete Campus. Collected larvae were kept individually, provided with artificial diet, and their development was observed. Data on seasonal occurrence, percentage parasitism and host stage attacked were compiled for months, for the period from June 2002 to the present, and compared to data of monthly precipitation and temperature in the area. The most important mortality factor of collected *H. armigera* larvae was parasitization of tachinids, *Palexorista zonata* Curran, and *Linnaemya longirostris* Macquart. Parasitization of the both species peaked in different time of the year and total parasitism sometimes exceeded 50%. The results encouraged us for further investigations of these parasitoids as biological control agents of the pest.

Techniques for efficient mass rearing of *Serangium ryukyuense* (Coleoptera, Coccinellidae) as a biological control agent

K Niijima, M Taniguchi
Division of Applied Entomology & Zoology, Faculty of Agriculture, Tamagawa University, Machida City, Tokyo 194-8610, Japan; nkeiko@agr.tamagawa.ac.jp

The ladybird beetle, *Serangium ryukyuense* native to Okinawa, southern part of Japan is considered to be a desirable biological control agent for whiteflies because it has high voracity in both the larval and adult stages, and adults are long-lived and multivoltine, producing more than 15 generations a year with no diapause under laboratory conditions. We have developed a simple, low-cost and labour-saving technique for rearing this species using artificial diets containing lyophilized drone-honeybee brood powder, autolyzed yeast and sucrose at a ratio of 5:3:2. This diet successfully sustained more than 20 generations and addition of methyl-*p*-hydrobenzoate at 1% prevented moulting during the larval period. The rearing cages were simple and cheap. Cannibalism was reduced by corrugated cardboard. A method of easy egg collection using yarn as an oviposition substrate was developed. The possibility of adult storage was also studied; adults survived more than 5 months at 7° or 15°C at 12L/12D and resumed normal oviposition when the temperature was increased to 25°C, demonstrating the potential for long-term, low-temperature storage of this species.

Life history of *Euselasia bettina* and *E. chrysippe* (Lepidoptera: Lycaenidae: Riodininae) on *Miconia calvescens* (Melastomataceae) from Costa Rica

K Nishida
Sistema de Estudios de Posgrado en Biología, Escuela de Biología, Universidad de Costa Rica, 2060 San José, Costa Rica; knishida@cariari.ucr.ac.cr

The life history and early stages of *Euselasia bettina* (Hewitson, 1869) and *E. chrysippe* (Bates, 1866) on *Miconia calcvescens* Schrank & Mart. ex DC., are described and illustrated. The species possess six larval instars and the larvae are processionary throughout their development. The eggs are laid in clusters on the underside of leaves—the mean number of eggs in each cluster: *E. bettina* 89 (SD=9; range=82-99; n=3) and *E. chrysippe* 70 (SD=20; range=44-113; n=29). The larvae are gregarious foliage consumers that feed, rest, and molt synchronously. A speices of Aphelinidae was reared from eggs of these two species, and a species of *Calolydella* sp. tachinid fly was reared from late instar larvae of *E. chrysippe*. *M. calvescens* is currently registered as one of the threatening invasive weeds in Tahiti and in Hawaii, and these two *Euselasia* species are currently considered as one of the potential biological control agents (Miconia Project Hawaii-University of Costa Rica 2004). This information will be useful for the biological control workers and personnel responsible identifying insects in quarantine in Hawaii.

Purification & functional characterization of insecticidal sphingomyelinase C produced by *Bacillus cereus*

H Nishiwaki, K Ito, K Otsuki, H Yamamoto, K Komai, K Matsuda
Faculty of Agriculture, Kinki University, 3327-204 Nakamachi, Nara 631-8505, Japan; nhisa@nara.kindai.ac.jp

A group of antlions, the larvae of lacewing Myrmeleontidae, makes cone-shape pits to capture prey. When antlions bite prey, they inject regurgitant including acute toxic factors into the prey to anesthetize it. We have found that *Bacillus cereus* isolated from the larvae of *Myrmeleon bore* secretes proteins that paralyze and kill insects when injected. One of these active proteins was purified from the culture broth of *B. cereus* using anion-exchange and gel-filtration chromatographies to a single polypeptide with a molecular mass of 34 kDa. The purified insecticidal protein was able to paralyze German cockroaches, *Blattela germanica*, within a short period after injection. On the basis of the N-terminal and internal amino acid sequences of the purified protein, the toxin was identified as sphingomyelinase C. A recombinant sphingomyelinase C expressed in *Escherichia coli* was as potent as the native protein in killing the cockroaches. Site-directed mutagenesis (His151Ala) that reduced the maximum catalytic rate of sphingomyelinase C also abolished the insecticidal activity, suggesting that the rapid insect toxicity of sphingomyelinase C results from its phospholipid-degrading activity.

Differences in distribution of *Orius* spp. in relation to flowering height of plants

T Noda, T Shimizu, K Kakimoto, N Hinomoto, K Kawasaki
1-2 Ohwashi, Tsukuba, Ibaraki 305-8634, Japan; nodat@affrc.go.jp

Anthocorid bugs *Orius sauteri*, *O. strigicollis*, and *O. minutus* are common species distributed in mainland Japan. Although these bugs can be found on a variety of plants, especially on these flowers, the microhabitat for each species seems to be different. While *O. sauteri* adults were abundant on flowers at lower than 20cm above the ground such as white clover, *O. minutus* were mainly found on flowers at higher than 200cm above the ground such as chestnut and apple trees. *O. strigicollis* has a narrow distribution area compared to the other 2 species. In the regions where *O. strigicollis* is distributed, this species tended to inhabit the flowers at intermediate height above the ground between 20cm and 200cm. This preference seems to have no relation to families to which plants belong and pray species for *Orius* spp. inhabited on the plants. The habitat segregation observed in this study might make the coexistence of *Orius* spp. possible without severe competition.

Identification of tachinid parasitoids (Diptera: Tachinidae) of Nearctic *Choristoneura* species using puparia (Lepidoptera: Tortricidae)

JE O'Hara
Invertebrate Biodiversity, Agriculture and Agri-Food Canada, 960 Carling Avenue, Ottawa, Ontario, Canada, K1A 0C6; oharaj@agr.gc.ca

Leafrollers of the genus *Choristoneura* (Lepidoptera: Tortricidae) comprise 17 species in the Nearctic region and include such serious agricultural and forestry pests as the spruce budworm (*C. fumiferana*), western spruce budworm (*C. occidentalis*), jack pine budworm (*C. pinus*), obliquebanded leafroller (*C. rosaceana*) and large aspen tortrix (*C. conflictana*). Twenty-seven species of Tachinidae have been recorded as parasitoids of Nearctic *Choristoneura* species, of which 15 are commonly or occasionally reared and 12 represent rare or accidental parasitism or erroneous records. A paper is under preparation to provide identification keys to the adults and puparia of the 15 tachinid species in the former group, and will include a review of the biology of each species. These tachinids belong to six tribes in the Exoristinae and Tachininae and display a wide range of parasitic attack strategies, though all parasitize late instar *Choristoneura* larvae. Tachinid puparia obtained from parasitized *Choristoneura* have distinctive differences in the posterior spiracular discs that permit the species to be identified, thereby obviating the need to rear the tachinids to the adult stage. A key to, and illustrations of, the puparia of the 15 common or occasional tachinid parasitoids of Nearctic *Choristoneura* species are presented.

Identification & distribution of proteinases & other enzymes along the midgut of *Bracon hebetor* (Hymenoptera: Braconidae)

SR Magro, AB Dias, WR Terra, JRP Parra
Dept. de Entomologia, Fitopatologia e Zoologia Agrícola - ESALQ/USP, Cx.P. 9, 13.418-900 – Piracicaba/SP; jrpparra@esalq.usp.br

Bracon hebetor is a gregarious ectoparasitoid and the understanding of *B. hebetor*'s digestive process and the identification and evaluation of the relative importance of its midgut proteinases could be used for development of artificial diets for this insect. The results suggest a homogeneous pattern of enzymes activity distribution. To estimate the relative contribution of proteinases to the total activity, midgut samples were applied onto a High Q column (Econosystem-Bio Rad) equilibrated with 20 mM Tris HCl buffer pH 7.5 and eluted with a linear gradient from 0 to 0.6 M NaCl and 1 M NaCl in the same buffer. The eluted fractions were assayed with fluorescent FITC-casein in the presence and absence of activators and inhibitors and also with synthetic substrates designed for each proteinase class. The following compounds were used as activators or inhibitors: 17mM SBTi, 500mM benzamidine, 100mM chymostatin, 4mM EDTA, 2mM DTT, 1mM TLCK and 40 mM E-64. The synthetic substrates used were ZFR-7-amido-4-methylcoumarin (trypsin), Suc-AAF-7-amido-4-methylcoumarin (chymotrypsin) and e-amino-caproyl-S-benzyl-cysteinyl-7-amido-4-methylcoumarin (cysteine-proteinase). The results showed that trypsin is the most important digestive proteinase in *B. hebetor*. It is responsible for almost all the protease activity upon FITC-casein. No cysteine-proteinase activity was found and the chymotrypsin activity detected was negligible.

California's avocado thrips, *Scirtothrips perseae* Nakahara: why is it a non-pest in its native home of Mexico and Guatemala ?

PA Phillips
"University of California, Cooperative Extension, 669 County Square Drive # 100, Ventura, CA 93003 USA; paphillips@ucdavis.edu"

The avocado thrips is just one of several recent invasive species that have challenged California's existing IPM programs. *S. perseae* was new to science, only receiving its scientific name in 1997, shortly after its arrival in southern California. Its origin was suspected to be Mexico or Central America. Subsequent foreign exploration by this author and Dr. Mark Hoddle at UCR confirmed it native range to be Mexico and Guatemala. A severe pest of southern California avocados, *S. perseae* was never recorded as a significant pest of avocado in its native home. Research conducted in these countries confirmed the presence of breeding populations of avocado thrips within commercial Hass orchards. However, these populations never reached the astronomical levels experienced over the last 5 years in southern California. Additionally, the Mexican and Guatemala populations were confined to the new growth, never moving to the tender new fruit to cause feeding scars as it does in southern California. Although there were some differences between the thrips populations in Mexico and in Guatemala, they remained confined to the flush growth, their preferred feeding substrate, which continued through the fruit set and early development periods. In the native subtropical home of the avocado, fruit set occurs during the growth flush period, while in the cooler, temperate climate of southern California avocado fruit set is delayed by 2 months. This results in the major growth flush period ending just as avocado thrips populations have peaked and young avocado fruitlets are developing. Under these conditions in southern California the thrips move from the hardening and maturing foliage to the succulent fruitlets where they continue to feed and breed, causing significant fruit rind scarring.

The role of egg parasitoides in the IPM of sunn pest in Romania

C Popov
"915200 Fundulea-Calarasi, ICDA Fundulea, Romania, fundulea@ricic.ro"

Sunn pest (*Eurygaster integriceps)* presents a special importance for winter wheat crop. At present, the crop protection is achieved by the chemical method: about seven million ha. all over the world, from which approximately 600,000 ha. in Romania. The biological control implementation are not finished yet. Currently, the oophagous parasites develop numerous populations (30-55% parasitisation levels), but cannot ensure the sunn pest populations control. The following oophagous species are identified: *Telenomus chloropus, Trissolcus grandis, T. simoni, T. rufiventris, T. pseudoturesis, T. semistriatus, Anastatus bifasciatus, Ooencyrtus telenomicida,* the first two species being important and largely extended. The control treatments strongly distroyed the oophagous populations too. The research emphasized the best protection ways of oophagous natural fauna and their integration in the sunn pest management. During the sunn pest egg laying, the oophagous develop only 1.5-2 generations. The parasitisation level is ensured by the hibernating oophagous generation. By the diminution of the treated areas against sunn pest adults, the efficiency of parasitisation natural background is ensured. The period of oophagous embryonary development is greater than that of sunn pests. The correct application of treatments against sunn pest nymphae protects the parasites unreared yet. They constitute the natural reserve for the next year.

DAFF's procedures for biological control agent applications

TK Qin
Biosecurity Australia, Australian Government Department of Agriculture, Fisheries and Forestry, GPO Box 858, Canberra, ACT 2601, Australia; tingkui.qin@daff.gov.au

The Australian Government Department of Agriculture, Fisheries and Forestry (DAFF) is responsible for approval of the importation under the *Quarantine Act 1908*, for host-specificity test list and for release of biological control agents for the control of weeds and invertebrates. When assessing biocontrol application, Biosecurity Australia (DAFF-BA) consults widely with stakeholders including commonwealth and state/territory government departments and research organisations. BA provides recommendations to the Australian Quarantine and Inspection Service (DAFF-AQIS). If the recommendation is accepted, AQIS issues a permit for the importation of the agent into a quarantine approved premise and sends a letter of approval for host specificity test list and for release of the agent from quarantine. The Australian Government Department of the Environment and Heritage (DEH) also regulates the import of live species under the *Environment Protection and Biodiversity Conservation (EPBC) Act 1999*. If a DEH permit is required, the AQIS' permit can not be acted upon unless accompanied by a DEH permit. DAFF's procedures for dealing with biological control agent applications have been developed in consultation with DEH. The detailed process is available at www.daff.gov.au/plantbiosecurity, which include descriptions of information requirement and processing of the applications, a flowchart showing the procedure and an electronic application from. A joint application form is used by DAFF and DEH

Egg load of lab-cultured *Anaphes iole* Girault (Hymenoptera: Mymaridae)

EW Riddick
USDA-ARS, P. O. Box 5367, Mississippi State MS, USA; ewriddick@ars.usda.gov

Anaphes iole Girault (Hymenoptera: Mymaridae) is a solitary egg parasitoid of *Lygus* bugs (Heteroptera: Miridae) in North America. Ongoing research is considering factors that might enhance the in-vivo rearing of *A. iole* using *Lygus hesperus* Knight as host. The following hypotheses were tested: (1) egg load was related to body size and not affected by female age, and (2) egg load depletion was not affected by mate presence and time (in days) that females were exposed to hosts. Initial egg load averaged 48 mature eggs and egg load was neither related to body size (hind tibia or forewing length) nor affected significantly by age (0, 1 or 2 d old honey-fed females). Mate presence (females with or without males) and exposure time (1, 3 or 5 d on the same host patch) had no effect on egg load depletion. The results of this study suggest that *A. iole* females are certainly pro-ovigenic and initial egg load does not correlate with body size or age. Since mated and unmated females deplete most of their egg load in 24 h, time-efficient production of progeny may result when ovipositing parasitoids are exposed to suitable hosts for just a few days.

Rodolia cardinalis Mulsant in Galapagos: evaluation of the first biological control program in Galapagos

H Rogg, C Causton, P Lincango, C Calderón, C Sevilla, N Chasiliquin
Charles Darwin Foundation, Puerto Ayora, Isla Santa Cruz, Galápagos, Ecuador; hrogg@fcdarwin.org.ec

The cottony cushion scale, *Icerya purchasi* Maskell, was first reported in Galapagos in 1982. Within a few years, this cosmopolitan pest spread to more than 15 islands threatening more than 80 native plant species as well as indirectly threatening several endemic insect species by critically endangering their host plants. After a thorough risk assessment study that included feeding range studies, *Rodolia cardinalis* was released in 2002 as the first biological control agent intentionally imported to control an alien invasive species in Galapagos. More than 1800 coccinellid beetles were released on 15 islands. A long-term monitoring system was developed to determine if *Rodolia cardinalis* is able to establish in the various Galapagos habitats and if it exclusively feeds on the cottony cushion scale. Two years after the first release, *Rodolia cardinalis* has established at most release sites and has actively spread to at least one island where no release was conducted. Evaluation of predation on *Icerya purchasi* at specific sites shows a significant reduction of scale populations and subsequent recovery of plant populations. However, the likely permanent presence of the cottony cushion scales in Galapagos requires a long-term control and monitoring program including a continuous rearing of *Rodolia cardinalis*.

Impact of transgene products in honeydew & honeydew quality on parasitoid survival

PAM Hogervorst, FL Wäckers, J Romeis
Agroscope FAL Reckenholz, Reckenholzstr. 191, 8046 Zurich, Switzerland; joerg.romeis@fal.admin.ch

When phloem-feeding insects feed on a genetically modified plant, the honeydew can contain amounts of the transgene product as has for example been reported for plants expressing snowdrop lectin (GNA). This could pose a risk for honeydew-feeding insects such as parasitoids. Our studies show that GNA dissolved in a sucrose solution has a direct toxic effect on adults of the aphid parasitoid *Aphidius ervi* (Hymenoptera: Braconidae). However, in the case of GNA-contaminated honeydew the negative impact of the toxin is likely affected by the nutritional quality of the honeydew, as honeydew in itself is often a poor food source relative to a sucrose solution. We have investigated the suitability of honeydew from two aphid species (*Sitobion avenae* and *Rhopalosiphum padi*) feeding on GNA-expressing or control wheat plants as a food source for *A. ervi*. In addition, the honeydew was analysed for its GNA content, and carbohydrate and amino-acid composition; factors that are of importance for the nutrition of honeydew-feeding insects.

Comparison on efficiency of *Trichogramma embryophagum* & *T. brassicae* egg parasitoids of carob moth

M Yousefi, L Salehi
Dept. of Plant Protection, Faculty of Agriculture, The Univ. of Guilan, Rasht, Iran; salehi@guilan.ac.ir

The carob moth, *Spectrobates ceratoniae* is a seriuos pest which has a specific feeding habit on pomegranate fruit between the green husk and the brown in all orchards in Iran. Because conventional control methods have proven ineffective, current emphasis is on the introduction and release of host-specific biological control agents. Rate of parasitism by two wasps *Trichogramma embryophagum* and *T. brassicae* was studied on densities of 5, 10, 20, 40 and 80 carob moth eggs at two different places: fruit crowns and on the same size white papers at 25±3ºC, 14 hours photoperiod and 65±5%RH in Guilan university. The results indicated that the number of hosts parasitised by *T. embryophagum* was higher than *T. brassicae* in all conditions. The percentage of eggs parasitised by both parasitoids on the papers was considerably higher than on the fruit crowns in all densities. The mean percentage parasitism of the carob moth eggs caused by *T. embryophagum* and *T. brassicae* reached to 74±2.9 and 47±3.1% respectively at density 10 on paper. Meanwhile, it was 47.5±2.7 and 24.5±3.5% respectively for two species at density 20 on fruit crown. Our results indicated that two parasitoid species could access eggs of *S. ceratoniae* in pomegranate fruit crown. However, *T. embryophagum* seems to be the most efficient species to control the pest than *T. brassicae* in the field.

Fungus derived from hindgut of passalid beetle

H Sato, C To-anun
FFPRI, Tsukuba Ibaraki 305-8687, Japan; hirokis@ffpri.affrc.go.jp

A species of *Leidyomyces* was discovered from *Aceraius helferi* (Coleoptera: Passalidae) collected in Chiang Mai, Thailand. A pair of the beetle was collected from a decayed log. Hindguts of the beetles were derived by dissection. Linings of the hindguts were observed after rinsing with distilled water. Several tufts of no-branching hyphae that were sharing a holdfast (attaching structure) were observed. This fungus was observed only at the former part of hindguts. The tufts were consisted of over fifteen hyphae growing up to 750um. This fungus was identified as a genus *Leidyomyces* by both its sharing feature of holdfast and living site of the gut. Diameter and length of the holdfast was 11-25um and 11-32 um, respectively. Distal part of thallus was septate and showed a series of cell: length x diameter= 26-41 x 14.5-18 (um) average 33.5 x 15.8 (um), (N=16). Each of the cells produced a spore (primary infestation sporangiospore) inside; the genus *Leidyomyces* is consisted of only one species *L. attenuatus*. The size of the spore of our specimens was larger comparing with that of *L. attenuatus*.

Selection of insect & fungal agents for the biological control of *Emex* species within Australia

JK Scott, PB Yeoh
CSIRO Entomology, Private Bag 5, P.O. Wembley WA 6913, Australia; john.k.scott@csiro.au

The annual weed species, *Emex australis* and *Emex spinosa* (Polygonaceae) are approved targets for biological control in Australia. *Emex australis* originates from southern Africa and *E. spinosa* from the southern Mediterranean region. The insects associated with these plants have been surveyed in their regions of origin as well as within Australia and a range of insects and fungi assessed as potential biological control agents. Three insect species, *Apion miniatum*, *Lixus cribricollis* and *Perapion antiquum* have been tested for host specificity and subsequently approved and released in Australia. Despite concerted efforts and some massive releases, all have failed to establish within grain growing regions, the area where the weed is a problem. The reasons postulated for this have included predation by ants, suboptimal host plants, summer temperatures being too high, the absence of suitable summer refuge sites and the lack of alternative food sources in summer. This poster summarises the likely causes for lack of establishment of each potential agent and develops criteria for selection of any future agents being considered for these weeds.

The biology of *Psyllaephagus bliteus* (Hymenoptera: Encyrtidae), a parasitic wasp that attacks the red-gum lerp psyllid (Hemiptera: Spondyliaspididae)

KR Sime, KM Daane, DL Dahlsten, JW Andrews, RL Zuparko
Division of Insect Biology, 201 Wellman Hall #3112, University of California, Berkeley, CA, 94720; ksime@nature.berkeley.edu.

Psyllaephagus bliteus Riek (Hymenoptera: Encyrtidae) was released throughout California in 2000 and 2001 to control the red-gum lerp psyllid, *Glycaspis brimblecombei* Moore (Hemiptera: Spondyliaspididae). A *Eucalyptus* feeder native to Australia, *G. brimblecombei* was first discovered near Los Angeles in 1998 and had spread throughout the state by 2000. The experiments discussed herein were designed to collect basic biological information on *P. bliteus* that would supplement and improve the control program. Our specific objectives were to determine adult longevity and fecundity, to determine the larval development strategy, and to determine host-stage preference for oviposition and host-feeding. We found that although adults can live several months in the glasshouse, maximum fecundity occurs shortly after emergence. Females live longer than males at all temperatures studied. Host-feeding is common and inflicted upon nymphs of all stages. Eggs are laid into nymphs of any age but larval development begins after the host reaches the 5th instar. Most eggs are recovered from 3rd instars. However, oviposition is attempted equally into 3rd, 4th, and 5th instars. Observations of host-handling behavior suggest that the large lerps of 4th and 5th instars impede oviposition and thus protect older nymphs from parasitism by *P. bliteus*.

Utilization of *Eocanthecona furcellata* (Wolff) (Hemiptera:Pentatomidae) for augmentative biological control of the lemon butterfly, *Papilio demoleus* (Lepidoptera: Papilionidae) in Thailand

W Suasa-ard, O Kern-asa, W Amornsak
National Biological Control Research Center (NBCRC), Kasetsart University/National Research Council of Thailand, P.O.Box 9-52, Jatujak,Bangkok 10900, Thailand; agrwis@ku.ac.th

Utilization of *Eocanthecona furcellata* (Wolff) for augmentative biological control of the lemon butterfly *Papilio demoleus* was investigated in citrus orchard.Two plots of citrus orchard were selected as control and released plot. About 1,000 third-instar nymphs of *E .furcellata* produced from NBCRC-CRC, Kampaengsan, Nakhon Pathom were released every month in released plot covering an area of 8 acre at Suphanburi province. After inoculative release the population of *E .furcellata* developed well and increased to higher levels than in control plot, while the population of *P .demoleus* decreased to lower level than in control plot. Two months after released *E. furcellata* showed satisfactory evidence of control over the population of *P. demoleus* in the released plot.

Diversity of parasitoid fauna of *Liriomyza* spp. (Diptera: Agromyzidae) on vegetable crops in Bali & Lombok

IW Supartha, PM Ridland
Department of Plant Pests and Diseases, Faculty of Agriculture, Udayana University, Denpasar, Bali, Indonesia; iw_supartha@hotmail.com

Detailed surveys for parasitoids of the polyphagous agromyzid leafminers, *Liriomyza huidobrensis* and *L. sativae*, on a range of vegetable crops in Bali and Lombok were conducted from June 2001 until October 2003. The most abundant of the 14 parasitoid species recorded from sampled leaves were *Hemiptarsenus varicornis* Girault, *Opius* sp., *Neochrysocharis* sp. and *Asecodes deluchii* (Boucek). *H. varicornis* parasitised both *Liriomyza* spp. and was recorded from a wide range of host plants in most cropping locations and altitudes (10-1200 m a.s.l) in Bali and Lombok. *Opius* sp. was mainly observed on *L. huidobrensis* infesting potato crops in highland areas (>1000 m) (especially in Baturiti, Tabanan and Pancasari and Buleleng), while *Neochrysocharis* sp. and *A. deluchii* were more frequently observed on bean crops infested with *L. sativae*, especially yard-long bean, at lowland locations.

Coevolution between *Wolbachia* & *Trichogramma* under local mate competition

Y Tagami, K Miura, Y Suzuki
Hiroshima University, 739-8528 Higashi-hiroshima, Japan; tagamiy@affrc.go.jp

Local strains infected with parthenogenesis-inducing *Wolbachia* have been found in gregarious egg parasitoid wasps, *Trichogramma kaykai* and *T. dendrolimi*. In case of *T. kaykai*, the embryonic mortality of infected individuals is much higher than that of *Wolbachia*-free ones. In contrast, *Wolbachia* infection does not significantly affect the mortality in *T. dendrolimi*. To explain the difference in the interaction between *Wolbachia* and *Trichogramma*, we developed a lattice model in which the positive effect of fertilization on the immature survival rate and the effect of female-biased sex ratios under local mate competition are incorporated. Simulation results revealed that the sex ratio has a prominent effect on the successful invasion of *Wolbachia*-infected wasps into a population. If mating occurs randomly and the sex ratio is not biased in *Trichogramma*, infected wasps can easily invade even though the immature mortality of infected wasps is high. However, if the sex ratio is extremely female-biased, then infected wasps hardly establish in a population unless the mortality cost is negligible. On these bases we discuss the coevolution between *Wolbachia* and *Trichogramma*.

Development & reproductive ability of *Lysiphlebus japonicus* parasitizing the apple aphid *Aphis spiraecola*

M Takanashi
Nabeyashiki 92-24, Shimokuriyagawa, Morioka, Iwate-pref., 020-0123 Japan; aphidpar@affrc.go.jp

Host age specificity, developmental periods, age-specific survival rate and fecundity of *Lysiphlebus japonicus* Ashmead were determined in the laboratory to evaluate its potential abilities as a biological control agent against the apple aphid *Aphis spiraecola* Patch. An apple leaf with ten aphids of each instar was given to a female parasitoid. Aphids stabbed once by the parasitoid were transferred on an apple seedling in a test tube (40mm in diameter, 120mm in height), which was kept in a constant temperature condition until the mummification. Mummies were enclosed individually in a small glass vial, and the date of adult emergence was recorded. Newly emerged female was mated and given sufficient number of 1st instar aphids every day for the life. All the hosts were kept rearing, and the number of mummified individuals were counted for the estimation of daily number of oviposition. As the results, *L. japonicus* attacked all stages of *A. spiraecola* and no difference was detected in the developmental period and survival rate of offspring among host ages at oviposition. Adult female survived average 4.2 days at 20'C and total 220 eggs were laid during the period. Age-specific fecundity was highest at the first day of the adult life.

Geographic variation in the abundance of *Aphidius ervi* & *Praon pequodorum* (Hymenoptera: Braconidae), parasitoids of the pea aphid

KJ Tilmon, AR Ives
Department of Zoology, University of Wisconsin, Madison, WI 53706, USA; kjtilmon@wisc.edu

Aphidius ervi (Hymenoptera: Braconidae) was introduced to the United States in the late 1950's and early 1960's for biological control of pea aphid [*Acyrthosiphon pisum* (Hemiptera: Aphididae)], and is now widely distributed in North American alfalfa, often achieving high levels of parasitism. *Praon pequodorum* (Hymenoptera: Braconidae) is a native aphid parasitoid which also includes the pea aphid in its host range. Prior to the introduction of *A. ervi*, *P. pequodorum* was a common parasitoid of pea aphid in alfalfa in the southern part of the State of Wisconsin. Since the establishment of *A. ervi* in this region, *P. pequodorum* abundance in alfalfa has decreased dramatically, though we lack information from other habitats and other parts of the state. Here, we examine geographic and habitat variation in the relative abundance of these two parasitoids, and discuss implications for competition and indirect non-target interactions between them.

The egg parasitoids of the brown marmorated stink bug, *Halyomorpha halys*, & the factors influencing its complex structure & dynamics

M Toyama, T Funayama, F Ihara
National Institute of Fruit Tree Science, Fujimoto 2-1, Tsukuba, Ibaraki 305-8605, Japan; tym@affrc.go.jp

The egg parasitoids of the brown marmorated stink bug, *Halyomorpha halys*, was examined. In parasitoids collected from egg masses of *H. halys* set on various regions, places and seasons, the *Trissolcus* species (Hymenoptera: Scelionidae) were overwhelmingly dominant, though their ratios varied. Most of these species collected from *H. halys* were also collected from *Plautia crossota stali*, whose habitat is similar to *H. halys*. *T. platuiae* in particular, was a dominant parasitoid of both the stink bugs. In parasitism on *H. halys* egg masses, this wasp exhibited a variation. *T. platuiae* strains collected from *H. halys* egg masses showed a higher performance on *H. halys* egg masses than those from *P. c. stali* egg masses. In addition, it was found that wasps reared on *H. halys* eggs increased the success rate of parasitism to *H. halys* eggs compared with those reared on *P. c. stali* eggs. On the other hand, the wasp always showed a high adaptability to *P. c. stali* regardless of its origin or development source. This result suggests that the parasitism of *H. halys* eggs is affected by the population dynamics of *P. c. stali*, which has a higher reproductive rate.

Evaluation of entomopathogenic nematodes for control of *Corythucha ciliata* Say (Rhynchota, Tingidae) overwintering adults – preliminary note

O Triggiani, E Tarasco
Dibca, University Of Bari, Via Amendola 165/A 70126 Bari, Italy; triggian@agr.uniba.it

Corythucha ciliata Say (Rhynchota, Tingidae) is a dangerous pest of plane-trees (*Platanus occidentalis* Listen). In Italy plane-trees are often located in urban areas where the chemical control can cause problems not only for the environment but also for humans. For this reason the potential of 3 Italian entomopathogenic nematodes (EPNs), as biological control agents for *C. ciliata,* was evaluated through both laboratory and field experiments. In the laboratory *Steinernema feltiae* (ItS-CL2), *S. carpocapsae* (ItS-MR7) and *Heterorhabditis bacteriophora* (ItH-CE1) were compared in petri dishes lined with filter paper against overwintering adults of *C. ciliata*. All nematodes produced high mortality rates. *S. carpocapsae* and *H. bacteriophora* produced significantly greater adult mortality rates than did *S. feltiae*. Efficiency of the EPNs was then evaluated in field trials, spraying EPN suspensions on tree trunks, where the adults of *C. ciliata* usually spend the winter under the bark. Among all the nematodes the mortality percentages of *C. ciliata* in field conditions were quite low when compared with those in the laboratory. *H. bacteriophora* produced a significantly greater adult mortality rates than did *S. carpocapsae* and *S. feltiae*. Although more studies and experiments are needed to improve the EPN potential in field conditions, these preliminary results showed that EPNs, and *H. bacteriophora* in particular, are promising candidates for further evaluation as biological control agents against *C.ciliata* overwintering adults.

Population dynamics of the diamondback moth, *Plutella xylostella* (Lepidoptera: Yponomeutidae) & it's parasitoids in Kyushu, southern part of Japan

H Uematsu
University of Miyazaki, Miyazaki, 889-2192 Japan; a01106u@cc.miyazaki-u.ac.jp

Population dynamics of the diamondback moth (DBM) and its parasitoids were studied for 4 years in two cabbage fields. One of the fields was set up in the net house (12 meters square and 3 meters high, screened on four sides and top by 9mm-meshed net) which prevented crucifer pests such as white butterflies and common cutworm from injuring the cabbage. Another field was maintained with standard farming practice. Cabbage plants were grown 5 to 6 times per year at each field. Population dynamics of DBM and its parasitoids were monitored twice a month in warm seasons and once in winter. Two populations of DBM showed same pattern of seasonal occurrence. DBM densities rapidly increased in March or April, and reached the highest level in May. Thereafter, DBM populations declined to the brink of extinction in June. Two species of parasitoids, *Diadromus subtilicornus* and *Cotesia plutellae* were found as dominant natural enemies of DBM. Percent parasitism by *C. plutellae* and *D. subtilicornus* in May of 2000-2003 were 36-61% and 65-87%, respectively.

Experimental release of a parasitoid, *Dastarcus helophoroides* (Fairmaire) (Coleoptera: Bothrideridae), on *Monochamus alternatus* Hope (Coleoptera: Cerambycidae)

T Urano
Momoyama, Fushimi, Kyoto 612-0855, Japan; urano@ffpri.affrc.go.jp

I conducted two release experiments of *Dastarcus helophoroides* for the biological control of *Monochamus alternatus* that is the primary vector of the pinewood nematode, *Bursaphelenchus xylophilus*. First, parasitoid eggs were released on logs that were infested by *M. alternatus* in outdoor cages as a preliminary experiment. Percent parasitism totaled 49.7 %, which greatly differed among the logs. Survival of *M. alternatus* was 45.9 % in logs onto which *D. helophoroides* eggs were released, while that in control logs was 96.4 %, which confirmed the effect that *D. helophoroides* can have on *M. alternatus* survival. When many *M. alternatus* adults had already emerged before the hatching of the released eggs began in the logs, the percent parasitism tended to be low. Second, *D. helophoroides* adults were released on dead pine trees in a stand damaged by pine wilt disease. Mean percent parasitism in 2002 and 2003 was 43.3 %. Survival of *M. alternatus* was 21.6 % in the released trees and 85.0 % in control trees. Percentage of dead *M. alternatus* by unknown factors reached 35.1 %, which was estimated to include many individuals that were parasitized but the parasitoids were dead in early developmental stage.

Quantitative evaluation of the predatory bug, *Orius strigicollis* (Heteroptera: Anthocoridae) as biological control agent against thrips

S Urano, K Shima, K Kakimoto
National Agricultural Research Centre for Kyushu Okinawa Region, Nishigoshi, Kumamoto 861-1192, Japan; uranos@affrc.go.jp

A simple analytical model was constructed to evaluate the effectiveness of released natural enemies on annual crops. This model was applied to the life history parameters of the predatory bug, *Orius strigicollis*. The model used the ratio of insect pest and natural enemy, just when the pest population began to decrease. The result showed that the predator, *O. strigicollis*, suppressed more thrips population in low (17ºC) and high (29ºC) temperatures than in intermediate (20-26ºC). In a grower's greenhouse where green pepper was grown, the population of thrips and the released *O. strigicollis* were investigated. Three species of thrips, *Frankliniella intonsa*, *Frankliniella occidentalis*, and *Thrips palmi*, were found. When the pest population began to decrease, the pest-natural enemy ratios were compared with that of the pre-evaluation ratios. The result showed that *O. strigicollis* population at the ratio of 70:1 (active stage of thrips/adult bug) ensured the decrease in the population of thrips. Depending on complex situations in growers' greenhouses, the quantitative evaluation and usage of *O. strigicollis* will be discussed.

Effects of host diet on the fitness of *Microctonus hyperodae* Loan (Hymenoptera: Braconidae), a parasitoid of the Argentine stem weevil, *Listronotus bonariensis* (Kuschel) (Coleoptera: Curculionidae)

MA Urrutia, SD Wratten, CB Phillips
Box 53, Lincoln University, Lincoln, New Zealand; urrutiam@lincoln.ac.nz

The argentine stem weevil (*Listronotus bonariensis* (Kuschel) (Coleoptera: Curculionidae)) is a South American species which is New Zealand's most damaging pest because of ryegrass damage. It has been estimated to cost the pastoral industry between NZ$78-251 m per year. The South American parasitoid wasp *Microctonus hyperodae* Loan (Hymenoptera: Braconidae) was released in New Zealand in 1991 as a potential biological control agent of the weevil. *M. hyperodae* is a proovigenic species, so its lifetime complement of eggs is set at emergence as an adult from the host. Adult fitness is likely to be affected by host nutrition, because the parasitoid resources carried over from the larval to the pupal and adult stages vary with the size and nutritional quality of the host and the time available for larval development. This research has investigated the effect of tri-trophic level interactions on the parasitoid by manipulating host diet (i.e. pollen availability) and measuring effects on parasitoid fitness (i.e. egg load). This proposed mechanism, whereby the third trophic level may benefit from "resource subsidies" made available to the second trophic level, leads to the suggestion of a new mechanism of enhancing parasitoid fitness- "Indirect Conservation Biocontrol".

Biological control of tephritid flies: the USDA-ARS program in Hawaii & efforts to mitigate fruit fly threats worldwide through international cooperation

RI Vargas, RC Bautista, EJ Harris, HC Revis
U. S. Pacific Basin Agricultural Research Center, USDA-ARS, P. O. Box 4459, Hilo, HI 96720 USA; rvargas@pbarc.ars.usda.gov

Establishment of melon fly (*Bactrocera cucurbitae*) (1895), Mediterranean fruit fly (*Ceratitis capitata*) (1910), and oriental fruit fly (*Bactrocera dorsalis*) (1945) in Hawaii prompted the introduction of many natural enemies. Initial efforts were undertaken in 1912 by F. Silvestri, who searched primarily for parasitoids of melon and Mediterranean fruit flies. Exploration for additional natural enemies intensified when oriental fruit fly was discovered and a total of 32 natural enemies were released between 1947 and 1952. Today, as a result of these efforts, the egg parasitoid *Fopius arisanus* and the larval parasitoids *F. vandenboschi*, *Psyttalia fletcheri*, *P. incisi*, *Diachasmimorpha longicaudata*, and *D. tryoni* are established. They have played a major role in sustained reduction of fruit flies throughout the Hawaiian Islands. During the past 25 years, investigations have addressed parasitoid ecology, biology, and mass rearing methods. More recently, efforts have addressed better utilization of these species through releases of parasitoids in combination with sterile flies for area-wide suppression of fruit flies, integration of reduced risk insecticides with parasitoids into area-wide IPM programs, and shipments of parasitoids from Hawaii to other areas of the world for classical biological control of fruit flies.

An *Endoreticulatus* species from *Ocinara lida* (Lepidoptera: Bombycidae) in Taiwan

WH T'sui, CY Wang, LF Solter, CH Wang
Department of Entomology, National Taiwan University, Taipei 106, Taiwan; wangch@ntu.edu.tw

A microsporidian species is described from the *Ficus* pest, *Ocinara lida*, in Taiwan, The taxonomic position of this species was primitively determined by the soluble protein content of spores and the small subunit rRNA gene sequence (SSUrRNA sequence). Analysis of the SSUrRNA indicated that this isolate from *O. lida* is a member of the genus *Endoreticulatus* and belongs to the microsporidian groups II based on the phylogenetic analysis among microsporidia. The exact taxonomic position of this isolate was confirmed again based on its ultrastructural characteristics of spore and life cycle. The congruent results between SSUrRNA sequence analysis and ultrastructural characteristics show that this isolate is more closely related to *E. bombycis* than *E. schubergi* Zwölfer.

Mass-rearing & sterilisation alter mating behaviour of male Queensland fruit fly

CW Weldon
Fruit Fly Research Centre, School of Biological Sciences A08, University of Sydney, NSW, 2006, Australia; cweldon@bio.usyd.edu.au

The effects of domestication and irradiation on mating behaviour of males of *Bactrocera tryoni* (Froggatt) (Diptera: Tephritidae) were investigated by caging wild, laboratory-domesticated and sterile (laboratory-domesticated, gamma-irradiated) males with wild females. Mating strategies of mass-reared males were different from that of wild males, although mating behaviour of wild and sterile males was similar. Mass-reared males were found to engage in mounting of other males much more frequently than wild and sterile males, and began calling earlier. Unnatural selection pressures imposed in mass-rearing conditions may explain changes in mass-reared male behaviour. It is likely that the difference between mass-reared and sterile male behaviour is due to a decrease in sexual motivation and overall mating performance as a result of irradiation. Male calling did not appear to be associated with female choice of mating partners, although this does not exclude the possibility that calling is a cue used by females to discriminate between mating partners. Despite differences in behaviour, frequency of successful copulations and mating success were similar between wild, mass-reared and sterile males, suggesting that wild females in the field may not discern a difference between wild males and sterile male *B. tryoni* released in sterile insect technique programs.

Area-wide biological control of citrus pests in California

RA Weppler, JG Morse
Private Bag 260, Horsham, VIC, 3401, Australia; rob.weppler@dpi.vic.gov.au

For 80 years, the Fillmore Citrus Protective District (FCPD) has successfully conducted area-wide control of citrus pests. The FCPD was formed in 1922 to eradicate California red scale, *Aonidiella aurantii* , while reducing the risk of infestation to the individual grower. Prior to the formation of the FCPD, 87% of red scale findings in Ventura Co. occurred in this district. By 1928, this was reduced to only 6%. The Fillmore insectary was built in 1926 to rear a predator of the mealybug, *Pseudococcus calceolariae*. The insectary has reared over 25 natural enemies introduced by the University of California during the past 80 years. Black scale was the major pest prior to the introduction of *Metaphycus helvolus* in 1937. Release of *M. helvolus* reduced insecticide applications in the FCPD from 80% of orchards each year to less than 5%. Red scale became the major pest having been partially controlled by the black scale treatments. The FCPD began rearing and releasing *Aphytis melinus* in 1960. In 1986, less than 1% of the FCPD acreage required insecticide treatment. Various pests have threatened the FCPD, but in the end, the collapse of the Valencia market forced the insectary to shut its doors in 2000.

Program for biological control of purple loosestrife in Illinois, USA.

RN Wiedenmann, SL Post, CG Helm, DJ Voegtlin, MR Jeffords.
Center for Ecological Entomology, Illinois Natural History Survey, 607 E. Peabody Drive, Champaign, IL 61820 USA; rnwieden@uiuc.edu

Since 1994, we have been involved in rearing and distributing *Galerucella* spp. (Coleoptera: Chrysomelidae) beetles for control of purple loosestrife in wetlands in Illinois, USA. Adult beetles reared at the Illinois Natural History Survey have been distributed to cooperators throughout the state, for release at > 230 wetland sites. Success at numerous sites has shown reduction of loosestrife flowering and densities, and many of these sites have shown sufficient regeneration of native flora to keep loosestrife at low densities. We have implemented an education program in which nearly 400 educators have bent rained about wetlands, native biodiversity, invasive species and biological control, using purple loosestrife as a model. Educators have been given all supplies to grow loosestrife and *Galerucella* beetles in classrooms, with the release of beetles by K-12 students into nearby wetlands. Placing biological control into the classroom has led to an increased awareness and acceptance of biological control by the public, which will be necessary as other weeds of natural areas are targeted in the future.

Control of lettuce aphid by the Tasmanian lacewing in New Zealand

PJ Workman, GP Walker, MS Qureshi, FH MacDonald
New Zealand Institute for Crop & Food Research Limited, Private Bag 92169, Auckland; workmanp@crop.cri.nz

Lettuce aphid (*Nasonovia ribisnigri*) was detected in Christchurch on lettuce in March 2002 and has spread to all lettuce growing regions in New Zealand. The indigenous Tasmanian lacewing, *Micromus tasmaniae*, was an effective predator of this aphid in spring trials (Oct-Dec) at Pukekohe (South Auckland) in 2002–04. In both years aphid populations at harvest in unsprayed plots of lettuces where *Micromus* established were equivalent to or lower than in lettuces to which topical insecticides had been applied weekly. Lettuces from the unsprayed plots were deemed saleable; the mean number of aphids per lettuce was less than 4 in both trials. The mean number of *Micromus* (all stages) peaked at 4.6 and 3.6 per lettuce. Biological control was not maintained in the summer trials (Jan-Mar) when populations of aphids were too high and *Micromus* numbers too low. At harvest the mean numbers of aphids in lettuce from unsprayed plants in the two summer trials were 408 and 121 respectively. Even in treatments where selective insecticides (pirimicarb and pymetrozine) were used, aphid numbers over summer were unacceptably high. *Micromus* is an important predator in a developing IPM programme featuring selective insecticides, imidacloprid drenches, lettuce aphid resistant cultivars, and naturally occurring fungal pathogens for aphid control in field lettuce crops.

Organization & molecular characterization of genes in the polyhedrin region of the *Lymantria xylina* multinucleocapsid NPV

C-Y Wu, C-H Wang
Department of Entomology, National Taiwan University, No. 1, Sec. 4, Roosevelt Rd., Taipei 106, Taiwan, picorna.tw@yahoo.com.tw

A multinucleocapsid nucleopolyhedrovirus (MNPV) was isolated from the casuarina moth, *Lymantria xylina*. This virus (LyxyMNPV) has been considered to be closely related to the *L. dispar* MNPV (LdMNPV) based on its *in vitro* host range and protein content. Here, the relatedness of the LyxyMNPV and LdMNPV genomes was examined. Restriction maps with the endonucleases *Bam*HI, *Eco*RI, and *Eco*RV showed significant differences between the two viruses, but most of both DNAs hybridized strongly to each other in reciprocal hybridization experiments. An *Eco*RV-K fragment (4.6 kbp) of LyxyMNPV (polyhedrin gene content region) was compared to the corresponding region of LdMNPV genome, and the results revealed that it is a conservative region in genetic organization. Both polyhedrin genes showed the highest relatedness in their sequence identity (92%) while genes for LdOrf163/-like and LdOrf162/-like peptides (located at the upstream of polyhedrin gene) and essential structural protein and protein kinase (located at the downstream of polyhedrin gene) showed relative low identity. Furthermore, the gene of LyxyNPV LD130-like protein (located outside the LyxyMNPV *Eco*RV-K fragment) was also sequenced, and it showed 93% identity to that of LdMNPV. Therefore, we conclude that LyxyMNPV is a new virus but is a member of the LdMNPV group.

Control of yellowish elongate chafer, ***Hepthophylla picea*** **(Coleoptera: Scarabaeidae) by entomopathogenic fungus,** *Beauveria amorpha*

D Yaginuma, H Hiromori, M Hatsukade
Department of Applied Entomology, Faculty of Agriculture, Shizuoka University, Ohya 836, Shizuoka 422-8529, Japan; w3612014@ipc.shizuoka.ac.jp

Yellowish elongate chafer (YEC), *Heptophylla picea* is the major pest of tea plants, or many kinds of plants in Japan. Especially, larval damage is very serious in tea fields. In general, larvae are controlled using chemical insecticides (fenitrothion). But the effect of fenitrothion is not enough, because larval habitat is a deep in soil at the application time of chemical insecticides. We searched alternative agent of chemical insecticides. The entomopathogenic fungus, *Beauveria amorpha* (Strain: HpBa-1) is the effective control agent to YEC larvae. This fungus has the high virulence to YEC larvae under laboratory and field conditions. YEC larvae have behavioral features, which they move to surface of soil (0~10cm) to consume tea root. This phenomenon appears in early winter, so *B. amorpha* should be applied at this time. Study the dynamics of *B. amorpha* spores at low temperatures (temperature of early winter: 10 °C) *in vivo* and *in vitro* is necessary to control YEC larvae using *B. amorpha* effectively. In this study, we investigated ecology and effects (virulence, inhibition of food consumption) of *B. amorpha* at low temperatures. Furthermore, we suggest the appropriate time of application of this fungus.

Isolation of a highly toxic strain of *Bacillus thuringiensis* & its effects on the growth & development of *Spodoptera exigua* (Lepidoptera: Noctuidae)

XL Yang, HY Zhang, ChJ Yang
Research Centre of Urban Pest and Department of Plant Protection, Huazhong Agricultural University, Wuhan 430070, The People's Republic of China and Biocontrol Technologies, AgResearch, Canterbury Agricultural and Science Centre, P.O. Box 60, Lincoln, New Zealand; hongyu.zhang@mail.hzau.edu.cn.

In this study, a strain of *Bacillus thuringiensis* YL-17 highly toxic to *Spodoptera exigua* was isolated from 23 stock *B. thuringiensis* isolates. Its lethal and sublethal effects on *S. exigua* were evaluated through investigating 50% lethal concentration (LC_{50}) values and development and mortality in response to sublethal doses of *B. thuringiensis*. The LC_{50}s of pure crystals, pure spores and the spore-crystal complex were 22.1μg/ml, 230.2μg/ml and 20.2μg/ml, respectively. The toxicity of *B. thuringiensis* YL-17 mainly results from its crystal. When it applied to eggs, *B. thuringiensis* YL-17 did not affect the hatch rate, but the neonate mortality increased significantly ($P<0.05$) with an increase of treated concentration and egg age. Ingestion of the spore-crystal complex significantly ($P<0.05$) inhibited the growth of third instar larvae, significantly ($P<0.05$) extended the duration of larval development, and caused a significant ($P<0.05$) reduction in the weight of pupae, the pupation rates and the adult emergence rates of larvae that survived. There was no significant effect ($P<0.05$) on adult sex ratio among the survivors. These results show that *B. thuringiensis* YL-17 not only has a direct effect, causing death of *S. exigua* larvae, but at lower doses also produces sub-lethal detrimental effects on larvae and pupae.

Pathogenicity of *Metarhizium flavoviride* to rice planthoppers

R Zhang, B Geng
Institute of Entomology & State Key Lab for Biocontrol, Zhongshan University, Guangzhou 510275, P.R. China; ls11@zsu.edu.cn

The susceptibility and virulence of entomopathogenic fungus *Metaarhizium flavoviride* to the developmental stages of brown planthopper (BPH), *Nilaparvata lugens* (Stal) and whitebacked planthopper (WBPH), *Sogatella furcifera* (Horvath), were investigated under laboratory conditions. Three concentrations of *M. flavoviride* ranging from 10^6 to 10^8 conidial/ml were included in the assay. The tested stages of hosts were small nymphs (1-2 instars), large nymphs (3-5 instars) and adults. It was shown that both stages of hosts were susceptible to the fungal infection. The BPH and WBPH infection by *M. flavoviride* were observed mostly on days from 1 to 21 after exposure. All the planthoppers killed sporulated well and displayed typical signs of *M. flavoviride* infection under microscopic examination after overnight incubation in the moist chamber. The adults were more susceptible to infect *M. flavoviride* than their nymphs and the small nymphs were most resistant to fungal infection. The cumulative mortality at all stages was concentrations-dependent.

Key words: Planthopper, *Metarhizium flavoviride*, susceptibility, virulence

A method to trap and rapidly segregate subterranean termites (Isoptera: *Rhinotermitidae*) for laboratory bioassays

MN Acda
Dept. of Forest Products and Paper Science, College of Forestry and Natural Resources University of the Philippines Los Banos, College, Laguna 4031, Philippines; mna@mudspring.uplb.edu.ph

A simple technique to trap and rapidly segregate large number of subterranean termite (*Rhinotermitidae*) using bamboo culms is described. The technique separates termites from their natural substrates by placing moist, weathered bamboo culms on top of broken nest debris. Termites immediately migrate from their natural substrates to the dark and moist cavities of the culms allowing rapid collection by tapping out one end onto flat trays when sufficient numbers of termites aggregate in the interior cavities. Field trapping technique involves the use of bundles of weathered, moist bamboo culms placed horizontally along foundation walls or strategic locations in a known area infested with termites. Termites readily feed on the nutrient rich bamboo, aggregate inside the cavities while feeding and then collected by tapping out one end onto flat trays. These techniques provide a fast, inexpensive and efficient method of trapping and segregating tens of thousand of live termites with no or minimal injury.

Killing insects in malting barley and canola with heat – are the seeds alright?

SJ Beckett
CSIRO Entomology, GPO Box 1700, Canberra ACT 2601; Stephen.beckett@csiro.au

Serious problems confront chemical disinfestation of insects in stored products. Methyl bromide is becoming costly and non-quarantine usage phased out. Phosphine is increasingly regulated and insect resistance is growing. Resistance to protectants is also common and pesticide residues are more unacceptable to markets. In comparison, heat disinfestation has the advantages of being chemical and resistance free, and is also rapid. Extensive work has demonstrated that the most heat tolerant of stored product insects can be successfully removed from large tonnages of wheat without any adverse effects on the grain. There is considerable value in expanding the use of this physical method to the disinfestation of malting barley and canola. However, there are vital quality parameters of the commodities that may potentially be heat sensitive. This poster summaries results of germination tests on the two seed types, barley micro-malting and canola oil quality analysis, for a range of heat treatments required to disinfest *Rhyzopertha dominica* and *Trogoderma variabile* at temperatures from 50ºC to 60ºC. The implications of the results for the feasibility of using heat disinfestation are outlined.

Rapid degradation of termiticides under field conditions

MA Horwood
State Forests of NSW, PO Box 100, Beecroft NSW 2119 Australia; martinh@sf.nsw.gov.au

In Australia, some state regulatory agencies may collect soil samples to determine the adequacy of termiticide application by pest controllers. Soil tests may be carried out months or even years after treatment, making an accurate knowledge of termiticide degradation rates crucial if determinations are to be valid. Termiticide degradation was investigated as part of a field trial in southern NSW. Termiticides were mixed with soil at label rates to a depth of 700 mm. One day and one year after treatment samples were collected to a depth of 75 mm. Mean losses at 12 months were: chlorfenapyr 24%, bifenthrin 30%, imidacloprid 94%, fipronil 96%, chlorpyrifos 99%. Fifteen months after treatment, plots treated with chlorpyrifos, fipronil and imidacloprid were sampled again, to a depth of 450 mm in 150 mm increments. In soil below 150 mm, chlorpyrifos and fipronil content was little changed from time of application whereas major losses of imidacloprid had occurred throughout the soil profile. These results have implications for termite treatment regulation in Australia. Regulatory agencies have relied upon degradation rates observed in laboratory experiments to determine *in situ* treatment adequacy. My field study results suggest that termiticides can degrade more rapidly than these studies have indicated.

Laboratory and field trials with juvenogens as potential termite control agents

I Hrdý, J Kuldová, Z Wimmer, M Lenz, PV Gleeson
Institute of Organic Chemistry and Biochemistry, Academy of Sciences of the Czech Republic, Flemingovon; hrdy@uochb.cas.cz

Juvenogens are complex compounds from which the active part of the juvenile hormone (JH) mimicking molecule is liberated by metabolic processes within the insect body. Eight juvenogens were prepared from parent juvenoid alcohols. They showed a high juvenilizing effect in tests with the termite *Prorhinotermes simplex.* This effect is manifested by differentiation of termite workers into presoldiers, soldiers or soldier/worker-intercastes. *cis*-Ethyl *N*-{2-{4-[2-butanoyloxycyclohexyl)methyl]phenoxy}ethyl}carbamate was tested with *Zootermopsis angusticollis, Kalotermes flavicollis, Cryptotermes declivis, Reticulitermes santonensis*, and *R. flaviceps* and proved efficacious in force-feeding (FF) and in choice bioassays. After application of 0.5 mg ml^{-1} in FF experiments with the two economically important species of *Reticulitermes,* approx. 57% resp.73% of workers changed into soldiers. In *Z. angusticollis* application of 0.05 mg ml^{-1} caused differentiation in 62% soldiers; 57% soldiers differentiated after topical application of 1mg of compound per termite. Differentiation of excessive soldiers induced by juvenogens may cause disruption of the social structure and ultimately the death of the colony, a concept that is currently being evaluated in the field with Australian species of termite. Juvenogens are promising candidates as actives in bait technology for control of subterranean termites. Financial support of the Grant Agency of the Academy of Sciences of the Czech Republic (grant No. S4055104) is gratefully acknowledged.

The effect of amylase inhibitor on target and non-target stored-product mites

V Stejskal, J Hubert, J Hýblová, L Marešová-Dolečková, M Mareš
Institute of Crop Production, Drnovská 507, Prague 6, CZ 161 06; hubert@vurv.cz;

A combination of biological control and biochemical control of stored-product mite was evaluated in laboratory conditions. The inhibitor of digestive enzyme amylase was applied as a biochemical acaricide. The amylase inhibitor had a potential to suppress the population of pest flour mite (*Acarus siro*), however, did not lead to extinction of the flour mite. Predatory mite (*Cheyletus malaccensis*) is a predator of flour mites in granary habitats, which is used in biological control of the pest mites as an alternative or complement to application of pesticides in postharvest protection. The suppressive effect of the amylase inhibitor on the target flour mite and the non-target predatory mite was tested *in vitro* and in *vivo*. The experiments *in vitro* indicated a high enzymatic activity of digestive amylases and low enzymatic activity of proteinases in flour mites as an evolutionary adaptation to starch being the main energy source. Oppositely, the predatory mites had high content of proteinases and low content of amylases indicating an intensive digestion of proteins from animal tissues. The amylase inhibitor was found more effective against the flour mite amylases than the predatory mite amylases. The experiments *in vivo* were performed on diet enriched by the amylase inhibitor in a trophic system with *A. siro* and *C. malaccensis*. In comparison to control condition, the applied level of the amylase inhibitor reduced population growth of *A. siro* to 35 %. No adverse effect of the amylase inhibitor on predator longevity and the length of oviposition period was observed. The prey reared on the inhibitory diet influenced negatively the females of *C. malaccensis* as they produced less eggs than those reared on the control prey. The lower energy content of prey (namely its weight) grown on the inhibitory diet was compensated by higher predatory rate of *C. malaccensis*. The results show that the biochemical acaricides are good candidates for regulation of stored-product mites in combination with biological approach. The data are discussed in the context of using of GMO methods in the integrated control of mite pests in post-harvest protection. *The project was supported by grant COST OC 842.20 and GACR 203/02/P081*

Movement of adult *Cryptolestes ferrugineus* (Coleoptera: Cucujidae) in stored wheat in response to temperature gradients and moisture differences

F Jian, DS Jayas, NDG White
Department of Biosystems Engineering, University of Manitoba, Winnipeg, MB, R3T 5V6. Canada

The movement and distribution of adult *Cryptolestes ferrugineus* (Stephens) (Coleoptera: Cucujidae) were determined in 100×100×1000 mm wheat columns with or without 5 C/m temperature gradients (from 27.5±0.2 to 32.5±0.2 C or at 27.5±0.2 C) under half of the columns with 12.5% or 14.5% m.c. wheat and the other half with 16.5% m.c. wheat. Adults introduced in the middle of the horizontal wheat columns with uniform temperature showed no bias in the direction of net displacement, with the distribution pattern gradually becoming more uniform when time increased from 1 to 144 h. Adults responded to both temperature gradients and moisture differences in columns of wheat with temperature gradients and moisture content differences. The response was different at different moisture conditions. Adults were more sensitive to moisture differences and moved faster in 12.5% m.c. wheat than in 14.5% m.c. wheat. Adults stayed in warmer sections in both high and low moisture regions. At different moisture conditions, adults changed their preference (e.g., preferred high moisture grain in dry grain, and preferred warmer temperature in wet grain).

Essential oils as fumigants in stored grain protection

I Kalinovic, V Rozman
Faculty of Agriculture in Osijek, Trg Sv. Trojstva 3, 31000 Osijek, Croatia; kirma@pfos.hr

Essential oils from croatian aromatic plants: lavander, laurel, rosemary and thymus, and their single components had contact and fumigant activity to the major stored grain pests resistant to the phosphine-based fumigants applied so far. By gas-chromatography nine most significant oil components were determined: 1,8-cineole, camphor, eugenol, linalool, carvacrol, thymol, borneol, bornyl-acetate, linalyl-acetate, and applied to the wheat and corn samples infested with seven pest species: *S. granarius*, *S. oryzae*, *S. zeamais*, *R. dominica, T. castaneum, O. surinamensis,* and *C. ferrugineus*. Laboratory and storages analyses showed that highly susceptible primary species to the nine isolates were genus *Sitophilus*, followed by *R. dominica*, when treated with camphor, linalool, and 1,8-cineole, and secondary species *O. surinamensis* when treated with 1,8-cineole, camphor, linalool, and thymol. *C. ferrugineus* was susceptible in treatments with 1,8-cineole, eugenol, camphor, and carvacrol. The exception was *T. castaneum* where application of plant preparations appeared to be insignificant. The most effective component and carrier of fumigant and contact toxicity was 1,8-cineole, followed by camphor, eugenol, carvacrol, linalool, and thymol. Borneol, bornyl-acetate, and linalyl-acetate were less effective. All the components tested showed no negative influence on reological properties of wheat flour.

Spatial orientation of the mould mite in the computer-programmed olfactory field

T Kojima, M Sakuma
Lab. Insect Physiology, Grad. School Agric. Kyoto Univ., Kyoto, 606-8502, Japan; kojima@kais.kyoto-u.ac.jp

The attractiveness of food odors to the mould mite, *Tyrophagus putrescentiae* (Schrank) (Acarina: Acaridae) was demonstrated in a micro-locomotion compensator (MLC) as well as in a classical choice-chamber. The MLC has been developed for use in experiments on the orientation mechanisms of tiny animals. The positioning system of the MLC constantly returns a mite walking on a glass plate to the central position by sliding the plate. While driving the MLC, the main computer switches a micro solenoid-valve to generate odor cues in airflow over the mite. If the odor is generated by position in a virtual olfactory field created by the MLC, the mite would exert a similar olfactory response as in a real choice-chamber. In practice, odorous zones with attractant were defined on the glass plate in a checkered pattern, and the test animal was exposed to the odor while it stayed in the zones. The frequency of stays in the odorous zones positively correlated with the odor concentration to provide a reliable estimate of the attractiveness using probit analysis.

Control of onion thrips (*Thrips tabaci*) in stored red onions with pyrethrum insecticide

MD Lang, J Hills, MT Greenhill
175 Allport Street East, Leith, TAS, 7315, Australia; mlang@agronico.com.au

The onion thrip, *Thrips tabaci*, is a worldwide pest of onion crops. In the 2001/2002 season, damage caused by onion thrips feeding on red onions stored in Tasmania led to more than 50% of onions being lowered in quality and value. This study examined the efficacy of PestigasTM, on juvenile and adult *Thrips tabaci* in laboratory trials and in onions in simulated storage conditions. PestigasTM is a high pressure aerosol insecticide containing natural pyrethrum and piperonyl butoxide. In laboratory trials, mortality was significantly higher in adults than juveniles, with 72% and 54% mortality respectively. Increasing the rate of PestigasTM from 150g/300m3 to 1.2 kg/300m3 increased mortality of thrips, with significantly higher thrips mortality (i.e. 81%) when applied at 1.2kg/300m3. In simulated storage trials, significantly less larvae (i.e. first and second instar) and adults were alive in onions treated with a single application of PestigasTM at 1.2kg/300m3. The largest PestigasTM treatment effect occurred with adult thrips where treatment reduced the average count from 6.8 adults in untreated onions to 1.8 adults in PestigasTM treated onions. Repeated applications of PestigasTM at 1.2kg/300m3 reduced the number of live thrips from 70-100% in comparison to untreated onions. Further trials investigating the effect of repeated applications of PestigasTM on onion quality and thrips survival are being undertaken.

Study on biology of *Lasioderma serricorne* F. under laboratory conditions

S Liaghat; L Salehi, A Shragard
Dept. of Plant Protection, Faculty of Agriculture, The University of Guilan, PO Box 3179, Rasht-Iran; popilionidae007@yahoo.com

Two series experiments were carried out on the biology of tobacco beetle, *Lasioderma serricorne* F. (Col.: Anobiidae) a destructive pest in tobacco warehouses in Iran at constant temperature 29±1oC and 70-75٪RH and in the variable temperature ranging between 20-27 and 14-65٪ RH in Guilan University. There were highly significant differences among all developmental stages at two mentioned conditions. The average developmental time of a generation was 60.69±1.59 and 127.58±1.35 days at constant and variable temperature and humidity, respectively. The percentage of mortality in all stages was higher in variable condition than mortality in constant temperature except, incubation period that was higher at constant temperature. Temperature and humidity affect on longevity of tobacco beetle and females lived longer than males in both conditions. Most oviposition occurred within 5 days of females emergence. Mean number of eggs laid by a female was 73.17±6.76 and 78.47±4.65 in variable and constant conditions, respectively.

Susceptibility of some dried medicinal plants to the attack of *Oryzaephilus surinamensis* (L.) (Coleoptera: Silvanidae)

DP Locatelli, M Stampini
Facoltà di Agraria Istituto di Entomologia agraria - Via Celoria, 2 - 20133 Milano- Italy; daria.locatelli@unimi.it

The susceptibility of 24 dried medicinal plants commonly used in food industry to the attack of *Oryzaephilus surinamensis* (L) was valued. 50 eggs, with 4 replications for each test carried out at 26 ± 1°C and 70 ± 5% r.h. were placed on 20g of dried vegetal. The development of the beetle was observed on *Angelica archangelica*, *Citrus aurantium*, *Crataegus oxyacantha*, *Foeniculum vulgare*, *Juniperus communis*, *Matricaria chamomilla*, *Rheum officinale*, *Silybum marianum*, *Valeriana officinalis* and *Vitis vinifera*. The highest mean number of adults (42.0 ± 2.16), the shortest mean period of development (35.0 ± 0.00 days) and the highest mean index of susceptibility (4.6 ± 0.06 %) were observed on *Silybum marianum*. The lowest mean number of adults (2.5 ± 0.58), the longest mean period of development (84.5 ± 1.29 days) and the lowest mean index of susceptibility (0.5 ± 0.12 %) were observed on *Matricaria chamomilla*. Various factors affected the insect development on 14 medicinal plants: quality and quantity of nourishment, presence of repellent, antifeedant active ingredients or with insecticide action, besides for the substrates structure (shape, dimension and state).

Program participants' knowledge and perceptions of effectiveness of the French Quarter Formosan Termite program

A Morgan
Dept. of Entomology, 404 Life Sciences Bldg, LSU, Baton Rouge, LA, USA 70803

Under Operation Fullstop, the LSU Agricultural Center, in cooperation with the Agricultural Research Service, began a large area pilot test in the New Orleans French Quarter. The program was designed to demonstrate the effectiveness of area-wide management of pests like the Formosan subterranean termite. Four years after the beginning of the program, data indicated that the population of the Formosan termite in the original 15-block area of the French Quarter program was being reduced, indicating to LSU Agricultural Center and ARS personnel that the program was working. It became evident, however, that the French Quarter program needed to be evaluated from the viewpoint of the participants of the study in order to assess their perceptions of the effectiveness of the program and to measure their knowledge of educational aspects of the program. Based on results of the study, it was concluded that the majority of the participants thought that the program was important, effective, and should be continued and expanded to other areas of the French Quarter. Knowledge scores derived from specific survey questions indicated that the participants were knowledgeable about termite biology, identification, prevention, control, and management.

A survey of natural enemies on stored-rice insect pests in Thailand

S Nakamura, K Konishi, Y Nakatani, K Ogata, P Visarathanonth, R Kengkarnpanich, J Uraichuen
JIRCAS, 1-1 Owashi, Tsukuba, 305-8686, Japan; s.nakamura@affrc.go.jp

Although rice is the most important food crop in Asia, losses of stored rice due to insect infestation in the ASEAN countries are tremendously high during storage and distribution, under hot and humid climatic conditions. Biological control by using natural enemies is one of the effective methods to control stored-product insect pests. For improvement in the use of these natural enemies, it is necessary to clarify the fauna of natural enemies of stored-rice insect pests. Thus, we surveyed parasitoids and predators of stored rice pests all over Thailand. As the results, 29 species of hymenopterous parasitoids of 7 families and 53 species of predators belonging to 5 orders were collected from rice stores in Thailand. Some parasitoids (*Proconura minusa*, *Theocolax elegans*, *Cerocephala dinoderi*, *Anisopteromalus calandrae*, *Lariophagus distinguendus* and *Bracon hebetor*) and some other hemipteran species (*Amphibolus venator*, *Peregrinator biannulipe* and *Xylocoris flavipes*) were most abundant all over Thailand, and were estimated as potential biological control agents for stored-rice insect pests.

Water dependence of Japanese subterranean termites, *Coptotermes formosanus* **Shiraki and** *Reticulitermes speratus* **(Kolbe)**

T Nakayama, T Yoshimura, Y Imamura
Research Institute for Sustainable Humanosphere, Kyoto University, Gokasho, Uji Kyoto 611-0011, Japan; nakayamatomoe@rish.kyoto-u.ac.jp

In Japan, *Coptotermes formosanus* Shiraki and *Reticulitermes speratus* (Kolbe) are economically major species. The purpose of this study is to determine the relationship between the feeding activities of these Japanese subterranean termites, and their environmental conditions in terms of water. First, relationships between desiccation and physiological damages to both species were evaluated. Among 9 combinations (20, 25, and 30°C-50, 70, 90% relative humidity (RH)) of the desiccating condition (without a water supply), the longest and shortest survival periods of both species were obtained under the 20°C-90% RH and 30°C-50% RH conditions, respectively. Comparing to tolerances of mass loss for recovery from the damages caused by desiccating condition, higher body mass was measured in *R. speratus*. Secondly, effects of RH, temperature, and moisture content (MC) of wood on the feeding activities of termites are evaluated under natural condition (with a water supply). The optimum temperature-RH combinations for feeding activities were 30°C-90% RH for *C. formosanus*, and around 30°C and 70-90% RH for *R. speratus*. In addition, feeding preferences were found in the middle MC (79-103%) blocks for *C. formosanus*, and the middle and high MC (140-182%) blocks for *R. speratus*, whereas even wood blocks of low MC (6-12%) were attacked.

An environmentally friendly alternative to phosphine gas

M Perera, A Knight, R F Vargas, R Emery, A Barton
Plant Biotechnology Research Group, School Of Biological Sciences And Biotechnology, Wa State Agricultural Biotechnology Centre, Murdoch University, Perth, WA 6150, Australia; mperera@ murdoch.edu.au

The Australian grain industry is worth about $7 billion per annum, with approximately 80% of production exported. To maintain a competitive edge, the Australian grain industry needs to market a predictably high quality product. There are serious problems caused by both introduced and indigenous insect pests of storage grain, and by the fact that these insect pests have developed resistance to commercial fumigants. Fumigation with phosphine gas is the key component in the management of insect pests in stored grains. These stored-grain pests in Australia now exhibit resistance to phosphine at levels more than 200 times the original lethal dose. Therefore the industry is searching for alternatives. In this study we have tested different concentrations of eucalyptus oil and its major component, 1,8-cineole against rust-flour beetle (*Tribolium castaneum*) and lesser grain borer (*Rhizopertha dominica*). The results were evaluated against the discriminating dose of the commercial fumigant -phosphine gas. The preliminary results indicate that 1,8-cineole could be useful in developing an environmentally friendly fumigant to control stored grain pests.

Distribution of the warehouse beetle *Trogoderma variabile* (Coleoptera : Dermestidae) as a pest of bulk grain storage in Australia

DP Rees, N Starick, EJ Wright
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia; david.p.rees@csiro.au

The warehouse beetle *Trogoderma variabile* was first detected in Australia in the late 1970s, in southern New South Wales (NSW). Despite several attempts at eradication, *T. variabile* became a persistent and hard- to- eliminate pest of storage structures and a pest of bulk-stored canola. To update knowledge on its distribution a survey was undertaken. During the summers of 2001-02 and 2002-03 pheromone-baited sticky flight traps were deployed around grain storage and handling facilities on the Australian mainland. Results indicate that *T. variabile* is now widespread through the south eastern 'wheat belt', from northern NSW to eastern South Australia (SA), but remains uncommon in Queensland (Qld.) and Western Australia (WA). Of grain growing regions, only the Eyre Peninsula of western SA appears free of this pest. Comparison with 1990-93 data shows that *T. variabile* has consolidated its position in south eastern Australian 'wheat belt' where it is now effectively ubiquitous. Spread of *T. variabile* into Qld. may be limited by climate. Its apparent rarity in WA is hard to explain, but may be partly due to the lower densities of suitable habitats (human settlements and poorly run 'private' and on-farm storage) making successful dispersal to new sites more difficult and slower.

Area-wide pest management of Formosan subterranean termites in the French Quarter, New Orleans, Louisiana, USA

DR Ring, AL Morgan, AR Lax, FS Guillot
400 A Life Sciences Building, Department of Entomology, Louisiana State University Agricultural Center, Baton Rouge, Louisiana 70803, USA; dring@agctr.lsu.edu

The Formosan subterranean termite, *Coptotermes formosanus*, is a serious pest where it has become established and is one of the most destructive insects in Louisiana. A pilot test was begun in 1998 in the French Quarter to demonstrate the effectiveness of using area wide management. All properties in a contiguous 15 block area were treated using commercially available baits or non repellent termiticides. In 2002 the treatment zone was expanded. Glue boards were used to estimate alate numbers and in-ground monitors for foraging activity. Alates were sampled once a week in April and two to three times weekly from May to July 15 in 1998 through 2003. Monthly monitoring of foraging activity began in January, 1999. These data showed that area-wide management reduced termite activity by 50 %. Isolated areas of "high" termite activity remain inside the test area. Inspections of properties using infrared and acoustic detection technologies are being conducted to allow discovery and treatment of colonies which have, so far, escaped treatment. A third expansion began in March of 2003. Continued treatment, expansion, and monitoring are required to assess the long-term effects of the area wide management program.

Amylase inhibitors as protein biopesticides

J Hubert, L Dolečková, M Pravcová, M Horn, J Hýblová, I Kluh, F Kocourek, V Stejskal, M Mareš
Institute of Crop Production, Drnovská 507, Prague 6, CZ 161 06; stejskal@vurv.cz;

The amylase inhibitors represent a perspective protectant of stored-food commodities against pest arthropods. We review current knowledge on amylase inhibitors of plant origin, and present the experimental work on their efficacy against the selected storage insect and mite pests. Six structural classes of plant amylase inhibitors of protein character were characterized on molecular level including Lectin, Knottin, Cereal, Kunitz, Thaumatin and γ-Purothionin types. The research on amylase inhibitors encompasses three levels with decreasing frequency of published reports (a) *in vitro* inhibition of insect amylases (53 reports), (b) *in vivo* data on increasing mortality or weight losses of insects (12 reports), (c) application in GM-plants (2 reports). There are no reports available on effect of the amylase inhibitors on storage grain mite pests. We present here both *in vitro* and *in vivo* analysis of suppression of amylase activity in *Acarus siro* as a model mite species. Systematic research is necessary to select the amylase inhibitors with defined propertied and to modify their characteristics by genetic engineering. The biochemical screening correlated with standardized biotests will intensify application of these biopepticides in the crop biotechnology industry. The project was supported by grants GACR 522/04/1286, GACR 203/02/P081, MSMT OC D16.001 and MSMT P1OC 853.003

Development of experimental procedure for determining material susceptibility to termite attack

A Stewart
39 Kessels Road, Coopers Plains, Queensland, 4108, Australia; a.d.stewart@uq.edu.au

As part of an ongoing project investigating risk-based interactions of termites and protective barrier systems, I developed a laboratory methodology for studying the interaction of termites and barrier materials. The test materials are sheets of polyurethane or other synthetic formulations up to 3mm in thickness. Test material is clamped between two glass tubes, one of which leads to a home container housing termites and the other to a food resource. The assay system allows the close observation of termite behavior by using agar and other transparent media as foraging substrates within the glass tubes. Termites from the home container typically tunnel through the foraging substrate and come into contact with the tested material within 24 hours of introduction. The tenacity of termite attack is increased if the surface of the material is scarified rather than shiny. Small breaches in the form of 0.5 mm holes also intensify and focus termite damage. Both *Coptotermes acinaciformis* and *Shedorhinotermes seclusus* have been able to breach high density polyethylene barriers when used in this assay. The assay will be used to determine desirable physical and chemical characteristics of synthetic barrier materials for protection from termite attack under laboratory conditions.

A theoretical approach to evaluate the performance of gravel physical barriers against termites

T Yoshimura, S Ozeki, M Oyoshi, Y Yanase, Y Fujii, S Okumura
Research Institute for Sustainable Humanosphere, Kyoto University, Gokasho, Uji, Kyoto 611-0011, Japan; tsuyoshi@rish.kyoto-u.ac.jp

The performance of gravel physical barriers against termites is generally described that the gap between gravel particles is too small to the termite penetration, and that even the single particle is too heavy to be removed by termites. However, no theoretical approach such as the arrangement of mandibles and maxillaes of target termite species has been conducted to date. The maximum openings of mandibles and maxillaes of workers of a Japanese major pest species *Coptotermes formosanus* Shiraki were 0.45 mm and 0.88 mm, respectively. In addition, the minimum gap between mandibles and maxillaes was 0.07 mm. This theoretically results in that C. *formosanus* workers can remove particles with less than 1.9 mm diameters if the particle is spherical in shape. Since the maximum head width of *C. formosanus* workers is approximately 1.2 mm, particles with less than 2.9 mm diameters are small enough to prevent termite invasion. These results well coincide with the laboratory test results that many kinds of gravel materials with 1.7 – 2.0 mm diameter have good performance against workers of *C. formosanus*, and that the workers allowed to penetrate into glass beads with >2.8 mm diameter.

Thaumetopoea Processionea (LINNAEUS), a serious problem in densely populated areas (Lepidoptera: Notodontidae)

Henk (H.) Stigter.
"Plant Protection Organisation (NPPO), Geertjesweg 15, 6706 EA Wageningen, The Netherlands h.stigter@minlnv.nl"

Thaumetopoea processionea has become a serious problem at many localities in The Netherlands, Belgium and Germany since its rediscovery in 1987. After more than a century the oak processionary caterpillar (*Thaumetopoea processionea* Linnaeus) re-entered the northwestern parts of Europe. Although definitely not a common species in The Netherlands and Belgium, it was occasionally observed locally in high numbers during the nineteenth century. The main host plant of the oak processionary caterpillar in The Netherlands, Belgium and Germany is common oak (*Quercus robur* Linnaeus). Caterpillars of a number of moth species may present danger to man. In the processionary caterpillar the hazards are caused by the many thousands of urticating micro-hairs developing on the larvae from the third larval stage onwards. The hairs are easily released by touching the caterpillars or their nests and they can float on air over longer distances. After penetrating the skin, the urticating hairs can cause miniscule and painfull wounds. Since 1997 the population of *T. processionea* in The Netherlands as well as in Belgium decreased however, since 2000 the population is on the increase again in many areas. This time even more in a northerly direction.

Tennessee and Kentucky Stored Grain Project: An Update on Progress

Dr. C.R. Patrick, Dr. D.W. Johnson, Dr. M.J. Buschermohle
605 Airways Blvd., Jackson, TN 38301, USA, russ1212@utk.edu

A cooperative effort with the University of Kentucky and the University of Tennessee was established in 2001 to determine if basic procedures and the use of existing pesticides labeled to control insects in wheat would be sufficient to prevent damage from stored grain insects in farm bins in each state. To this date there has been progress in reducing insect problems in demonstration grain bins using these established methods of insect control. This project is funded by an IPM grant to purchase necessary materials and monitoring equipment needed to complete the project.

On Farm Research trials on evaluation of pulse protectants against pulse beetle, *CALLOSOBRUCHUS MACULATUS* (F.) infesting gram , *CICER ARIETINUM* (L.)

Shiv K. Singal, *M.K.Gargand Subhash Chander*
Department Of Entomology, Ccs Haryana Agricultural, University, Hisar-125 004- Haryana –India, E-Mail :Shiv_Singal@Hau.Nic.In

Farm trials of groundnut oil 3.75 ml/kg + turmeric powder 1.75 g/ kg , mustard oil 3.75ml/ kg **+ t**urmeric powder1.75 g/ kg , *neem* oil 10ml/kg and 7 cm sand covering on gram were evaluated against *C. maculatus* on egg basis, adult emergence and damaged grain in treated and untreated gram after 60,120 and 180 days storage. Pulse protectants significantly protected treated gram from damage as compared to untreated after 60,120 and 180 days .After 60 days, 0.0 % damage was recorded in gram treated with groundnut oil 3.75 ml/kg + turmeric powder 1.75 g/kg , mustard oil 7.5 ml/kg + turmeric powder 1.75 g/kg , 7 cm sand covering and *neem* oil 10ml/kg as compared to 6.1% damage in untreated .After 120 and 180 days storage , similar results were observed on gram treated with protectants except in untreated gram wherein damage 21.92 and 46.40 % was recorded, respectively. Groundnut oil 3.75 ml/kg + turmeric powder 1.75 g/kg, mustard oil 7.5 ml/kg + turmeric powder 1.75 g/kg, 7 cm sand covering on gram and *neem* oil 10ml/kg proved effective in protecting treated gram from beetle for 180 days. 43 Demonstrations on mixing pulse protectants were shown in households.

The Bioconversion of Putrescent Waste

PA Olivier
P O Box 250, 519 West Dejean Street, Washington, Louisiana, USA xpolivier@hotmail.com

Imagine a bioconversion process that reduces the weight and volume of food waste by over 95% within a matter of just a few hours. The process requires no energy, no electricity, no chemicals, not even water. The process is housed within a container that resembles a small plastic garbage bin. The unit has no moving parts and requires no maintenance. Since it must be emptied once each year or two, it eliminates altogether the collection, transport and land-filling of food waste. The process generates very little odor, and at the same time, it very effectively repels houseflies and other filth-bearing flies. The unit requires very little expertise or experience to operate, and it can handle the daily food waste of more than 25 people. The process is driven by the larvae of the black soldier fly, *Hermetia illucens*, an insect that poses no threat to humans and has never been associated in any way with the transmission of disease. Upon reaching maturity, the larvae migrate out of the unit and into a collection bucket without any human or mechanical intervention. This self-harvesting grub represents a bundle of nutrients that rivals in commercial value the finest fish meal.

Susceptibility of some dried medicinal plants to the attack of *Oryzaephilus surinamensis* (L.) (Coleoptera: Silvanidae)

DP Locatelli & *M Stampini*

"Facoltà di Agraria Istituto di Entomologia agraria - Via Celoria, 2 - 20133 Milano- Italy. e-mail: **daria.locatelli@unimi.it**"

The susceptibility of 24 dried medicinal plants commonly used in food industry to the attack of *Oryzaephilus surinamensis* (L) was valued. 50 eggs, with 4 replications for each test carried out at 26 ± 1°C and 70 ± 5% r.h. were placed on 20g of dried vegetal. The development of the beetle was observed on *Angelica archangelica, Citrus aurantium, Crataegus oxyacantha, Foeniculum vulgare, Juniperus communis, Matricaria chamomilla, Rheum officinale, Silybum marianum, Valeriana officinalis* and *Vitis vinifera*. The highest mean number of adults (42.0 ± 2.16), the shortest mean period of development (35.0 ± 0.00 days) and the highest mean index of susceptibility (4.6 ± 0.06 %) were observed on *Silybum marianum*. The lowest mean number of adults (2.5 ± 0.58), the longest mean period of development (84.5 ± 1.29 days) and the lowest mean index of susceptibility (0.5 ± 0.12 %) were observed on *Matricaria chamomilla*. Various factors affected the insect development on 14 medicinal plants: quality and quantity of nourishment, presence of repellent, antifeedant active ingredients or with insecticide action, besides for the substrates structure (shape, dimension and state).

Dispersal, dispersion and trap catch of storage insects in buildings

RT Arbogast, SR Chini, PE Kendra
"P.O. Box 14565, Gainsville, FL 32604, USA; tarbogast@gainesville.usda.ufl.edu"

Traps are widely used for monitoring storage pests, because they are sensitive indicators of infestation and often yield abundant data for analysis, but biological interpretation of trap catch can be difficult. Accordingly, the objectives of trapping in a particular situation should be carefully defined, because the objectives will determine how the data should be analyzed and interpreted. The main purpose of trapping in buildings (warehouses, processing plants, retail stores, etc.), aside from insect detection, is to identify foci of infestation and points of entry. Thus, interpretation of trap catch in buildings focuses on population distribution (dispersion) rather than population density. The number of insects captured by any trap is determined by the frequency of insect-trap encounters and trap efficiency. Frequency of encounter depends upon numbers dispersing (from foci of infestation and entry points), the attraction of the trap, and trap location (relative to foci of infestation, entry points and pathways of dispersal). Pathways of dispersal and their influence on dispersion of trap catch are examined, and their importance in trap catch interpretation is discussed.

New innovations and trends for insect pest management in stored and processed food

FH Arthur
USDA-ARS, 1515 College Avenue, Manhattan, KS, 66502, USA; arthur@gmprc.ksu.edu

There is increased interest in using integrated controls to manage insects in stored products, which include a continuum from raw grain to processed food products. However, integrated pest management (IPM) in stored products, particularly in stored and processed food, often involves multiple components that may or may not use sampling as part of the decision-making process. This is in sharp contrast to classical IPM as developed for managing insects in field crops, partly because of the consequences of insect infestation in finished or packaged food products. Examples of components used in an IPM program for stored processed food include but are not limited to reduced risk-insecticides, cleaning and sanitation, pheromone monitoring to track population dispersal, lethal temperatures and heat treatments, and spatial mapping for targeted pesticide application. Selected examples from recent research will be used to illustrate concepts and ideas. Future trends and potential impacts on research will also be described and discussed.

Eavesdropping on marsupial moles and their invertebrate prey

J Benshemesh, G Jung, D Massie
PO Box 2130, Alice Springs, NT, Australia; joe.benshemesh@nt.gov.au

Obtaining information on the lifestyles and habits of subterranean animals is often a great challenge. Marsupial moles (*Notoryctes* spp.), are among the most elusive and least known vertebrates in Australia, and are currently regarded as Endangered. The most fossorial of marsupials, *Notoryctes* live in the vast arid sandy deserts of Central Australia. They are insectivorous, apparently specializing on underground colonial insects such as ants and termites, and very rarely venture to the surface. Underground they use their spade-like hands to tunnel through the sand and backfill as they move along. Using geophones, we have recorded the tunneling sounds of *Notoryctes* that were caught on the surface and released, and these signature sounds appear distinctive and unique. In order to learn about marsupial mole ranging behaviour, activity cycles and abundance we have developed a system to track an animal's movements underground using a grid of geophones. The system records from up to 32 geophones simultaneously over an area of about 0.3 ha, and operates on an adjustable recording schedule. While the system has been designed to elucidate aspects of the conservation ecology of marsupial moles, we also hope to be able to plot, dig up and identify invertebrates by their signals.

Mapping weevil and larger grain borer resistance and putative resistance factors in tropical maize.

DJ Bergvinson, S García-Lara, A Burt, JT Arnason
CIMMYT, Apdo Postal 6-641, D.F., 06600, Mexico; d.bergvinson@cgiar.org

The maize weevil, *Sitophilus zeamais* (Motsch.) and larger grain borer, *Prostephanus truncatus* (Horn) are important pests of stored maize (*Zea mays,* L.), which cause severe losses in tropical agroecologies. The International Maize and Wheat Improvement Center has utilized germplasm bank accessions to develop sources of resistance as well as a molecular map to quantitative trait loci (QTL) associated with storage pest resistance in a tropical maize (Population 28). Resistance to the maize weevil was evaluated using four susceptibility parameters under controlled condition. Using composite interval mapping (CIM), five QTL on chromosomes 4, 5, 6 (2 QTL), and 9 explained 24% of the phenotypic variance (σ^2_p) for grain damage. Eight QTL explained only 22.5% of σ^2_p for grain weight loss. Nine QTL (31% of σ^2_p) were identified for the Dobie Index. Four main areas for resistance were identified in bin 1.05, 6.00/1, 6.05, and 9.05, with 6.01 accounting for the most phenotypic variation. These regions map in areas know to carry genes associated with cell wall biochemistry that may be considered candidate genes for using in marker assisted selection or genetic engineering.

Efficacy of spinosad and chlorpyrifos-methyl for controlling insects infesting stored wheat

EL Bonjour, TW Phillips, JT Pitts
Dept. of Entomology and Plant Pathology, 127 Noble Research Centre, Stillwater, Oklahoma 74078-3033, U.S.A.; ELB4119@okstate.edu

Laboratory and field experiments were conducted to compare the efficacy of spinosad, chlorpyrifos-methyl, and a combination of spinosad and chlorpyrifos-methyl as grain protectants on stored wheat. Bioassays for adult mortality and progeny production were conducted at 28 C and ~65% relative humidity. Any treatment that contained spinosad at 1 ppm or greater effectively controlled adult *Rhyzopertha dominica* and prevented progeny development in both laboratory and field studies for 48 weeks. Spinosad alone and at higher combinations effectively controlled *Sitophilus oryzae* adults in laboratory studies but did not prevent progeny production probably because eggs are laid inside kernels where larvae are protected from pesticide exposure. Spinosad effectiveness against *Tribolium castaneum* adults decreased through time with few progeny produced. *Oryzaephilus surinamensis* adults were poorly controlled at the lower treatment levels. Although over 90% of *Plodia interpunctella* eggs hatched, no surviving larvae were found in any insecticide treatment through 36 weeks whereas >92% of the eclosed eggs were recovered as larvae from controls. Overall, combining chlorpyrifos-methyl with spinosad did not improve efficacy, and in some cases the combination decreased the effectiveness of spinosad. Spinosad will be an effective alternative insecticide against *R. dominica* when it receives registration for use on stored grains.

Cockroach bait aversion and the development of a new gel bait formula

GA Braness, N Bao, T Macom, J Barile
7666 N. Atkins Place, Kansas City , MO 64152; gary.braness@bayercropscience.com

Cockroach baits are the most effective and widely used formulation for cockroach management in the United States. Among bait types, gel baits are the preferred formulation of pest management professionals. For many professionals gel baits have totally replaced residual sprays, dusts, aerosols and other cockroach treatments. Baits continue to perform well in the majority of sites; however, in an estimated 5% of accounts in the U.S. baits are not providing the high levels of control professionals have come to expect. Cockroach gel bait aversion occurs as cockroaches develop a feeding aversion to the food ingredients in baits. This characteristic is passed on to offspring and has resulted in reduced bait acceptance and poor control. Bait aversion is not new. Aversion to gel baits by the German cockroach, *Blattela germanica* was first reported in 1990 by Maxforce researchers working with professionals in Orlando, FL. After considerable research it was discovered that cockroaches had developed an aversion to glucose, a major component in gel baits. Glucose was replaced with fructose in a new Maxforce gel bait formula and once again cockroaches were highly attracted to the bait. During the summer of 1999, professionals again discovered bait averse cockroaches. Maxforce researchers (now Bayer Environmental Science) began work to better understand the problem and to make further improvements to the Maxforce bait formula. Suspected averse cockroach stains were collected by professionals from sites across the U.S. and sent to Bayer's research laboratory in Clayton, NC. Existing Maxforce bait formulas and competitive gel baits were tested against the averse strains. All baits tested were less effective against the averse strains than susceptible laboratory strains. Next, the Maxforce bait formulas were dissected to determine the component(s) that were responsible for the aversion. Greater than 50 new bait formulas were tested for bait consumption and mortality against averse strains. Ultimately, a final formula was selected for commercial development. Field testing with professionals confirmed the new formula's efficacy in controlling averse cockroach strains. Bayer Environmental Science launched Maxforce^{Ò} FC Select Roach Killer Bait Gel in the spring of 2004 for use by professionals in the U.S. This presentation will provide basic information on cockroach bait aversion, review laboratory and field research, and offer recommendations for effective cockroach management stressing good IPM practices.

Influence of pest population structure and movement behavior on interpretation of pheromone monitoring programs in flour mills

JF Campbell
USDA ARS Grain Marketing and Production Research Centre, 1515 College Ave, Manhattan KS, 66502, USA; campbell@gmprc.ksu.edu

A long term monitoring project was conducted at a wheat flour mill. Results suggest pest populations interact over one of two spatial scales and this difference in scale is critical for effectively implementing IPM programs. For *Plodia interpunctella* and *Trogoderma variabile* at this location, pheromone trap captures outside were higher than inside, inside and outside captures were correlated, both indoor and outdoor trap captures cycled with season, fumigations did not reduce indoor trap captures, they were rarely if ever found in product samples, and marked *P. interpunctella* was demonstrated to enter buildings from outside. This pattern suggests that sources of insects lay over a spatial scale larger than the mill and movement effectively linking activity inside and outside the mill. *Tribolium castaneum*, in contrast, tended to have lower pheromone trap captures outside compared to inside, recovery in traps and product declined after fumigation and then increased until the next fumigation, inside trap captures did not follow a seasonal cycle, and was the primary species found infesting product. This suggests that source patches for this species lay over a spatial scale primarily contained within the mill itself with pheromone traps capturing primarily insects moving among these internal patches.

Response of insect grain pests to temperature choice tests

S T Conyers, CH Bell
Central Science Laboratory, Sand Hutton, York, N. Yorks YO41 1LZ U.K; s.conyers@csl.gov.uk

Replacement of conventional chemical treatments with novel physical and biological methods to eradicate storage beetles requires better understanding of pest behaviour. Temperature is known to influence locomotory activity and population dynamics but its importance relative to other factors such as gravity and light is still not understood. Laboratory experiments are therefore being undertaken to establish how representative species respond to thermal gradients under various conditions. The movement of three species, *Cryptolestes ferrugineus* (Stephens), *Oryzaephilus surinamensis* (L.) and *Sitophilus granarius* (L.), was assessed under non-uniform temperature conditions. This was done first in 2-D arenas (390 mm long x 90 mm wide) where the only variable environmental cue was a temperature gradient (3 zones) generated in the floor of the arena. Later experiments used a 3-D arena where the 3 different zones were generated within sections of pipe (200 mm long x 70 mm diameter) filled with wheat at 60% rh. Results with the 2-D arenas have shown a hierarchy of attractancy for temperatures above 25°C as (in ascending order) *S. granarius, O. surinamensis* and *C. ferrugineus.* A wild strain *of O. surinamensis* showed a preference for low temperatures (15°C) but subsequent trials with the 3-D arena have reversed this result.

Some recent developments in wood preservation with respect to termite management

JW Creffield, DG Humphrey, LJ Cookson
Private Bag 10, Clayton, VIC, 3169, Australia; Jim.creffield@csiro.au

Low-cost, general-purpose preservatives such as creosote, pentachlorophenol and water-borne inorganics have performed well, but are now under increasing scrutiny worldwide with regard to environmental, health and safety concerns. There is a global trend to replace such conventional preservatives and reduce the heavy metals (chromium and arsenic) which are contained in the most widely used water-borne preservative, copper-chromium-arsenic (CCA). Hence, the development and acceptance in some countries of alternatives such as ammoniacal copper quaternaries (ACQ's), copper azoles, CuHDO and other formulations. There is a trend to more specific niche-market preservative formulations, especially where safer and environmentally benign protection systems may be required. Boron compounds have made a remarkable reappearance, particularly for termite management, targeting either house framing or exterior timber products where resistance to leaching is required. The development of natural products to protect wood and wood products from termite attack is gaining momentum. Envelope treatments of wood with novel solvents and more environmentally-friendly actives that are functional under reduced penetration requirements are gaining acceptance. Protection of wood-based composites from termite attack by adding to the adhesive insecticidal additives of low mammalian toxicity is becoming more common. Interest continues in chemical modification and heat treatment of wood to impart resistance to termite attack.

OH BUGGER! THEY'RE BACK! The resurgence of bed bugs in Australia

SL Doggett, MJ Geary, RC Russell
Dept. of Medical Entomology, University of Sydney & ICPMR, Westmead Hospital, Westmead, NSW, 2145, Australia; stephend@icpmr.wsahs.nsw.gov.au

Over the last 50 years, with housing improvements and modern insecticides, bed bug infestations became a rare event. However, the situation has reversed in many countries, including Australia. Since 2001, we have recorded a 250% increase in bed bug samples. The Pest Control industry mirrors this trend, with one company reporting a 700% rise in treatments. The majority of the infestations has been in budget accommodation with high overseas guest numbers. There are likely many contributing factors for this resurgence. Globalisation has probably encouraged the spread of the insect via travellers and Australian Quarantine record the majority of interceptions from personal baggage via air travel from the Asia/Pacific region. We have recently identified the Tropical Bed Bug (*Cimex hemipterus*) that can invade warmer regions. Poor control operations have contributed to the problem. Our Department has been working with the Pest Control Industry and investigated a number of infestations. Treatment failure is a recurring theme, and many pest controllers have a poor understanding of the biology of this cryptic species and do not recognise and treat all harbourages. We foresee this trend will continue unless there is a concerted effort to inform the various stakeholders and develop more appropriate control methodologies.

Monitoring for parasitoids and stored-product moths

PG Fields, M Schöller
AAFC, 195 Dafoe Rd, Winnipeg MB R3T 2M9 Canada; pfields@agr.gc.ca

In Germany and Austria, the control of the stored-product moths; Indian mealmoth *Plodia interpunctella* and the Mediterranean flour moth *Ephestia kuehniella* in food processing facilities and retail shops is achieved by releasing large quantities of *Trichogramma evanescens* Westwood using the inundative release strategy. These chalcid wasps lay their eggs into the moth eggs, thus killing the eggs and preventing the development of the pest. To assess efficacy, pheromone traps are used to monitor moth populations. To assess the effectiveness, and range of activity of *Trichogramma* spp., sentinel eggs are used. These are sterile moth eggs, placed throughout the facility, and collected at a later date and the parasitism noted. Monitoring the parasitoids with the help of sentinel eggs can also help to optimise the number and position of release points. The biocontrol of stored-product moths in Germany and Canada will be presented.

Use of acoustics in detection and studying activity of larvae of a soil nursery pest, *Otiorhynchus sulcatus* F. (Coleoptera: Curculionidae)

J R Fisher
3420 N. W. Orchard Ave., USDA, ARS, HCRL, Corvallis, Oregon, 97330, USA; fisherj@science.oregonstate.edu

The black vine weevil, *Otiorhynchus sulcatus* F., is a ubiquitous pest of ornamentals and small fruits throughout the Northern hemisphere, particularly, in areas where the environment is mediated by maritime and large inbound lake air flows N of 40° latitude. Primary damage to these crops is by the larvae that feed from late summer until the next spring on roots. Estimated damage in the state of Oregon is > $3 million USD/year. There are limited windows for control of these pests and a zero tolerance for plants that contain the pest. Detection for the past 150+ years has been by digging and sifting, limiting sampling quantity and efficiency. A portable hand-held acoustical detection device has been developed that can examine up to 15 container plants per hour. Pitfalls and successes and the feasibility of the use of acoustic detection for the European and North American nursery industry for this and other root feeding insects will be discussed. Information on the use of acoustics for activity studies of the larvae will also be discussed.

Acoustic detection of soil insects in pastures

KL Flanders
208 A Extension Hall, Auburn University, AL 36849-5624, USA; flandkl@auburn.edu

All too often, soil insect pests in pastures do significant damage before they are detected. Routine scouting techniques, which would involve excavation, would be too costly in this agro-ecosystem.. Modern acoustic technologies show promise as nondestructive tools for detecting hidden insects in the soil. Laboratory and controlled field studies, previously published, have shown acoustic detection methods can detect white grubs in the soil. A two-year study was designed to compare two estimates of soil insect infestation: acoustic detection and excavation. It was not expected that either method would give a perfect estimate of soil insect infestations. Soil insects tend to occur in patches. Destructive and non-destructive soil arthropods are often present in the same area. From a pest management point of view, identification of "hot spots" in the field are more important than perfect point to point correlation of acoustic and excavation data. The pros and cons of four data analysis methods will be compared: 1) point-to-point correlations of acoustic and excavation data, 2) point to point comparisons of kriged estimates of insect infestations (acoustic method or excavation method), 3) contingency table analysis, and 4) mapping of management zones, a precision agriculture approach, based on geostatistical analysis.

Long-term protection of Madam John's Legacy Museum in New Orleans, Louisiana, from subterranean termites using hexaflumuron

ED Freytag, ES Bordes, MR Gilberg, C Riegel, NY Su
New Orleans Mosquito and Termite Control Board,6601 Stars & Stripes Blvd., New Orleans, LA 70126; efreytag@usa.net

The use of the SentriconÒ *Termite Colony Elimination* System for the control of subterranean termites in Madam John's Legacy House, a historic property in New Orleans, Louisiana, is described. A combination of in-ground (IG) and above-ground (AG) bait stations containing the active ingredient, hexaflumuron, was employed. A total of 208 g of bait matrix was consumed by the *R. flavipes* colony and it was eliminated by 21 October 1997. The stations became inaccessible in November 1997 due to a major renovation of the property. After the renovation, additional IG bait stations were placed in the soil through access holes cored through the concrete every 10 feet around the perimeter of the property and inside parts of the building with shared walls. Baiting resumed on 29 December 1998 with a total of 40 g of matrix consumed in the IG stations, and 229.2 g of matrix consumed in the AG stations. By 24 August 1999, only dead *C. formosanus* alates, soldiers, and workers were found in the AG stations and feeding stopped in the IG stations by 14 October 1999. This study demonstrated the importance of the AG component of the Sentricon System in structures that have little or no soil access and also illustrates the importance of controlling moisture-related problems in structures prior to the application of AG termite bait.

Insect pests in hospitals: Occurrence, possible risk they can pose for health and control methods

A Gliniewicz, K Pancer, E Mikulak, M Kochman, B Sawicka, D Rabczenko, H Stypułkowska-Misiurewicz
National Institute of Hygiene, 00-791 Warszawa; 24, Chocimska Street. Poland; agliniewicz@pzh.gov.pl

Although in hospitals high level of pest management performance should be maintained, they are not pest free. The evaluation of insect pests occurrence in hospitals in Poland carried out in 2000-2003 showed, that 86,7% hospitals were infested by German cockroaches (*Blattella germanica* L.), 53,3% - by fleas, 20,0% by Oriental cockroaches (*Blatta orientalis*) and Pharaoh's ants (*Monomorium pharaonis* F.). Flying insects: wasps, mosquitoes, flies were present in 26,7%; 13,3% and 60,0% of examined objects respectively. Insects belonging to predominant species: *B. germanica*, caught in hospital wards and kitchens, were tested bacteriologically. About 80 bacterial strains were isolated from external parts of their bodies. Several of them, such as *Pseudomonas aeruginosa, Serratia marcescens, Citrobacter freundii, Enterobacter cloacae, Klebsiella oxytoca* are known as agents causing nosocomial infections. Susceptibility tests to selected antimicrobial agents pointed out, that several of isolated strains showed MLSb mechanisms of resistance (staphylococci), produced ESBL or/and Amp C-type beta-lactamases (Gram(-) rods). Such strains, resistant to antibiotics, may be reservoirs of resistance genes, which can be transmitted into other bacteria. Several isolated strains showed also resistance to surface disinfectants. The examined susceptibility to insecticides mostly used in hospitals showed considerable levels of insecticide resistance in tested strains of *B. germanica*.

Efficacy of *Cinnamomum* (Nees) oil and its major constituent against phosphine resistant and field strains of lesser grain borer *Rhizopertha dominica* (F.) (Coleoptera: Bostrichidae)

MM Hasan, MR Uddin
"Laboratory for Stored Product Protection, Department of Zoology, Rajshahi University, Rajshahi 6205, Bangladesh; mmhbgd@yahoo.com"

The insecticidal activities of *Cinnamomum* oil and its major constituent zimtaldehyde against phosphine resistant and field strain adults of lesser grain borer *Rhizopertha dominica* (F.) were examined using feeding deterent and fumigation methods. Results show that both the components significantly ($p<0.001$) affect the mortality of adults of phosphine resistant and field strains. It also shows that phosphine resistant strain exhibits much more tolerant than the field strains for both the components indicating the higher lethal values. In a feeding deterent and fumigation test, zimtaldehyde was much more effective against the adults *R. dominica* than the *Cinnamomum* oil for both the strains. However, zimtaldehyde, major active constituent of *Cinnamomum* oil, may be suitable as fumigants of vapor-phase insecticides because of their high volatility, fumigations efficacy, and their safety.

Baiting systems for subterranean termite management

MI Haverty, VR Lewis
Pacific Southwest Res. Station, USDA Forest Service, P.O. Box 245, Berkeley, CA 94701 USA

Baits present a different paradigm for termite management. Rather than using barriers to exclude termites from a wooden structure, baits are designed to kill termites and reduce termite populations. Successful baiting should result in a building without termites threatening its structural integrity. Early baits incorporated sodium arsenite as the active ingredient. Refinements in the 1970s included use of decayed wood as an "attractant" and mirex, a slow-acting toxicant. Bait development accelerated in the 1990s; commercial products are now available. Many controversial assumptions and concepts underlie the baiting paradigm and include: random versus directed foraging, site fidelity, attraction, recruitment, and colony suppression versus elimination. Defining these ideas is demanding and has created spirited debate among researchers, chemical manufacturers, service providers, and regulators. Labor-intensive efforts, extended timeframe for the desired outcome, and conflict of interests in funding sources for research, also pose additional challenges to the large-scale adoption of subterranean termite baiting. The past and present history of baiting and current definitions of terms and underlying assumptions will be reviewed. Additional efficacy testing is needed using newer assessment technology, particularly the use of portable x-rays to view inside walls.

Paratransgenesis – a new approach to termite control

C Husseneder, JK Grace
Dept. of Entomology, Louisiana State University AgCenter, 404 Life Science Bldg., Baton Rouge, LA 70803; chusseneder@agcenter.lsu.edu

Indigenous gut bacteria of the Formosan subterranean termite (*Coptotermes formosanus* Shiraki, Isoptera: Rhinotermitidae) were used as shuttles to deliver, express, and transfer foreign genes in termite colonies. *Enterobacter cloacae* was transformed with a recombinant plasmid containing genes encoding ampicillin resistance and the Green Fluorescent Protein (GFP). Termites from three colonies were fed with filter paper inoculated with transformed bacteria. Transformed bacteria were detected in termite guts by growing the entire gut flora under selective conditions and checking the cultures visually for fluorescence. We demonstrated that: (1) transformed bacteria were ingested rapidly and the GFP marker gene was expressed in the termite gut; (2) transformed bacteria established a persistent population in the termite gut; (3) transformed bacteria were efficiently transferred throughout a laboratory colony; (4) transformed *Ent. cloacae* were transferred into soil, however, they did not accumulate over time and the GFP plasmid was not transferred to other soil bacteria. Transgenic bacteria may be used to shuttle detrimental genes into termite colonies for improved pest control. To that end, we are screening gene products for their efficacy against termites and their obligate protozoan symbionts. Genes found to be detrimental will be engineered into natural gut bacteria and introduced to termites.

Contributions and possibilities of DNA biotechnology on termite management strategies at the dawn of the 21st century

TM Jenkins, BT Forschler
Dept. of Entomology, The University of Georgia, 1109 Experiment Street, Griffin, GA 30223-1797, USA; tjenkin@griffin.uga.edu

DNA biotechnology has had a major impact, particularly in the last six years, on the study of termite biology. An array of DNA marker technologies are being used to assess the temporal and spatial aspects of termite population structure, judge the efficacy of management strategies and unravel questions of taxonomy and gene flow. When used in collaborations with other scientific methodologies, DNA techniques have the potential to change the conceptual framework of termite management. Genomic and cDNA libraries have been developed and are being mined for DNA markers as well as developmental and structural genes that could lead to genetic-based management strategies that are environmentally and human friendly. Our presentation will, therefore, focus on: the historical development of DNA biotechnology for studying termite biology, the importance of that study for termite management strategies, and how DNA biotechnology may be integrated into termite management strategies for the 21st century.

High content of phenolic compounds in cocoa beans not utilised by storage pests

WA Jonfia-Essien, PG Alderson, G Tucker, G West
School of Biosciences, University Of Nottingham, Sutton Bonington Campus, Loughborough, Leicestershire, LE12 5RD, UK; stxwaj@nottingham.ac.uk

Over the last decade, the consumption of cocoa (*Theobroma cacao* L.) has increased, however the yield of the crop in Ghana has been on the decline. To improve yield, alternative hybrids have been developed from crosses between Amazon, Trinitario and Amelonado genotypes to augment the Series II hybrids, which are already grown by farmers. Storage trials with these new hybrids have revealed that insect pest attack, which is very prevalent in dried / stored cocoa beans of the traditional type, is not a problem. Adults of *Tribolium castaneum* (Herbst) of the family Tenebrionidae and *Lasioderma serricorne* (F.) of the family Anobiidae, both Coleoptera, were introduced to dried cocoa beans and stored for 113 days at 33 ± 1°C and relative humidity of 72 ± 2 %. The beans of the hybrid varieties did not support the growth of the insects, which consequently died during the period of storage. In contrast, the traditional type supported the growth and multiplication of the insects and there was extensive damage to the beans. Analysis of the beans showed that the phenolic content of the hybrid varieties was higher than in the traditional type, and this may explain why there was an adverse effect on the insects.

Population genetics of Indian meal moth, *Plodia interpunctella*

S Kambhampati, T Grace, B Subramanyam
Department of Entomology, Kansas State University, Manhattan, KS 66506 USA; srini@ksu.edu

The Indian meal moth, *Plodia interpunctella* (Pyralidae: Lepidoptera) is a serious pest of stored food throughout the world. Its worldwide distribution is believed to have been accelerated by human commerce. It is also known to be resistant to a variety of commonly used insecticides. No information is available on the breeding structure of Indian meal moth at local, national, and global scales. Therefore, we developed polymorphic microsatellite loci to quantify the breeding structure and population genetics of Indian meal moth worldwide. Samples were obtained from selected counties within Kansas to investigate the fine-grained breeding structure. Samples were also obtained from several states in the USA and many countries in the world. Sampling is also being undertaken throughout the year at one storage facility in Kansas to understand the temporal variation in breeding structure. Results will be presented and discussed in the context of global movement of the Indian meal moth, implications for insecticide resistance management, and gene flow among subpopulations.

Perimeter treatment for subterranean termite control

ST Kamble, RW Davis
Department of Entomology, University of Nebraska, Lincoln, NE 68583-0816, USA; skamble1@unl.edu

Pest Management Professionals had the opportunity to use newer, non-repellent active ingredients for subterranean termite control. These active ingredients provide control through reduction of termite populations. The pest control industry has asked if the newer non-repellents may provide acceptable subterranean termite control with less than full-conventional treatments. The study was undertaken to evaluate the applications with exterior perimeter plus localized interior treatments. In this study, 43 termite infested structures were treated with Termidor (fipronil) WG or SC using either an Exterior Perimeter Treatment (EP) or Exterior Perimeter with Localized Interior Treatment (EP/LIT). The 95% of structures exhibited no termite activity from 1st inspection date to 18-36 months after treatments. One EP site had recurring activity at 12 MAT at an interior area not treated at time of initial treatment. Another EP site had continuing activity at an interior site not treated at initial treatment through 6 MAT. All of the structures that received the EP/LIT which included treatments at the points of termite activity exhibited 100% control through the course of this study. According to these data, Pest Management Professionals can expect to use 19%-48% less diluted termiticide when using a EP/LIT approach versus a full conventional treatment.

Borates as a tool for termite management

BM Kard, SC Jones
Dept. of Entomology and Plant Pathology, 127 Noble Research Center, Oklahoma State University, Stillwater, OK, USA 74078-3033; kard@okstate.edu

Borates are used worldwide as preservative treatments to wood and wood products. Formulations include aqueous solutions, pastes, gels, solid rods, powders, granules, glycol or paint mixtures, or mixtures with insecticides and fungicides or chemicals that enhance penetration into wood. Borates can provide resistance to damage by subterranean and dry-wood termites depending on their concentration and depth of penetration into wood. Their advantages are broad-spectrum toxicity to wood-destroying insects and some decay fungi coupled with low mammalian toxicity. Furthermore, borates typically are colorless, odorless, inexpensive, and practical to use. Because borates are water-diffusible, a major disadvantage is that they do not fix in wood; hence borate-treated wood is not suited for ground contact or exposure to weathering. For decades, Australia, New Zealand, and several European and South American countries have used borates to protect lumber, whereas the United States is a relative newcomer in this use. This presentation discusses laboratory and field trials to evaluate borate efficacy, as well as borate products and application methods. For example, in the United States an experimental borate bait demonstrated some success against field populations of a Sonoran Desert subterranean termite, and borate-containing plastic wraps around utility pole bases provided protection against termites and decay.

Termite baiting: a conservation and integrated termite management approach

LC Lee, AT Hung, D Ouimette, M Tolley, P Borth
Dow AgroSciences Asia Sdn Bhd, Level 6 CP Tower, Pusat Dagang Section 16, Petaling Jaya 46350, Selangor, Malaysia; lllee@dow.com

Termite control remains the biggest segment of business portfolio to the pest control industry. While conventional control methods such as residual spot treatment and chemical barrier are commonly practice, termite baiting technology since 1995 provides as an effective option to the industry and the public. Baiting technology is getting more popular as it controls/eliminates termite colony in less intrusive way to the property as compared with the post-construction method. In addition, significantly less chemical were used in treating termite infestation. Due to these, numerous invaluable historical sites infested with the subterranean termite were baited and restored in least damages manner. Most importantly, termite baiting plays a significant role in Integrated Termite Management (ITM) involving three continuous steps of monitoring-prevention-treatment, in addition to public education. While ITM concept has been long discussed and accepted in developed countries, it is now obviously changing the perception and practices of the termite control industry and the public of South East Asia and Greater China since introduction of baiting technology in this new millennium. The implementation challenges and solutions of ITM concept in these regions with specific references on hexaflumuron-based (Recruit®II) and noviflumuron-based (Recruit®III) termite baits are discussed.

Insecticide resistance in the German cockroach in Asia – problems and challenges

CY Lee, LC Lee
School of Biological Sciences, Univ. Sains Malaysia, 11800 Penang, MALAYSIA, chowyang@usm.my

Extensive usage and heavy reliance on the use of neurotoxic insecticides have led to the development of insecticide resistance in the German cockroach, *Blattella germanica* (L.), causing significant control failures to pest control operators world-wide. Despite being an important insect pest in Asia, reports on cases of insecticide resistance in field German cockroaches in this region had been limited to studies from Malaysia, Japan, Korea and Singapore. Most studies reported in the last 10 years are mainly from Malaysia. More than 80 field populations of this species that were collected between 1993 – 2000 showed broad spectrum resistance to all major groups of insecticides (organochlorine, organophosphate, carbamate and pyrethroid). Most of the collected strains possessed increased monooxygenase and esterase activities. Increased glutathione S-transferase activity was also found in a number of strains studied. The challenges of insecticide resistance in the German cockroach in Asia, and some of the management strategies adopted will be discussed.

Challenges to termite management with multi-genera faunas

CY Lee, LC Lee, C Vongkaluang, M Lenz
School of Biological Sciences, Univ. Sains Malaysia, 11800 Penang, Malaysia; chowyang@usm.my

Termites are an important group of insect pests in the Asia Pacific region. Due to the high diversity of termite species in this region, it is common to find several termite pest species to co-exist, and to infest buildings and structures. In Malaysia, there are 12 species of subterranean termites from 7 genera (*Coptotermes*, *Macrotermes*, *Microtermes*, *Globitermes*, *Odontotermes*, *Schedorhinotermes* and *Microcerotermes*) that can be readily found in- and around buildings and structures, particularly in suburbia and rural settlements. Similar observations with species in the genera *Coptotermes*, *Microcerotermes*, *Macrotermes*, *Hypotermes* and *Odontotermes* are also recorded in urban and rural Thailand. Termites from three to six genera (*Mastotermes*, *Coptotermes*, *Schedorhinotermes*, *Heterotermes*, *Nasutitermes* and *Microcerotermes*) may be found within the same location as structural pests in Australia, with the highest number of genera in the tropical north of the country. Since the introduction of baiting in Malaysia, secondary pest species are more frequently encountered. Following elimination of the principal pest species (*Coptotermes* spp.) with bait, it is not uncommon to find species from other genera such as *Macrotermes* and *Schedorhinotermes* infesting the same building or structure after several months. Most of these species particularly those belonging to genera such as *Macrotermes*, *Globitermes* and *Odontotermes* from the higher termite (Termitidae), however, do not respond well to paper-based bait matrices. Options for managing multiple genera termite pest faunas in the tropics are discussed.

Documenting the novelty of non-repellent, liquid termiticide management strategies

W Madden, B Reid
PO Box 903, Pymble, NSW, 2073, Australia; warwick.madden@bayercropscience.com

The advent of non-repellent termiticides in the 1990s was greeted with great scepticism in both the scientific and commercial market place, which had been preconditioned to thinking of termite control being exclusively predicated on repelling termite from structures. Since the coincident introduction of termite baiting systems and the launch of imidacloprid (Premise, Hachikusan), as a conventionally-applied liquid treatment, both the science and practice termite control have changed dramatically. This presentation will review the latest research documenting the pervasive effects non-repellent, liquid termite management strategies have on termites at both an individual and population level. Data on secondary kill in termite colonies, the mechanisms of transmission between termites, and the long-term impact on termite colonies/populations will be presented. The impact of these powerful performance factors on the protection of structures threatened with termite attack will be outlined. A discussion of what these new facts foretell about the future direction of termite management strategies will conclude the presentation.

Comparisons among technologies currently used for detection of hidden insect infestations in stored products

RW Mankin
PO Box 14565, Gainsville, FL 32604, USA; rmankin@gainesville.usda.ufl.edu

Insect infestations are of major concern to food producers and consumers, but there are few reliable means of detecting insect pests hidden in packaged products before they cause significant damage. Modern acoustic and microwave radar technologies show promise as nondestructive tools for detecting hidden insects in stored products. However, it has been difficult to overcome problems resulting from background interference, reduced transmission of acoustic signals through multiple layers of packaging, and low levels of movement by some of the most important pests like Indian meal moth larvae. To meet these challenges, researchers and engineers have improved the sensitivity of detection probes and improved the interfaces between the probes and the stored products. They have also developed improved techniques for identifying insect signals in high-noise backgrounds. This report discusses some of the newest technology and potential advances that are in the process of development.

Bio-efficacy of gamma radiation and fumigants on *Tribolium castaneum* (Herbst)

VK Mehta, GR Sethi, AK Garg, RK Seth
Department of Zoology, Shivaji College (University of Delhi), New Delhi 110 027, India.

Integrated effect of gamma radiation and four commonly used fumigants (EDCT, ethylene dibromide, carbon disuphide and methyl bromide) was studied by exposing the larvae and adults of *Tribolium castaneum* (Herbst). Two regimens were tested, (i) irradiation followed by fumigation, (ii) fumigation followed by irradiation. It was observed that the larvae and adults exposed to 50 and 100Gy (nearer to LD_{50}) doses of gamma radiation, respectively, if fumigated within 6 hr after irradiation, required higher doses of fumigants at LC_{50} level, but when fumigation was performed 7 days after irradiation, relatively lower doses of fumigants were needed to achieve similar results. On the other hand, the fumigation of *T. castaneum* life stages followed by irradiation did not affect their radio-susceptibility. These studies indicated that if irradiation preceded fumigation, the pest susceptibility towards fumigants might be altered, wherein management of stored pest could be effectively operated. However, no evident change in the susceptibility pattern was noticed when the survivors of the fumigation treatment were exposed to gamma radiation. In view of these observations, the ionizing radiation might be considered as an environmentally sound alternative or supplement to other control methods.

Microsatellites and insect infestations: a new tool to investigate an old problem

KM Mikac, G Clarke, N FitzSimmons, DP Rees
CSIRO Division of Entomology, GPO Box 1700, Acton, ACT, 2601 Australia, katarina.mikac@csiro.au

Microsatellites are considered the marker of choice for most population genetics studies because they are highly variable, codominant and reproducible. Microsatellites have been isolated and optimised for two psocid species, *Liposcelis decolor* and *L. entomophila* that are major pests of stored grain in Australia. Currently there is limited information on the invasion biology of *Liposcelis* species in Australia and an understanding of population structure and dynamics, gene flow among populations, geographic origin of source populations and dispersal mechanisms is required. Through the use of molecular methods a better understanding of the invasion ecology of *Liposcelis* species in Australia is possible and may assist in the development of strategies for the eradication, quarantine and potential future import of *Liposcelis* species or strains not present in Australia. To develop integrated control measures there is a need to understand the ecology of a pest in all its diversity. This will require a multidisciplinary approach utilising a diversity of methodologies. Molecular techniques such as microsatellites may provide a powerful addition tool to the field of stored product research.

Cost and efficacy comparison of IPM strategies with monthly spray insecticide applications for German cockroach (Dictyoptera: Blattellidae) control in public housing

DM Miller, F Meek
Department of Entomology, Virginia Tech, 216 Price Hall, Blacksburg, VA 24061, USA

The long-term costs and efficacy of two treatments for German cockroach control were compared in public housing. The "traditional" treatment for cockroaches consisted of monthly baseboard and crack and crevice treatment (TBCC) using spray and dust insecticides. The integrated pest management treatment (IPM) involved vacuuming followed by monthly or quarterly applications of bait and insect growth regulators. Technician time and the amount of product applied were used to measure cost in both treatments. Trap catch (24h) was used as an indicator of treatment efficacy. The cost of the IPM treatment was significantly greater than the traditional treatment, particularly at the initiation of the test. However, after Month 4 the cost difference between the two treatments was no longer significant. To evaluate the costs of treatment over the entire year, technician time and product quantities were averaged over the total units treated. The average IPM cost was significantly greater than that of the TBCC treatment. While the TBCC was less expensive than IPM, it was also less effective. The TBCC treatment did not reduce cockroach populations. Trap catch in the IPM treatment was significantly reduced from 24.7 cockroaches per unit prior to treatment to 3.9 cockroaches per unit by Month 4.

Australian spiders: venomous villains or toxic treasures?

GM Nicholson
Neurotoxin Research Group, Department of Health Sciences, University of Technology Sydney, P.O. Box 123, Broadway, NSW, 2007, Australia;
Graham.Nicholson@uts.edu.au

"There are several groups of medically important araneomorph and mygalomorph spiders responsible for serious systemic envenomation in Australia. These include the red-back spider *Latrodectus hasselti* (Theridiidae) and funnel-web spiders from the genera *Atrax* and *Hadronyche* (Hexathelidae). The venom of these spiders contains potent neurotoxins that cause excessive neurotransmitter release. In the case of red-back spiders this is due to the action of a-latrotoxins to cause synaptic vesicle exocytosis, while d-atracotoxins from funnel-web spiders modulate voltage-gated sodium channels to cause increased firing of nerve impulses. In addition, cupboard (*Steatoda* spp.) and mouse (*Missulena* spp.) spiders appear to contain similar types of neurotoxins that may lead to systemic envenomation. Fortunately a number of antivenoms are available to treat envenomation from the bite of *Latrodectus* and *Atrax/Hadronyche* species, with extensive cross-reactivity within each genera and, in some cases, in unrelated families. In Australia, however, there is no evidence that spiders cause necrotic arachnidism despite many spiders being implicated including white-tailed (*Lampona* spp.), black house (*Badumna* spp.), and wolf (Lycosidae) spiders. Despite their notorious reputation, venoms of funnel-web spiders, have provided a untapped source of insect-selective neurotoxins (w- and k-atracotoxins) for the future development of biopesticides and the characterisation of previously unvalidated insecticide targets.
"

Advances in termite detection using acoustical technology

W Osbrink, A Lax
USDA-ARS-SRRC, 1100 Robert E. Lee Blvd., New Orleans, LA, 70124 USA

An acoustical termite detection device was used to evaluate the presence of termites in the laboratory and field. Laboratory tests could detect differences in numbers of termites as well as detect changes in termite activity correlated with temperature differences. Field tests could detect termites in living trees. Differences in termite activity in trees were correlated with seasonal changes. Acoustical termite detection technology appears promising.

Tennessee and Kentucky stored grain project: an update on progress

CR Patrick, DW Johnson, MJ Buschermohle
605 Airways Blvd., Jackson, TN 38301, USA; russ1212@utk.edu

A cooperative effort with the University of Kentucky and the University of Tennessee was established in 2001 to determine if basic procedures and the use of existing pesticides labeled to control insects in wheat would be sufficient to prevent damage from stored grain insects in farm bins in each state. To this date there has been progress in reducing insect problems in demonstration grain bins using these established methods of insect control. This project is funded by an IPM grant to purchase necessary materials and monitoring equipment needed to complete the project.

New approaches to monitoring storage moths with semiochemicals

TW Phillips, C Nansen, C Konemann, P Morton, J Dillwith
Dept. of Entomology and Plant Pathology, 127 Noble Research Centre, Oklahoma State University, Stillwater, OK 74078 USA; tomp@okstate.edu

Studies were conducted with Indianmeal moth, *Plodia interpunctella*, to help improve use of sex pheromone-baited traps for males and to elucidate the behavioral activity of a new female attractant. The role of pheromone quantity and quality on spatial targeting of an infestation source was studied in controlled experiments using a grid of regularly spaced traps and known numbers and release locations of male moths. Loading rates of synthetic pheromone on rubber septa from 1 to 2000 ug, or females producing natural pheromone, had no affect on overall re-capture rate of released males or on the ability of trap-captures to indicate the location of the release site. Other experiments investigated the role of trap height and position on trap catch and showed that male moths preferred to orient to a pheromone source associated with a physical surface, such as the floor, ceiling, wall or a landing platform. An attractant for female *P. interpunctella* was developed that consists of a mixture of naturally occurring compounds from attractive food sources used for oviposition. Experiments on biological and environmental factors affecting response to the female attractant, as well as discussion of the application of this attractant to monitoring and suppression, will be presented.

Control of eastern subterranean termite *Reticulitermes flavipes* (Kollar) in Hamburg, Germany

R Plarre
Federal Institute for Materials Research and Testing, Unter den Eichen 87, 12205 Berlin, Germany; ruediger.plarre@bam.de

Reports of the eastern subterranean termite *Reticulitermes flavipes* from Hamburg can be dated back to the 1930ties. Control efforts in the fifties and eighties of the last century involved massive application of biocides into building walls and the surrounding ground, but only with temporal and limited success. Modern subterranean termite control is implemented by baiting techniques, which are specifically targeted and through which the amount of applied pesticide is limited to a minimum. Laboratory tests have shown that the attractiveness of wooden baits can be significantly increased through a predecaying process of the wood by the brown root fungus *Antrodia vaillantii*. Field data taken at the Hamburg site have shown, that *R. flavipes* can be successfully lured out of their natural feeding areas to brown root treated wooden stakes. Once these are accepted by foraging workers they are replaced by termiticide pressure treated stakes. Pesticide application is 0.5 ppm or lower. These low concentrations of the pesticide act lethal after trophallaxis and accumulation over time in the target organisms of the colony, the primary or secondary reproductives. The termite population in Hamburg was reduced to residual 5 % of its original size during the past 4 years.

The granary weevil, *Sitophilus granrius* L. (Coleoptera: Curculionidae) – a coevolutionary event with the dawn of neolithic agriculture?

R Plarre
Federal Institute for Materials Research and Testing, Unter den Eichen 87, 12205 Berlin, Germany; ruediger.plarre@bam.de

Among all stored-product insects the granary weevil is the only species never recorded outside storage facilities. Anatomical, physiological and behavioral aspects of recent and hypothetical ancestral species in the genus *Sitophilus* are presented and discussed in terms of adaptation to anthropogenic storage of grain. Preadaptations like full development inside the host kernel, endosymbioses with bacteria, and the reduction in flight activity to prevent water loss in a dry environment could have resulted in the evolution of a full synanthropic grain pest of cosmopolitan distribution. Faunistic, archaeological and historical evidences of the pests origin and spread in conjunction with early agriculture is reviewed.

Can pheromones and hormones be effectively used for termite management?

AK Raina
Formosan Subterranean Termite Research Unit, A.R.S., U.S.D.A., 1100 Robert E Lee Blvd., New Orleans, Louisiana 70179, USA; araina@srrc.ars.usda.gov

In termites, trail following chemicals are the most studied group of pheromones. Dodecatrienol and its variants appear to be the common theme in termite trail pheromones. Whereas one can envision their role in trail following among above ground foragers, it is not clear how such pheromones can be effective for the subterranean species that live and forage in well-established enclosed chambers and tunnels. In some species, both trail and sex pheromonal properties have been attributed to the same compound, perhaps at different concentrations. Among hormones, juvenile hormone (JH) and its effects have been studied in some detail. JH appears to be involved in egg maturation in reproductive forms as well as regulation of soldier formation. A possible use for pheromones and similar chemicals for termite management would be to increase the attraction of termite workers to bait stations. Sex pheromones, to attract and trap adults of one sex or confuse mate finding may be feasible in species producing relatively small swarms. JH and its analogs might be used to disrupt caste ratios leading to the death of a colony. Genes of peptide hormones, such as a diuretic hormone if discovered could be cloned into a suitable shuttle vector for delivery to a termite colony and disrupt the fragile water balance of these desiccation sensitive species.

Monitoring *Liposcelis* species (Psocoptera: Liposcelididae) in bulk grain stores

DP Rees
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia; david.p.rees@csiro.au

Psocids, *Liposcelis* species (Psocoptera : Liposcelididae) have in the last decade become much more important as pest of bulk grain storage in Australia. To understand biology and behaviour and to assess efficacy of control measures effective means to monitor populations are needed. To monitor *Liposcelis* populations infesting open topped bins of wheat and barley, three monitoring methods were assessed – pitfall probe traps inserted into grain, cardboard crevice trap (made from piece of corrugated cardboard 100x150 mm) and counting psocids found on a marked out target area – typically a handrail above the cell top. Cardboard crevice traps placed on concrete surfaces above the open cell top were found to be more sensitive that the same trap placed on the grain surface or pitfall traps. Catch also agree closely with mean numbers of psocids seen on handrails nearby. Handrail counts need to be repeated many times to give analogous results as counts very considerably within very short time frames. Cardboard traps are very cheap, easy to deploy and very sensitive. They are now in widespread use by the Australian grain storage industry to detect and monitor populations of *Liposcelis* spp.

Investigations into the early detection of phylloxera infestation using remotely-sensed and field spectrometry

L Renzullo, A Held, K Powell
GPO Box 1666, Canberra, ACT, 2601, Australia; luigi.renzullo@csiro.au

Phylloxera (*Daktulosphaira vitifoliae* Fitch) is an aphid-like, root-feeding insect whose devastating impact on the grape and wine industry is well documented. Once a vineyard is known to be infested with phylloxera, the only long-term management strategies are to replant affected vines with resistant rootstock and to establish quarantine protocols. In Australia, there is considerable interest in mapping phylloxera infestation as early as possible so as to minimise the financial burden to vineyard owners/managers and to contain the pest to as small an area as possible. Grapevine canopies show symptoms of phylloxera infestation some 2-3 years after being infested; by this time the infestation most likely extends much further than observations (airborne or ground-based) might suggest. The key to the early, or pre-visual, detection of phylloxera infestation is an understanding of the spectral and chemical response of grapevines to the pest. This paper demonstrates the current capabilities of multispectral and hyperspectral sensors on airborne and satellite platforms to detect phylloxera infestation in vineyards. With the aim of identifying the spectro-chemical signature of phylloxera in grapevine canopies, detailed discussion is given on the results and analysis of field spectrometry and leaf tissue chemistry from field campaigns to vineyards in central and northeastern Victoria, Australia.

Mating disruption of two stored-product moth species: comparisons of population estimation

C Ryne, O Anderbrant, C Löfstedt
Ecology Building, Solvegatan 37, SE-223 62, Lund, Sweden; Camilla.Ryne@ekol.lu.se

A comparison of two separate indoor mating disruption (MD) trials, using two different methods for population estimations will be presented. Mating disruption trials were applied to two localities, one chocolate factory (major moth pest: the almond moth (*Ephestia cautella*)) and one flourmill (major moth pest: the Mediterranean flour moth (*E. kuehniella*)). Chem Tica, Costa Rica, kindly provided one-component MD-dispenser, which emit 1µg of Z9,E12-14: OAc per day. One MD-dispenser per 100m^3 was applied in the localities, changed every three months. The flour mill population was measured by counting trap catches, using pheromone traps and the chocolate factory population was measured by using water buckets with sticky inside lining. The almond moth has previously been reported as being attracted and caught in buckets with water. Complete trap shutdown was observed in the flourmill, however moths could still be seen flying and sitting on walls. The water traps, which do not compete with the MD pheromones in the chemical communication channel, showed declining catches after one month of MD trials, indicating that MD was effective in decreasing the mating frequency in the population. Problems in how to interpret trap catches with pheromone traps are discussed as well as the biological relevance of water for *E. cautella.*

Feeding response of subterranean termite, *Coptotermes curvignathus* Holmgren (Isoptera: Rhinotermitidae) to *Azadirachta excelsa* (Jack) Jacobs (Meliaceae) extractives and its timber

AS Sajap, MLT Lardizabal, FB Ahmad, MH Sahri
Faculty of Forestry and [2]Faculty of Science and Environment, Universiti Putra Malaysia, 43400 UPM, Serdang, Malaysia; ahsaid@putra.upm.edu.my

Feeding response of subterranean termite, *Coptotermes curvignathus* Holmgren (Isoptera: Rhinotermitidae) to *Azadirachta excelsa* (Jack) Jacobs (Meliaceae) extractives and its timber was studied. The result shows that both methanol and hexane extracts from leaves and barks significantly inhibited feeding activity and survival rates of the termites. At 1000 ppm, the amount paper consumed was reduced by 27%. The mortality rates from leaf-hexane and leaf-methanol extractives were 26.6 and 17.1%, respectively, and from bark-hexane and bark-methanol were 34.4 and 28.9%, respectively. Mortality from the control was less than 10%. A choice study conducted in laboratory and field shows that timber from *A. excelsa* was the least preferred by the termites. Its susceptibility was equivalent to that of a medium hardwood, *Koompassia malaccensis* or three and four times less susceptible than that of *Hevea brasiliensis* and *Pinus caribaea*, respectively.

Food preference of the potato tuber moth and effect of three non-cultivated Iranian plants against female egg-laying on stored tubers

L Salehi, M Ajamhasani
Dept. of Plant Protection, Faculty of Agriculture, The University of Guilan, P.O.Box 3179, Rasht-Iran; salehi@guilan.ac.ir

Potato tuber moth, *Phthorimaea operculella* Zeller (Lepidoptera: Gelechiidae) was introduced to Iran in 1968 and has spread throughout the potato growing regions in many provinces including Guilan. Oviposition preferences on five cultivated host plants, potato, tobacco, tomato, pepper and egg-plant, were tested in the laboratory and in the field. Of the plants tested, tobacco was preffered host. Oviposition deterence of leaf powder and aqueous extracts of three non-cultivated plants, *Sambucus ebulus* (Caprifoliaceae), *Artemisia annua* (Asteraceae), and *Pterocarya fraxinifolia* (Juglandaceae) which are cheap, safe and easily available to the farmers, all inhibited egg-laying on stored potato tubers. The extract and leaf powder of *P. fraxinifolia* was most effective deterrent to females egg-laying on potato tubers (95 and 82%) followed by *A. annua* (94 and 54%) and *S. ebulus* (65 and 14% respectively)

Progress in post harvest and structural fumigation

BM Schneider, S Prabhakaran, CJ Voglewede, P Hughes
Dow AgroSciences, Forest Corp. Park, Level 5, 20, Frenchs Forest, NSW Australia; paulhughes@dow.com

Times of change are times of progress. With the phase-out of methyl bromide, progress in the post harvest and structural fumigation markets is being achieved with an emphasis on Precision Fumigation^{TM}, defined as optimizing fumigant use to maximize efficiency and minimize risk. An enhanced level of professionalism is being achieved with new fumigation products, treatment strategies, equipment, training, and fumigator attitudes. In the last few years, new fumigant products have been introduced: Eco$_2$Fume® and Vaporph$_3$os® (Cytec, West Paterson, NJ) two gaseous phosphine products and ProFume* gas fumigant, sulfuryl fluoride (Dow AgroSciences LLC, Indianapolis, IN). Several other fumigants are in development, including carbonyl sulfide, methyl iodide, and cyanogen (ethanedinitrile), but regulatory hurdles and development timelines are not clear. Also, new continuous reading fumigant clearance devices are now available. The phaseout of methyl bromide has stimulated research in postharvest pest ecology in grain storage, flour mills, and food processing plants, thus improving the timing, efficiency and economy of pest management programs. Stewardship and training requirements for fumigants have been enhanced, either mandated by government agencies or required by manufacturers. Overall, the level of fumigator expertise is improving as they investigate alternatives to methyl bromide, modern fumigation tools and more efficient fumigation practices.

Biogas application to check infestation by pulse beetle, *Callosobruchus maculatus* (Fab.) in stored green gram, *Vigna radiata* Linn.

DK Sharma, J Singh, VK Thapar, S Paul, G Singh
Department of Processing and Agricultural Structures, PAU Ludhiana, 141004, India, gursh198@yahoo.co.in

Biogas (methane: carbondioxide = 60: 40), which is abundantly available at farm houses in Punjab state of India, was evaluated for its efficacy to check infestation by pulse beetle, *Callosobruchus maculatus* (Fab.) in stored green gram, *Vigna radiata* Linn. The gas was passed at flow rate of 8.8 litres/minute through the grains (Var. ML 613) stored in PVC bins each of 100 Kg capacity (70 x 48 cm); average volume and time taken to fill a bin with the gas were 39.6 litres and 4.5 minutes, respectively. Before passing the gas, known-age eggs, grubs, pupae and adults contained in plastic containers (10 x 5 cm), were placed at the bottom, middle and top layers of grains in the bins. Exposures periods of 2, 4, 6, 8 and 10 days were given. Though, all the adults were killed with an exposure period of only 2 days but the 6-days' exposure resulted in 100 % mortality of both the eggs and the adults; larval and pupal stages harbouring inside the grains, however, remained insensitive even to an exposure period of 10 days. Germination and cooking qualities of the fumigated grains at the 6-days' exposure did not show any adverse influence on the grains stored over a period of 3 months during the peak activity period of the beetle (July to September) including rainy season.

On-farm research trials on utilization of solar energy bed for control of pulse beetle, *Callosobruchus maculatus* (F.) infesting gram, *Cicer arietinum* (L.)

SK Singal, S Chander, S Singal, MK Garg
Department of Entomology CCS Haryana Agricultural University, Hisar-125 004- Haryana –India; shiv_singal@hau.nic.in

On-Farm trials on utilization of solar energy bed for control of pulse beetle infesting gram were conducted in rural and urban houses. Earlier results on subsequent increase in infestation level of 10 ,20 and 30% due to pulse beetle in 2kg gram indicated that three exposures on solar bed each for 5,10 and 15 minutes at 60,120 and 180 days storage ,respectively, excluding control , control in increase in gram infestation level was comparatively much less than in unexposed .Results on subsequent control in increase from 30% gram infestation level by pulse beetle after three exposures on solar bed for 5 (45.2, 57.0 and 69.5%), 10 (38.0, 45.0 and 56.0%) and 15 minutes (31.5,32.1 and 31.9%) were better than control i. e .82.8 ,96.5 and 98.9% at 60,120 and 180 days after storage. Three exposures on solar bed for 15 minutes proved better than exposure of 5 and 10 minutes at 60,120 and 180 days after storage. 37 demonstrations on preparation technique of solar bed for adoption were given to women and men in rural and urban areas. Villagers took interest in solar bed preparation. Low cost technique of exposure on solar bed at regular intervals will eliminate beetle population and enhance quality of stored pulses .

Acoustic detection of Asian long horned beetle (Coleoptera: Cerambycidae) in wood: evaluation of factors affecting the spectral characteristics of vibrations resulting from larval feeding

MT Smith, RW Mankin
USDA-ARS, Beneficial Insect Introduction Research Unit 501 South Chapel Street, Newmark, DE 19713, USA; mtsmith@udel.edu

The use of acoustics to detect vibrations produced by insects living within concealed environments has been explored, including those living in wood. Insects feeding in wood produce vibrations by break wood fibers, and it are these vibrations that are of interests. However, a number of factors potentially affect the resonance properties of wood, including those inherent to the tree, the insect and the environment in which the tree is grown. Thus, studies were conducted to determine the effects of wood density, tissue, temperature and moisture, and larval instar on the frequency spectral characteristics of vibrations emanating from trees as they are being fed upon by the Asian Longhorned Beetle (ALB) larvae. This study represents an effort to capture the full range of the frequency spectra resulting from the breaking of wood fibers by ALB larva feeding within live host trees across the range of host tree species, tissues and environmental conditions in which ALB larva are found feeding under natural conditions in nature. As such, the goals of these studies were to develop a thorough characterization of ALB larval acoustical feeding signatures and to then use the resulting library to build a neural network.

Tunnelling geometry of subterranean termites and its implication in population management

NY Su
"Ft. Lauderdale Research and Education Center, University of Florida, 3205 College Ave., Ft. Lauderdale, Florida, 33314, USA; nysu@ufl.edu"

Understanding the food searching and acquisition behavior by subterranean termites is vital for managing their population, but it has been a challenging subject due to the cryptic behavior of these insects. Recent studies using laboratory foraging arenas indicated that tunneling geometry has a fractal dimension, and that termites were "attracted" to decayed woods and the extracts, possibly by the water soluble components of the decay wood extracts permeated in soil. The presence of sound woods, however, did not influence termite tunneling. Studies using a computer simulation program that was developed to identify critical components of tunneling geometry suggested vector navigation and path integration for subterranean termites. One evident benefit of these findings is the better placement of baits for the population control, but they may also aid the development of other control strategies.

Traps and product samples as indicators of insect activity in flour mills

BH Subramanyam, A Allen
Department of Grain Science and Industry, Kansas State University, Manhattan, KS 66506, USA; bhs@wheat.ksu.edu

Types and numbers of insect species associated with flour mills were monitored at Kansas State University's (KSU) pilot flour mill and four commercial flour mills located in central Kansas and Nebraska. The pilot mill was monitored over a 29-week period from June to January 2002, while each commercial mill was surveyed for a two-week interval during July 7-31, 2003. Traps located in each mill were sampled every 2-16 days, using food- and pheromone-baited pitfall traps (Trécé) for beetles and pheromone-baited sticky traps for moths (85-192 traps/mill). In addition, pitfall and aerial sticky traps were also placed outside each mill (6-20 traps). Furthermore, product samples were collected from four categories; dirty incoming wheat, moving mill stock, processing equipment, rebolt sifter scalps, and spilled stock found on floors and other structural surfaces. Available samples varied by floor and week due to fluctuations in amounts available. Size of samples ranged from 0.2-1006.7 grams with sample sizes between 1-118 samples/floor/week. Results showed that the pilot mill found fewer species (9 families and 2 orders) while the commercial mills showed a more diverse population of insects surveyed (24 families and 5 orders). High levels of *Plodia interpunctella* (Hübner) and *Tribolium castaneum* (Herbst) were found in all five mills with *Tribolium confusum* (J. du Val), *Typhaea stercorea* (L.), and *Ahasverus advena* (Waltl) found at high levels only in the four commercial mills.
High numbers of fungus feeders suggest more ideal conditions for mold growth and a need for improved sanitation practices. In addition, it appears that fewer infested product samples were located in the commercial mills (7.11%) than the pilot mill (44.4%). It is believed that the commercial mills could either have lower insect densities, immigrating insect populations, or a sampling scheme that doesn't provide a complete representation of the total insect population.

A global perspective on nuisance ant control

DR Suiter
"Department of Entomology, University of Georgia's Griffin Campus, 1109 Experiment Street, Griffin, GA U.S.A. 30223; dsuiter@griffin.peachnet.edu"

The world's population is becoming urbanized. In 1950, just 30% of the world's population lived in urban areas. By 2000 that percentage had swelled to 47%, and by 2030 the number is projected to be 60%. The United Nations predicts that almost all of the world's population growth by 2030 will be in urban areas. Urbanization often leads to problems directly associated with pests. Insects and rodents, for instance, infest and foul food at every stage. In this presentation, I will overview current trends in nuisance ant research and control globally. The most common methods of ant control include the use of toxic baits, liquid sprays, dusts, and granular formulations. Due to Central Place Foraging behavior exhibited by ants, control can be considered situational---that is, (1) direct nest treatment or physical removal when the nest is found; (2) baiting when only foragers can be found, and; (3) a combination of treatments when the nest cannot be found and foraging ants do not readily take bait or do not take enough to eliminate the reproductive capability of the colony. Finally, product formulation(s) and those area(s) that may need treatment are entirely dependent upon positive ant identification and thorough inspection resulting in an exact colony location or estimate thereof.

Detection of insect infestation in wheat transported in railroad hopper-cars

JE Throne, J Perez-Mendoza, PW Flinn, JF Campbell, DW Hagstrum
USDA-ARS Grain Marketing and Production Research Center, 1515 College Avenue, Manhattan KS 66502, USA; throne@gmprc.ksu.edu

Grain buyers typically decide whether to purchase a railcar of grain by taking a discharge sample from each compartment of a railcar and counting external adults or insect-damaged kernels (IDK) in the sample. To determine whether a discharge sample is representative of the level of insect infestation in a railcar, we examined levels of infestation in three-hopper railcars transporting wheat from country elevators to a mill. The most abundant species were *Rhyzopertha dominica* and *Cryptolestes ferrugineus* (84.5 and 14.2% of all insects collected, respectively). The immature stages of the two species were the most prevalent (> 95%). Number of insects or IDK in the discharge sample was not correlated with number of insects in the entire compartment. Numbers of immatures and IDK differed among railcars and compartments within railcars, but not among grain depths. The results indicate that each compartment of a railcar should be sampled to determine insect infestation, but that sampling at different depths within a compartment is less important; and that number of insects or IDK in the discharge sample is not representative of the insect infestation in the entire compartment. Grain buyers would benefit from development of a rapid technology for detecting internal insects in grain.

First report on the presence & medical importance of stinging ant in Southern Iran (Hym: Formicidae: Ponerinae)

S Tirgari, O Paknia, K Akbarzadeh
Department of Medical Entomology (Museum), School of Public Health and Institute of Public Health Research, Tehran University of Medical Sciences, Tehran 6446-14155, Iran; S_tirgari@yahoo.com

The importance of stinging ants, *Solenopsis spp*, in South and North America (Southern U.S) is well established. The report on the presence of stinging ants in Iran was quite astonishing to 50-years-history of Iranian Medical Entomology. The study was carried out since Nov. 2001 in Lar County in Fars and Sistan-Blouchestan Provinces. The specimens were collected from urban and rural habitats. The species was unanimously identified by colleagues at Natural History Museum of America in New York and Sam Huston State University in Texas, U.S., as *Pachycondyla sennaarensis* (Mayr, 1862). Local distribution of *P. sennaarensis* was surveyed in relation to urban and rural habitats where the majority of colonies were found in urban ranging between 1.24 colonies per 100 m^2 to 3 times more. A total of 152 persons out of 160 individuals who had experienced the sting of the ant, received medical treatment in local clinics and 6% of them were found to be highly sensitive. The stinging occurred indoor in 91% of the time in Lar city, in spite of the fact that 84% of the colonies were found in the yard and gardens and other places in houses.

Diffusivity (motility) of *Cryptolestes ferrugineus* adults in stored grain

F Jian, DS Jayas, NDG White
Department of Biosystems Engineering, University of Manitoba, Winnipeg, MB, R3T 5V6. Canada. Agriculture and Agri-Food Canada, Cereal Research Centre, 195 Dafoe Road, Winnipeg, MB, Canada. R3T 2M9

A method to calculate the diffusivity (motility) of the adult *Cryptolestes ferrugineus* (Stephens) (Coleoptera: Cucujidae) under a constant temperature or a temperature gradient was developed. The movement and distribution of the adults was governed by an advection-diffusion equation. To calculate the diffusivity of the adults in stored grain, published data were used.

Recent developments in the use of fungi for biological control of termites

MS Wright, AR Lax, A Raina
USDA-ARS-SRRC, 1100 Robert E. Lee Blvd., New Orleans , LA, 70124, USA; mswright@srrc.ars.usda.gov

Biological control of termites has often been suggested as an environmentally safe control method. Subterranean termites live in an environment conducive to the growth of microbes and establishment of epizootics; however, few successful biological control agents have been reported. The Formosan subterranean termite (FST), *Coptotermes formosanus* Shiraki, frequently infests and causes large voids in living trees. A strain of the fungus *Paecilomyces fumosoroseus* (Pfr) was found to cause 100% mortality to FST and native subterranean termite workers when only a small percentage of the termites were directly exposed. Pfr can be efficiently produced as a wettable powder thereby affording several formulation and delivery options. Field application of a liquid suspension of Pfr to active galleries in infested trees resulted in reduction of FST activity within 12 days based upon video surveillance. Reduced FST activity was observed for an additional 157 days and observations are ongoing. An isolate of another entomopathogen, *Metarhizium anisopliae*, was recovered from dead alates. Purified spores of this isolate caused 100% mortality of FST alates at 3 days in laboratory tests. The most effective formulations of these pathogens, singly and in combination, for application to termites in trees are being investigated.

A non-chemical approach for the management of subterranean termites

JR Yates III, M Lenz
University of Hawaii, 3050 Maile Way, Honolulu, HI, 96822, USA; yates@hawaii.edu

For many decades the principle method for preventing infestations by subterranean termites in residential and commercial structures has been with soil treatment termiticides. These pesticides ranged from the highly residual chlorinated hydrocarbons to the present third generation non-repellant compounds, and bait systems containing chitin synthesis inhibitors. However, as an alternative to chemical applications a number of physical barriers have been developed and tested for efficacy with several species of subterranean termites in the United States and Australia. This paper is a review of physical barriers that are currently commercially available in these countries.

Management of the Formosan subterranean termite: yesterday, today, tomorrow

JR Yates III
University of Hawaii, 3050 Maile Way, Honolulu, HI, 96822, USA; yates@hawaii.edu

Subterranean termite management has been of interest for decades to researchers, private industry and homeowners since these pests have escalated in economic importance in urban environments. The increase in importance of these destructive pests evolved from the paucity of effective management tools. Early attempts were limited to inorganic pesticides as spot treatments for infestations and it was not until the 1940's that liquid treatment barriers were available with the residual chlorinated hydrocarbons. Soil treatments with this insecticide group predominated for more than forty years when other chemistries began to appear. Within the last two decades subterranean termite management has evolved to safer and environmentally acceptable soil termiticides, termite baits, and physical barriers. Good termite management also includes effective termite detection, development of which has transformed from the traditional probe and flashlight to sophisticated electronic devices that incorporate microwaves, the infrared spectrum, x-rays and acoustic emissions. It is foreseeable that future technology will lead to subterranean termite bait attractants, improved termite detection techniques, possible genetic population size determinations and gene manipulations that can modify termite behavior.

Seasonal & spatial changes in insect density in commercial elevator bins.

Adult survival and reproductive effects of forced egg-retention time in *Aedes albopictus* after application of deet as an oviposition deterrent

A Ali, R Xue, DR Barnard
University of Florida, IFAS, MREC. 2725 Binion Road, Apopka, FL 32703-8504, USA; aali@mail.ifas.ufl.edu

The insect repellent deet (0.1% concentration) used as mosquito oviposition deterrent in the laboratory could influence the gravid female *Aedes albopictus* Skuse to retain and maintain mature eggs in her body. The egg-retention in female mosquitoes could benefit survival of the gravid females. The gravid females can lay the maintained eggs on availability of water or another liquid medium in the cage, but the length of forced egg-retention time could reduce the mean number of eggs laid per female. The gravid females that retained eggs also laid a higher percentage of non-tanning eggs, which increased with the egg-retention time. The rate (%) of egg hatch was not affected by deet used as oviposition deterrent. It was however, affected by egg-retention time in both treated (exposed to deet) and untreated (control) gravid females. The rate of egg hatch reduced after 3 weeks of retention, and after 6 weeks of retention the eggs of both treated and control gravid females could not hatch. The fecundity and fertility of gravid female *Ae. albopictus* was affected by the time duration of forced egg-retention.

Haematobia irritans **(Diptera: Muscidae) mitochondrial genome amplification and sequencing: potential of the long-PCR approach for calyptratae mitogenomics**

JG Barau, AML Azeredo Espin, AC Lessinger
Laboratório de Genética Animal, Centro de Biologia Molecular e Engenharia Genética (CBMEG), Universidade Estadual de Campinas (UNICAMP), Campinas, S.P. and Depto. Genética e Evolução, Instituto de Biologia, Universidade Estadual de Campinas (UNICAMP), Campinas, S.P.;
barau@unicamp.br

Long-PCR strategies have significantly improved the sequencing and characterization of insect mitogenomes essentially by providing an alternative way to purify sufficient mtDNA from limited amounts of individual template and thus stimulating a wide range of otherwise limited techniques on insect molecular and evolutionary biology. We optimized Long-PCR reactions for the amplification and sequencing of the complete mitogenome of the horn-fly, *Haematobia irritans* (Diptera: Muscidae), a key parasitic fly of cattle. *H. irritans* mitogenome was amplified using four conserved Long-PCR primers designed on Dipteran 16S lrDNA gene combined with two previously described 'universal' primers. Amplified products ranged from 8.5 to 9.3Kb depending on primer combination, with a 1.5Kb overlap. We obtained specific products on a microgram range providing sufficient mtDNA for several techniques, including RFLP analysis and the sequencing of the *Haematobia irritans* mitogenome from a shot-gun library approach. Using H16S primers, we also amplified long-PCR products from seven other Calyptratae key species of medical-veterinary importance: the screw-worm fly, *Cochlyomyia hominivorax*, the blowflies *Chrysomya albiceps*, *Chrysomya megacephala*, *Chrysomya putoria*, *Lucilia cuprina*, the botfly, *Dermatobia hominis* and another muscid, *Musca domestica*. These results contribute not only to achieve complete *Haematobia irritans* mitogenome but also stimulate Calyptratae mitogenomics.

The complete mitochondrial genome of the human botfly *Dermatobia hominis* **(Diptera: Oestridae)**

AML Azeredo-Espin, ACM Junqueira, AC Lessinger, TT Torres, ML Lyra, FR da Silva, AAM Maia
"Universidade Estadual de Campinas – Unicamp, Lab. Genética Animal, CBMEG, Campinas, SP, Brazil. PO Box 6010, 13083-875; azeredo@unicamp.br"

The botfly *Dermatobia hominis* is a parasite of humans and livestock, producing a furuncular myiasis. The larvae of *D. hominis* develops in the subcutaneous tissue causing economic loss and health problems, being one of the most important livestock pests in Latin America. The complete mitochondrial DNA (mtDNA) sequence of *D. hominis* was determined and has 16360 bp. The nucleotide composition is biased towards adenine and thymine, which accounted for 77.8% of the whole genome. The *cox1* gene has a Serine as the start codon, while incomplete termination codons were found for *cox1*, *cox2* and *nd5*. The control region, protein-coding genes, rRNA and tRNA genes are in the same order and orientation when compared to other dipteran mitochondrial genomes, except for a duplication of $tRNA^{Val}$ located approximately in the same position of the $tRNA^{Asp}$, but in the opposite strand. The identification of restriction sites on the sequenced mtDNA and the correlation with previous RFLP analyses provided insights for an overall scenario of the genetic variability and population structure of *D. hominis*, being helpful for monitoring the variation and dynamics of this species. The availability of complete mitochondrial sequences is an important source of sequence information for Diptera molecular and evolutionary approaches.

Are *Pediculus humanus* infected with *Wolbachia* spp.?

C Covacin, S Barker
Department of Microbiology and Parasitology, & Institute for Molecular Biosciences University of Queensland, Brisbane 4072, Australia; S.Barker@imb.uq.edu.au

Wolbachia spp. belong to the alpha-subdivision of the Protobacteria and are closely related to the Rickettsia and their relatives (Class Alphaproteobacteria, Order Rickettsiales). *Wolbachia* spp. are obligate intracellular bacteria and have been recorded in approximately 76% of insects studied. *Wolbachia* spp. are transmitted from mother to offspring through the cytoplasm of the egg. Horizontal and accidental transmission have also been recorded. The impact of a *Wolbachia* sp. on its host may vary. Enhanced fertility or fecundity, pathenogenicity, parthenogensis, feminisation, male-killing as well as cytoplasmic incapability (unidirection and/or bidirectional) may be caused by *Wolbachia* spp. infections. Cytoplasmic incapability has been linked to the transmission and inheritance of mitochondrial DNA in that it may provide the impetus for selective sweeps. The sweep of a mitochondrial-type through a population and from generation to generation may be enhanced in lice due to the short generation time, small population size and the founder effect that occurs as a result of dispersal of lice. Here we present our data on whether or not *Pediculus humanus* (body/cloths louse) and *Pediculus capitis* (head lice) may be infected with *Wolbachia* spp.

Triatoma mexicana in the state of Guanajuato, Mexico: preliminary results.

M Cabrera, G Rojas, Y Guevara, S Rosales, H Aguilar, M Vences, PM Salazar.
Lab Biol Parasitos, Fac Med, UNAM. Edif A 2º. Piso CP 04510; imay@servidor.unam.mx

Mexico have 7 genera and 24 species of Triatoma genus which are *Trypanosoma cruzi* vector's, some with habits intradomicile. In Guanajuato state have been reported 5 triatomines species, among them *Triatoma mexicana*, which is little studied. With the purpose of know their ecotopes, distribution, infection for *T. cruzi*, morfometric, citogenetic and of life cycle in the laboratory, 9 localities of three municipalities were studied in the northeast of the State. We collected 110 triatomines, adults 91(83%), nymphs 19 (17%), males 80 (73 %) and females 11 (10 %). Positive to *T. cruzi*. 5 (4.54%). Capture sites, 6 (4%) were captured indoors and 104 (96%) in the outdoors. The main ecotopes in the intradomicile were: bed, wall, kitchen light bulb and in the peridomicile were: external wall, courtyard light bulbs, stone wall and farmyard. This specie is attracted by the artificial light (tungsten). The season with more triatomines was spring. Studies of morfometric , citogenetic and biological cycle are not concluding. This vector doesn't present intradomiciliated habits like initially it had been reported, their biological cycle performance in the peridomicile is in the stone wall and farmyard in these sites we captured the biggest number of triatomines in the nymphs phase

Vertebrate integumentary chemicals: endogenously produced and acquired chemicals use to deter arthropods

JF Carroll, PJ Weldon, M Kramer
"USDA, ARS, APDL, BARC-East, Bldg. 1040, Beltsville, MD 20705, USA; jcarroll@anri.barc.usda.gov "

Ectoparasitic arthropods may be deterred from feeding on certain vertebrates by substances endogenously produced in the skin, pelage or plumage. Deterrent chemicals may also be acquired by them by rubbing against exogenous sources, i. e. anointing. Monkeys and birds rub themselves with millipedes that defensively discharge benzoquinones. Laboratory bioassays showed that three benzoquinones in millipede secretions deterred ticks and mosquitoes by repellency, toxicity and behavior alteration.

Spatio-temporal analysis of reinfestation by *Triatoma infestans* (Hemiptera: Reduviidae) following insecticide spraying in a rural community in northwestern Argentina.

MC Cecere, GM Vazquez-Prokopec, RE Gürtler, U Kitron.
Lab. Eco-Epidemiology, Depto. EGE, FCEN, University of Buenos Aires, Pab. II, Ciudad Universitaria, C1428EHA, Buenos Aires , Argentina;
carla@bg.fcen.uba.ar

The spatio-temporal reinfestation patterns by *Triatoma infestans* following a blanket insecticide spraying in a rural community (Amamá) was analyzed using geographic information system (GIS), satellite imagery, and spatial statistics. Domestic and peridomestic reinfestation by triatomine bugs was monitored from 1993 to 1997 after the apparent elimination of *T. infestans* in 1992. In addition to domiciles, *T. infestans* occupied pig and goat corrals, wood piles, trees, and additional sites associated with chickens. *T. infestans* was detected at least once in 75% of 2110 sites evaluated. The prevalence of sites positive at least once for *T. infestans* during the study period increased sharply from 1993-1995 (0.6-2.9%) to November 1997 (32%). The initial source of *T. infestans* was a pig corral in southern Amamá one year post-spraying. Subsequent infestations were clustered around this initial focus at a distance of ~400 m starting in 1995. In 1996, clustering was maximized in sites within the same compound or in neighboring compounds at distances of 25-175 m. These results indicate that an effective control program on the community level will be based on the spraying of actual epicenters as well as sites within a 450 m of these epicenters to prevent the propagation of *T. infestans*.

Vector biology and control research in southern Africa

M Coetzee, L Manga
"Vector Control Reference Unit, National Institute for Communicable Diseases, P.O. Box 1038, Johannesburg 2000, South Africa;
maureen.coetzee@nhls.ac.za"

In collaboration with the World Health Organization Regional Office for Africa in Harare, Zimbabwe, a multicentre study for the characterization of vector populations and capacity building for vector control in seasonal, epidemic-prone malaria transmission areas of southern Africa, was initiated. Namibia, Botswana, Zimbabwe, Swaziland and South Africa participated in mosquito collections, insecticide susceptibility testing and involvement in malaria transmission. *Anopheles arabiensis* was the major malaria vector in all five countries. Only Zimbabwe and South Africa gave indications of insecticide resistance in *An. arabiensis. Anopheles merus* was implicated in malaria transmission at one locality in central Zimbabwe. A further study on insecticide resistance in northern Kwazulu/Natal Province of South Africa was undertaken. The efficacy of spraying houses with both DDT and pyrethroids, either together as a single mix or one on top of the other was investigated as a possible resistance management tool. Capacity building was a major component of both these projects. Collaborators processed their own samples in the laboratory in Johannesburg, and two were registered for Masters degrees at the University of the Witwatersrand.

Identification of gene candidates for age determination in *Aedes aegypti* (Diptera: Culicidae)

PE Cook, I Iturbe-Ormaetxe, SL O'Neill
"Department of Zoology and Entomology, School of Life Sciences, The University of Queensland, Brisbane, Qld 4072 Australia; p.cook1@uq.edu.au"

Aedes aegypti is the principal vector of dengue, a disease of increasing global significance. Vector population age structure is a critical determinant of a vector population's capacity to transmit disease. Current age-grading methods are of limited value as age estimates are restricted to 15 days, while only females older than approximately 14 days can potentially transmit dengue. Development of an age-grading method that predicts mosquito age over the entire lifespan of *Ae. aegypti* would be a valuable tool for disease transmission studies and evaluating vector control strategies. Here, we describe gene candidates that show age related expression profiles, for a rapid PCR-based method of age determination. Candidate genes have been identified from published *Drosophila* microarray data of gene expression across adult age. *Drosophila* candidate gene expression was confirmed using Northern blots of pooled RNA samples across a range of age groups (adults 1-29 d, with 4 d interval). Gene orthologues from *Ae. aegypti* were isolated by PCR using degenerate primers and gene expression profiles were validated by Northern blots analysis as for *Drosophila*. The application of real-time reverse transcriptase PCR techniques to determine gene expression levels in individual female mosquitoes and the statistical tools to predict age will be presented.

Detection and characterization of the tRNA^{Ile} in the mtDNA control region of myiasis-causing flies (Diptera: Calliphoridae).

G Turqueto Duarte, ACM. Junqueira, TT Torres and AML Azeredo-Espin
"Universidade Estadual de Campinas – Unicamp, Lab. Genética Animal, CBMEG, Campinas, SP, Brazil. PO Box 6010, 13083-875; anacmj@unicamp.br"

The family Calliphoridae is formed by myiasis-causing flies, being known for its economic, medical, sanitary and forensic importance. Ecological similarities and the lack of morphological diagnostic traits may cause problems in the identification of species, especially for larvae. The mitochondrial DNA (mtDNA) is providing important clues for species identification and variability characterization. The control region (CR) represents the major noncoding region of the mitochondrial genome, with a bias towards A+T content. The CR has been divided in two different subregions, including the A domain with conserved sequence blocks and a hipervariable B domain. The entire CR could be recovered in two separated PCR reactions using a specific and universal primers combination. The efficient PCR amplification, sequencing and analysis of nine Calliphoridae species has shown a complete tRNA^{Ile} duplication into the B domain of four *Chrysomya* species: *C. albiceps*, *C. bezziana*, *C. chloropyga* and *C. megacephala*. The tRNA^{Ile} duplication could be used as a diagnostic marker for *Chrysomya* genus identification, since the duplication has not been reported for other related Calliphoridae genus. The characterization of the A domain for Calliphoridae species will allow the evaluation of this region as a molecular marker for evolutionary studies and for identification of Calliphoridae species.

Parasitoids of nuisance flies on Australian cattle feedlots

MM Elson-Harris, PE Green, RL Bright, R Urech, GW Brown, JA Hogsette, AG Skerman
Department Of Primary Industries And Fisheries, Lmb No 4, Moorooka, QLD, 4105, AUSTRALIA; marlene.elson-harris@dpi.qld.gov.au

Populations of adult and immature nuisance flies and associated parasitoids were monitored on three Australian feedlots with one southern Queensland (SQ) feedlot being continuously monitored over two years. In the SQ feedlot both sentinel pupae (cultured *Musca domestica* exposed for 1-2 weeks at various sites) and feedlot pupae, consisting largely of *M.domestica* (85%) and *Stomoxys calcitrans* (12%), were examined for parasitoids. The 4.2% of the sentinel pupae parasitised produced 7 species of parasitoids, with *Muscidifurax raptor* (52%) and *Spalangia cameroni* (39%), predominating. Parasitoids emerged from 10.3% and 11% of the *M.domestica* and *S.calcitrans* feedlot pupae respectively, with the emergence pattern indicating that both species were equally parasitised. Unlike the parasitised sentinel pupae, for feedlot pupae *Spalangia* spp. constituted 90% of the parasitoids with *S.endius*, *S.nigroaenea* and *S.cameroni* comprising 50%, 22% and 18% respectively. *M.raptor*, *Trichomalopsis* sp and Diapriids made up the remaining 10%. Some parasitoid preferences for various feedlot sites were evident but *S.endius* was the most common species found at all sites. Parasitoids, largely *S.endius* and *S.cameroni* were seen in 9% and 12% of pupae from feedlots in central NSW and central Qld respectively. Parasitoids appear to be one of the more important biological control agents on Australian feedlots.

Successional aspects of the sarcosaprophagous arthropods fauna associated to rabbit corpses in the nearing areas to Tenjo (Cundinamarca)

A Ordoñes, G Fagua, MA Dolores García García
Carrera 7ª No 43-82, Universidad Javeriana, Edificio 53; Bogotá, Colombia; fagua@javeriana.edu.co

The succession of adult sarcosaprophagous arthropods was studied using baited Schoenly traps and rabbits as model. The efficiency of the traditional methodology (Ptrad) against the use of baited Schoenly traps (PTC) was comparated. Modifications to the Schoenly trap were made in the material of the trap, a communication with the substrate, interchangeable collector bottles and the collector funnels. During the 42 days of sampling 11.847 individuals were collected included in 99 species (97 in PTC and 63 in Ptrad); this includes 43 families (43 in PTC, and 32 Ptrad) belonging to five troffic rolls: necrophagous, opportunists, parasites, prayers and accidental. Also significant differences in the species abundance, richness, diversity and dominance were found between PTC and PTrad. By multivaried analysis techniques five stages were determined: Fresh (72 hours), Active decomposition (78h), Advanced Decomposition (330h), dry Remains (288h) and Bones (144h). These stages deferred in duration with those found in other works as a result of the sampling efficiency. Significant differences between the five stages were found in the abundance of individuals, species richness, diversity, dominance and community composition. In conclusion the PTC showed to be more effective in collecting arthropod fauna and superior to Ptrad for evaluating the adult sarcosaprophagous succession process.

Altered colonization of dung from cattle treated with doramectin, eprinomectin, ivermectin or moxidectin

KD Floate
"PO Box 3000, 5401-1st Ave. S., Lethbridge Research Centre, Lethbridge, AB, T1J 4B1, Canada; floatek@agr.gc.ca"

Endectocides (e.g., abamectin, doramectin, eprinomectin, ivermectin, moxidectin) are used worldwide to control internal and external parasites affecting cattle. After application, most of the dose is excreted in the faeces of the treated animal where residues can either enhance or reduce the attractiveness of dung to coprophilous insects. By influencing the number of colonizing insects, residues may indirectly alter the rate of dung pat degradation. The current study compared collections of insects from pitfall traps baited with dung of untreated cattle versus dung of cattle treated 1 wk earlier with topical applications of ivermectin, doramectin, eprinomectin or moxidectin. The effect of residues on colonization previously has not been reported for the latter three compounds. In addition, these results are the first to compare directly the effects of faecal residues on colonization, when potential confounding factors of drug formulation, cattle diet, insect species, and time are held constant.

On the ubiquity and phylogeny of *Wolbachia* in lice

GK Kyei-Poku, DD Colwell, P Coghlin, KD Floate
"PO Box 3000, 5401-1st Ave. S., Lethbridge Research Centre, Lethbridge, AB, T1J 4B1, Canada; floatek@agr.gc.ca"

Wolbachia are intracellular bacteria of interest, because they profoundly affect the reproductive fitness of their insect hosts. Here, we provide the first report of *Wolbachia* in the two insect Orders Anoplura (sucking lice) and Mallophaga (chewing lice). We document the apparent ubiquity and diversity of *Wolbachia* in these orders with infections detected in each of 25 tested populations of lice, representing 19 species from 15 genera spanning eight taxonomic families. Phylogenetic analyses indicate a high diversity of *Wolbachia* in lice, as evidenced by the identification of 39 unique strains. Some of these strains are apparently unique to lice, whereas others are similar to strains infecting other insect taxa. *Wolbachia* are transmitted from infected females to their offspring via egg cytoplasm. Hence, the evolutionary radiation of *Wolbachia* strains is predicted to correspond with their host taxa. This prediction is met with strains in the *Wolbachia* taxon Supergroup B, which form a monophyletic clade. In contrast, strains in Supergroup A exhibit phylogenetic discrepancies that previously have been attributed to horizontal transmission between host species, possibly via a parasitoid vector. We interpret such discrepancies in the current study as evidence of genetic recombination between *Wolbachia* strains or between *Wolbachia* and non-*Wolbachia* bacteria.

Host preference in *Anopheles gambiae*: decision between plant and human volatiles in a wind tunnel

WA Foster, W Takken
Department of Entomology, 400 Aronoff Laboratory, 318 West 12th Ave., Columbus, OH 43210-1242, U.S.A.; foster.13@osu.edu

Both sexes of *An. gambiae* have small energy reserves at emergence, and at 27^{o}C they begin to die within 2 days. Thus, 1 night after emergence is a critical time to obtain food. In a 2-choice wind-tunnel olfactometer, they oriented in significantly greater numbers toward honey, a source of nectar-related volatiles, than to human-foot volatiles. This was true both when the volatiles were paired with blanks and when they were presented simultaneously. In the latter case, the difference in response was greater, indicating direct competition between the two kinds of volatiles. After 5 days of sugar feeding and mating, males still strongly preferred honey volatiles, but females responded almost exclusively to human volatiles. These results suggest that under some conditions in the field, females take their first meal preferentially from plants. Females given sugar on the night of emergence exhibited stronger responses to human volatiles the following night, indicating that energy status itself promotes blood feeding, independent of maturation.

Phylogenetic relationships of midges of the *Culicoides obsoletus* species complex (Diptera: Ceratopogonidae) based on ITS2 rDNA sequences

LM Gomulski, R Meiswinkel, JC Delécolle, M Goffredo, G Gasperi
"Dept. of Animal Biology, University of Pavia, Piazza Botta 9, 27100 Pavia, Italy; gasperi@unipv.it"

The midges of the genus *Culicoides* Latreille, 1809 include species that are vectors of orbiviral diseases of bluetongue and African horse sickness that cyclically decimate livestock in the Mediterranean Basin. Recent outbreaks of these diseases in regions where the known Afro-Asiatic vector, *C. imicola,* is absent has incriminated other *Culicoides* species belonging, amongst others, to the Obsoletus Complex of the subgenus *Avaritia* Fox, 1955. The lack of taxonomic clarity concerning these potential vectors stimulated the molecular analysis of 21 *Culicoides* population samples from 18 localities spread throughout mainland Italy. Nuclear ribosomal DNA ITS2 sequence variation was used to determine the genetic differentiation within and between the members of the Obsoletus Complex and related species, by means of AMOVA and phylogenetic analyses. Although morphological discrimination of the members of these complexes is extremely difficult, the molecular analysis clearly demonstrated a high degree of divergence between most of the species. Also evident is that the subgenus *Avaritia* comprises at least three species complexes, all of which are separate from the Imicola Complex which was represented by *C. imicola* as the outgroup. Furthermore, a simple PCR assay was developed which rapidly discriminates between the species of the complex, a prerequisite for vector identification.

"Differences in sensitivity to action of insect hormones analogues and agonists in several populations of *Culex pipiens* s.l. caused by insect pheromones"

'I Gelbic, J Olejnicek"
"Institute of Entomology, Institute Of Parasitology As Cr, Ceske Budejovice, Czech Republic; gelbic@entu.cas.cz"

"Increasing interest for effective insect control, especially of hematophagous insects is provoked by number of diseases transmitted by some species from these insect groups. One of many ways how to control these species is the use of analogues and agonists of insect hormones. These analogues were tested against larvae of different strains of *Culex pipiens*. Larvae of *C. pipiens molestus* and *C. pipiens quinquefasciatus* originated from different countries were used in experiments. *Culex quinquefasciatus* is serious hygienic problem - vector of filariosis. Larvicidal activity of the methoprene, 20-hydroxyecdysone RH-5992 and RH-2484 were tested. All used compounds show different activity among experimental strains. In our laboratory strains - originated from Cuba, Iraq, India (two strains), Taiwan all tested compounds had dose depended activity. Toxic effect, morphological effects - inhibition of larval pupal or pupal-adult transformation and delayed pupation were observed. Very high activity of methoprene and 20-hydroxyecdysone were found in Cuban strain. On the other hand RH compounds were very active in Taiwanian strain. For example 20-hydroxyecdysone was still very toxic at 5 ppm concentration in Cuban strain, while in the Indian strain same toxic effect was caused at concentration 100 ppm. Similar results were obtained with methoprene RH-5992 and RH-2485.
"

Gene expression in ticks induced by blood meal and lyme borreliosis spirochetes

N Rudenko, M Edwards, L Grubhoffer
Institute of Parasitology, Academy of Sciences and Faculty of Biological Sciences, University of South Bohemia, 370 05 České Budějovice, Czech Republic; liborex@paru.cas.cz

The castor bean tick, *Ixodes ricinus,* is the principal European vector of *Borrelia burgdorferi* sensu lato, the causative agent of Lyme borreliosis (LB). Differentially expressed genes that underlie the host response of *I. ricinus* to *B. burgdorferi* have not been investigated prior to this study. The characterization of genes that are induced following an infected blood meal is essential for gaining an understanding of the molecular mechanisms that underlie vector-pathogen interactions. Subtractive hybridization was used to isolate tick genes that were induced in whole ticks following a blood meal and a blood meal on a *B. burgdorferi* infected guinea pig. Novel cDNA clones with similarity to cytochrome c oxidase, salivary secreted protein, actin, glutenin and a cysteine protease pro-peptide were induced following a blood meal. Novel cDNA clones with similarity to thioredoxin peroxidase(s), dolichyl-phosphate glucosyltransferase, glutathione-S-transferase, defensin, ML domain containing protein and von Willebrand factor were induced following *B. burgdorferi* infection. Northern analysis and RT-PCR were used to verify that these genes were differentially expressed in ticks and to determine the site of their expression. (Supported by the Grant Agency AS CR No. A6022306.)

Immune proteins in the soft tick *Ornithodoros moubata*

P Kopáček, V Kovář, L Grunclová, T Saravanan, I Šauman, C Weise, L Grubhoffer
Institute of Parasitology, Academy of Sciences and Faculty of Biological Sciences, University of South Bohemia, 370 05 České Budějovice, Czech Republic.

Three proteins playing a role in the immune system and/or pathogen transmission were isolated from the soft tick *Ornithodoros moubata*.:1) An abundant tick plasma protein was isolated and identified as a protease inhibitor of a_2-macroglobulin (a_2M) family. Tick a_2M - **TAM** has an atypical structure in that it is composed of two noncovalently bound subunits of about 180 kDa. Each subunit is post-translationally processed in two disulfidically bound chains in a manner similar to the C3 and C4 components of complement. TAM sequence is closely related to the *Limulus* a_2M. TAM possesses at least 4 variants of bait region domain created likely by alternative splicing. 2) A sialic-acid binding lectin named **Dorin M,** apparently produced by tick hemocytes has been purified from tick plasma. Cloning and sequencing of the DorinM gene revealed that the protein shares significant similarity with the family of fibrinogen-related proteins (especially tachylectin 5A, B from the horseshoe crab and ficolins of vertebrates) which function as pattern-recognition molecules. 3) An anti-bacterial protein **lysozyme** was isolated from gut contents of engorged ticks. The enzyme is apparently upregulated upon bloodmeal. The features of lysozymes with anti-bacterial as well as digestive function seem to be combined in the tick gut lysozyme sequence.

Characterization of hemolipoproteins from ticks.

NP Gudderra, CS Apperson, RM Roe, DE Sonenshine, JF Andersen.
"National Institutes of Health, NIAID, Lab of Malaria and Vector Research, Medical Entomology Section 12735 Twinbrook Parkway, Room 2E-32C, Rockville, MD 20852, USA; ngudderra@niaid.nih.gov."

Hemolymph proteins in ticks have not been completely studied. The hemolymph protein most studied in ticks has been vitellogenin (Vg). Besides Vg, another major hemolymph storage protein, a carrier protein (DvCP) and heme-binding lipoprotein (HeLp, for Heme LipoProtein) has recently been studied in two hard tick species but not in soft ticks. DvCP from *Dermacentor variabilis* is identical to a heme-lipoprotein (HeLp) from *Boophilus microplus*. An analogous protein to DvCP was reported in the soft tick, *Ornithodoros parkeri* (OpCP) but its tissue distribution and biochemical properties have not been fully understood. Further characterization of OpCP and biochemical characterization of major hemolipoproteins from other important tick species is in progress. Biochemical and molecular comparison of major hemolipoproteins across tick species and their significance to tick biology will be discussed.

Molecular detection of several tick-borne pathogens from ticks in Japan.

H Inokuma, H Hiraoka, S Taroura, T Beppu, Y Yoshizaki, Y Shimada, Y Sakata, K Itamoto, M Okuda.
Faculty of Agriculture, Yamaguchi University, Yamaguchi 753-8515, Japan; inokuma@yamaguchi-u.ac.jp

Detection and analysis of several tick-borne pathogens, including *Rickettsia, Ehrlichia, Hemoplasma, Borrelia* and *Babesia,* from ticks recovered from dogs and cats in Japan were attempted using molecular techniques. A total of 1136 tick samples from dogs and 132 from cats were examined for tick-borne pathogens by using genus- and species-specific PCR, and sequence analysis. Some well-known pathogens such as *Anaplasma platys, Mycoplasma haemofelis, Mycoplasma haemominutum, Babesia gibsoni, Babesia canis* and *Borrelia garinii*, were detected and some new information on their distribution in Japan were added. DNA fragments of some new species were also found in the present study. Several rickettsial DNA closely related to *Rickettsia japonica, R. helvetica, R. canada,* or *R. akarii* were detected. Ehrlichial DNA closely related to a nevel *Ehrlichia* sp. detected in Tibet, Thailand and Africa were detected from *Hamaphysalis* ticks. Unique sequences that were similar to those of *Babesia odocoilei* and *Babesia divergens* were also obtained from *Ixodes ovatus*. *Borrelia valaisiana*-like DNA were detected from *Ixodes granulatus* in Okinawa. The combination of PCR and sequence analysis used in this study was demonstrated to be useful for detection of tick-borne pathogens from ticks. These can be excellent tools for epidemiological study of tick-borne diseases.

Species composition and dispersal of nuisance flies breeding on poultry farms in southern Australia

PJ James, C Krawec, NA Schellhorn, P Pepper
Department of Primary Industries, Animal Research Institute, LMB No 4, Moorooka, QLD, 4105 Australia; peter.james@dpi.qld.gov.au

"Ability to disperse and vectorial capacity makes flies a significant biosecurity and food safety risk on poultry farms. Although the species and biology of flies breeding on these farms has been widely studied overseas there have been few studies in Australia. We monitored numbers and species of flies breeding on egg farms in southern Australia over a 12 month period and assessed the dispersal of the major species using mass marking of resident fly populations with fluorescent dye. The little house fly, *Fannia cannicularis* and to lesser extent false stable fly *Muscina stabulans* were the major species for most of the year. In contrast to most overseas studies, *Musca domestica* was absent or present in only low numbers at most times. Most *F. cannicularis* remained within 700 m of the farm whereas marked *M. stabulans* were trapped at distances of up to 2 km. Modelling of total trap catches by distance predicted maximum dispersal distances of 1.6 km for *F. cannicularis* and 2.4 km for *M. stabulans.*

y-Season mosquito breeding associated with irrigation at Kununurra, Western Australia: potential impact on arboviral disease transmission.

A Jardine, MD Lindsay, J Heyworth, P Weinstein
M431, School of Population Health, The University of Western Australia, 35 Stirling Highway, Crawley, WA, 6009, Australia; andrewj@sph.uwa.edu.au

This study describes a preliminary investigation into the role of the Ord River Irrigation Area at Kununurra in mosquito production during the dry season. Specifically, the study aimed to test the hypothesis that irrigation has provided the opportunity for year-round breeding of arbovirus vector mosquitoes. A ten-day adult and larval mosquito sampling survey revealed that breeding was occurring during August, the iest month of the year at Kununurra, supporting the hypothesis that mosquitoes can breed year-round. Significantly larger numbers and percentages of adult *Culex annulirostris*, an important disease vector in Australia, were collected within the irrigation area (n=3706, 44.6%) compared to reference areas outside the irrigation area (n=363, 9.8%) (mean difference 76.2 per trap per night; 95% CI 38.6, 113.7; $p<0.001$). Larval *Cx. annulirostris* were also collected at several sites within the irrigation area, whereas none were collected at reference areas. Year-round mosquito breeding at Kununurra may increase human health risk from arboviral disease, as has been borne out by recent elevated notifications of Ross River virus disease in the late y-season compared to other towns in the Kimberley region. Mosquito management needs to be given a high priority to ensure this health risk is not further exacerbated. Strategies to reduce mosquito breeding should primarily focus on modification of breeding habitats and altering of irrigation protocols.

Comparative analysis of Calliphoridae complete mitochondrial genome sequences with other dipterans.

ACM Junqueira, AML Azeredo-Espin
"Universidade Estadual de Campinas – Unicamp, Lab. Genética Animal, CBMEG, Campinas, SP, Brazil. PO Box 6010, 13083-875; anacmj@unicamp.br"

In the view of the medical, veterinary, economic and forensic importance of Calliphoridae species, a comparative analysis of their nucleotide sequences with other dipterans would be useful for the molecular evolutionary studies of this family. Mitochondrial DNA (mtDNA) has been used mainly because of its maternal inheritance, accelerated rates of substitution, and lack of recombination. Of the 1020 Calliphoridae species described, 45 are listed in GenBank, including two complete mitochondrial genomes of the species *Cochliomyia hominivorax* and *Chrysomya chloropyga*. The comparison of the nucleotide content, skewness, aminoacid sequences, and codon usage between the mtDNA of Calliphoridae species and among the dipteran species can provide important features for studies in different taxonomic levels. Until now, the *cox1* gene is the most used molecular marker for studies among Calliphoridae and across a broad range of insects, but the comparison of individual and concatenated sequences of another mitochondrial genes among dipteran species have shown distinct degrees of conservation, indicating that some of them also should be employed as reliable molecular markers. The complete mitochondrial genomes are an useful source for improving primer designing, molecular identification of species, and for elucidate the potential of individual and combined genes for molecular systematic studies of Diptera.

Dispersal of house flies in the agricultural and urban environment: population dynamics Study using microsatellite markers

S Chakrabarti, S Kambhampati, L Zurek
Kansas State University, 123 West waters Hall, Manhattan, Kansas-66506, USA.

The house fly, *Musca domestica* L., is a synanthropic species with worldwide distribution. Due to their unrestricted movement, mode of feeding, developmental habitats, and attraction to places where food is prepared and stored, house flies greatly amplify the risk of human exposure to food-borne and other pathogens. Flies that develop in animal productions where antibiotics are frequently used for prophylaxis and growth promotion carry antibiotic-resistant bacteria that maybe transmitted to food intended for human consumption, leading to illnesses that are difficult to treat. However, no studies have been undertaken to quantify the extent of house fly movement between rural to urban areas. Therefore, our objective is to examine the population genetics of house flies and estimate the extent of dispersal/migration from rural to urban areas and *vice versa* in Kansas. As a first step, we developed polymorphic microsatellite loci for house flies. Here we report on the isolation, characterization, and optimization of microsatellite loci and preliminary results on population dynamics of house flies.

Comparative study on the nocturnal behavior of *Aedes* mosquitoes using a new device equipped with photoelectric sensor

H Kawada, M Takagi,
"Department of Vector Ecology & Environment, Institute of Tropical Medicine, Nagasaki University, Nagasaki, Nagasaki 852-8523, Japan;
vergiss@net.nagasaki-u.ac.jp"

The nocturnal behavior of non-blood fed *Aedes aegypti* and *Ae. albopictus* females was observed using a new automatic recording device equipped with photoelectric sensor. Carbon dioxide, heating and the contrast of black and white color were used for the attractive factors for mosquitoes. The nocturnal host seeking activity positively correlated to the increasing light intensity in both species. *Ae. aegypti* was found to be more sensitive to light than *Ae. albopictus.* The threshold of light intensity for activation of the nocturnal host seeking activity was < 0.1 lux (ca 0.01 foot candle) in *Ae. aegypti* and > 10 lux (ca 1 foot candle) in *Ae. albopictus,* respectively. Complete darkness in the daytime, on the other hand, deactivated the host seeking activity of *Ae. aegypti,* irrespective of their intrinsic circadian rhythm, which might well explain the importance of the sense of sight in *Ae. aegypti.*

Rainfall events determine the abundance of carrion feeding beetles in a West African savanna

FT Krell, M Boutros, S Krell-Westerwalbesloh, C Linder
Soil Biodiversity Programme, Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, U.K.; f.krell@nhm.ac.uk

Using carrion beetles on goat and warthog skins as a model system, we studied the influence of single rainfall events on the abundance and flight activity of insects in a tropical savanna (Parc National de la Comoé, Côte d'Ivoire). Although the attraction of the skins declined with time (due to degradation and desiccation), the freshness of the resource was not the major factor determining the abundance of carrion beetles. After rainfall events the number of beetles sharply increased, even with older skins. We recorded the same effect in regularly watered skins (simulating continuing freshness), showing that the humidity of the resource was not responsible for the peaks. The sharp abundance peaks after rainfall events is of relevance for both ecological field studies which have often a standardized sampling programme ignoring weather, and for forensic studies relying on a predictable succession of carrion users which can be strongly influenced by weather.

Environmental parameters of habitat on breeding behavior of *Aedes albopictus* in Chonju, Korea

JJ Lee, W Akram, KHAhn
"Faculty of Biol. Resources Science, Chonbuk Nat'l Univ., Chonju 561-756, Korea; (jjlee@chonbuk.ac.kr)"

Aedes albopictus during present studies has been associated with tree, automobile tires, very rarely apartment basements and open outdoor garbage containers. However, a contrast to the habitats of this insect is found; at one stage it seems that this mosquito can live in almost all places wherever there is debris, standing water regardless of the pH acidic or alkaline. Whereas, in certain cases it is evident that this insect is confined to a particular habitat, during the present investigation, it was quite evident that the outbreak of adult *Aedes* is very much dependent upon the percent humidity and temperature. The artificial habitats, that is abandoned tanks, cans, stray automobile tires if they are close to plantation or are in shade for most of the photoperiod they tend to be positive breeding sites for *Aedes* sp. In other situations, the same habitat in open with sunlight throughout the day tends to be negative breeding site. Water level in containers is also known to effect the population and species of the mosquitoes. Temperature and precipitation have been found to impose serious effects not only on the distribution of *Aedes* but also the size of the immature and adults as well.

Sheep lice control with entomopathogenic fungi

D Leemon, P James
"Animal Research Institute, Locked mail bag No 4, Moorooka, QLD, 4105, Australia; Diana.Leemon@dpi.qld.gov.au"

Preliminary investigations into the potential for the biological control of the sheep body louse (*Bovicola ovis)* by the entomopathogenic fungi *Metarhizium anisopliae* and *Beauveria bassiana* are reported. Scanning electron microscopy was used to investigate the uptake of inoculum from the wool by lice and bioassay methodologies using a wool substrate were developed to test pathogenicity. Fungal strains were identified that caused a 100 % mortality of lice after 5days. The level of lanolin in the wool and stage of louse development had a significant effect on mortality rates but there was no effect of temperature within the range of 31^{o}C to 38^{o}C. Further studies are investigating factors that influence the pathogenesis of fungal disease in lice.

The mitochondrial DNA control region of Muscidae species (Diptera: Calyptratae): evolution and structural organisation

MT Oliveira, AML Azeredo-Espin, AC Lessinger
Laboratório de Genética Animal, Centro de Biologia Molecular e Engenharia Genética (CBMEG), Universidade Estadual de Campinas (UNICAMP), CP 6010, CEP 13083-875, Campinas, SP, Brazil; lessinge@unicamp.br

The control region of insect mitochondrial DNA (mtDNA), also called A+T-rich region, is an interesting target for studies regarding the structure and evolution of the mtDNA. This non-coding region has an biased AT content, putative regulatory elements for transcription and replication processes, high levels of nucleotide substitutions and ins/dels events, and structural instabilities related to the organisation of internal sequence elements and its flanking genes. The sequence of *Haematobia irritans* and *Musca domestica* (Diptera: Muscidae) control regions have been determined and the sequencing of *Stomoxys calcitrans* control region is being conducted. Conserved sequence elements described for insect mtDNA control regions (such as poly-T streches, TA(A)n in tandem repeats, 'stem-and-loop' secondary structure and G+C-rich region) and conserved sequence blocks previously described for other Calyptratae species (myiasis-causing flies) have been identified in the Muscidae mtDNA control region. The share of such structural homologous elements among Muscidae and myiasis-causing flies suggests that Muscoidea and Oestroidea superfamilies have a similar regulatory mode for mtDNA transcription and replication processes. Intraspecific analysis of *H.irritans* populations using control region as a molecular marker are being conducted and length variation among specimens from Brazil, Argentina, Uruguay, Venezuela and Malaysia were already identified.

Key diagnostic characteristics of the third instar larvae of *Calliphora croceipalpis* and *Sarcophaga cruentata*

S Brink, TC van der Linde, L Basson, PWJ van Wyk
Department of Zoology & Entomology, University of the Free State, P.O. Box 339, loemfontein 9300 South Africa; vdlindet.sci@mail.uovs.ac.za

Following the death of a human, various insects involved in the decomposition process invade the corpse. This invasion takes place in an orderly sequence, called insect succession. This poster deals with those morphological characteristics used to distinguish between third instar larvae of the secondary invader *Calliphora croceipalpus* (Jaennicke) and the tertiary invader *Sarcophaga cruentata* (Meigen). All aspects of larval morphology were studied, but specific note was taken of the following aspects for diagnostic purposes: nature of the spines and spine band, anterior spiracles, posterior spiracles and the spiracular atrium of the posterior spiracles. The distinguishing characteristics of *S. cruentata* were the deeply recessed atrium cavity and the scalloping of the inner margin of the posterior spiracular plate. In *C. croceipalpus* the distinguishing characteristics were the shallow posterior spiracular atrium and the orientation of the spiracles. These key characteristics were compared to the key characteristics of the third instar larvae of the other species that form part of this study *viz. Lucilia cuprina* (Wiedemann), *Chrysomya chloropyga* (Wiedemann), *Chrysomya marginalis* (Wiedemann) and *Chrysomya albiceps* (Wiedemann).

The effect of temperatue on the development of the immature stages of *Hemilucilia segmentaria* (Fabricius) and *Hemilucilia semidiaphana* (Rondani) (Diptera: Calliphoridae).

PJ Thyssen, AX Linhares
"Departament of Parasitology, Institute of Biology, UNICAMP, CP 6109, CEP 13083-970, Campinas, SP, Brazil; aricio@unicamp.br "

Diptera larvae are among the most important carrion insects, because they are one of the most frequent and abundant organisms involved in animal decomposition process. This work objectived to determine the effect of temperature on the development of immatures of *Hemilucilia segmentaria* (Fabricius) and *Hemilucilia semidiaphana* (Rondani), two species of Neotropical blowflies commonly associated with animal carrion in rural and natural areas of Brazil, being two of the most important forensic indicators in the neotropics. The rearing of the immatures of both species was done using growth chambers with temperatures set at 10, 15, 20, 25, 30 and 35ºC, 12h photoperiod and 60 ±10% relative humidity. The mean developmental time from egg to pupation decreased as temperature increased. There were also differences in larval length, width and weight. These data were used to determine logistic growth curves to be used in estimating the age of the immatures of both species.

Larval competition differentially affects arbovirus infection and dissemination in *Aedes albopictus* and *Aedes aegypti*

BW Alto, LP Lounibos, S Higgs, SA Juliano
"University of Florida, Florida Medical Entomology Laboratory, 200 9th St. SE, Vero Beach FL 32962, U.S.A.; lounibos@ufl.edu"

We determined the species-specific effects of intra- and interspecific larval competition between the mosquitoes *Aedes albopictus* and *A. aegypti* on adult susceptibility to infection with the arbovirus Sindbis. We found higher infection rates and whole-body viral titer, but lower dissemination rates, for *A. albopictus* than for *A. aegypti*. For *A. albopictus* but not *A. aegypti*, intra- and interspecific competition resulted in greater infection rates compared to low-competition rearing conditions. Size-dependent and size-independent effects of competition influenced arboviral infection and dissemination of *A. albopictus* in opposite ways. At a single level of competition (i.e., at a single density), higher viral titers occurred in larger *A. albopictus,* but between competitive treatments adults from low-competition larval rearing conditions had greater mean body size and lower body titer and a lower proportion infected, compared to adults emerging from high-competition conditions. Competition experienced by larvae had no detectable effect on acquisition of infection by *A. aegypti*. Higher dissemination rates and less sensitivity of *A. aegypti* females to effects of larval competition are consistent with the greater role of this species as a vector of viruses to humans.

Mitochondrial DNA variability in screwworm fly from Uruguay.

ML Lyra, P Fresia, S Gama, J Cristina, AML Azeredo-Espin.
"PO Box 6010, CBMEG, UNICAMP, CEP 13083-875, Campinas-SP, Brazil; marilyra@unicamp.br"

The New World Screw-worm fly (NWS), *Cochliomyia hominivorax* (Diptera: Calliphoridae), is an obligate ectoparasite that causes primary myiasis in warm-blooded vertebrates throughout Neotropical regions. In Uruguay this pest is responsible for important economic looses to cattle breeding sector. In this work RFLP and PCR-RFLP analysis of mitochondrial DNA (mtDNA) were used to examine the genetic variability and population structure of six NWS geographic populations from Uruguay. RFLP analysis was performed using 5 restriction endonucleases and there were found 12 haplotypes. PCR-RFLP was used to survey mtDNA variation in control region and Cytochrome Oxidase subunits I and II. There were found 8 haplotypes utilizing 3 restriction endonucleases. The two techniques revealed the same pattern of haplotypes distribution, three haplotypes widely distributed and the remaining locally distributed. DNA diversity and divergence were estimated and the preliminary results revealed high genetic variability but no population subdivision. Our data are being compared with previous works that analyzed Libya samples collected during 1988 infestation in order to elucidate the origin of the introduction. The characterization of NWS intra specific genetic variability at the geographic level is necessary to monitoring the expansion in the current distribution and into screw-worm free areas. Financial support: FAPESP, CNPq, IAEA.

Paternal genome elimination in the human body louse, *Pediculus humanus* Linnaeus, 1758.

CJ McMeniman, SC Barker
Department of Microbiology and Parasitology, and Institute for Molecular Bioscience, University of Queensland, St Lucia, QLD 4072, Australia; c.mcmeniman@uq.edu.au

Eight F_1 and two F_2 families of human body lice, *Pediculus humanus*, were bred to examine the inheritance of alleles in this species. Alleles at four autosomal microsatellite loci segregated in two ways in these lice: (i) in a Mendelian fashion i.e. diplo-diploidy, and (ii) in a non-Mendelian fashion. We interpret the latter as paternal genome elimination, where parental males transmit, exclusively, their maternal genome to their offspring (functional haplodipoidy). Further investigations of this extraordinary finding may provide insight into how haplodiploidy evolves in insects.

Anthropogenic ecological change and insects of health concern in New Zealand.

M McIntyre, D Slaney, J Derraik, P Leisnham, A Snell, L Villa.
Ecology & Health Research Centre, Department of Public Health,Wellington School of Medicine & Health Sciences, Wellington South, New Zealand; mary.mcintyre@wnmeds.ac.nz

Key components of anthropogenic ecological change include land conversion to human uses and the fragmentation and disturbance of native ecosystems. This is combined with the spread of alien species and human commensals and loss of locally evolved species. New Zealand is a microcosm of some global issues in this regard. Our research examines ecological change and changes in the habitat, distribution and productivity of native and exotic mosquitoes, the relation of mosquitoes and potential arbovirus vector species, and the disease burden of bee & wasp stings in New Zealand.

Paternal genome elimination in the human body louse, *Pediculus humanus* Linnaeus, 1758.

CJ McMeniman, SC Barker
Department of Microbiology and Parasitology, and Institute for Molecular Bioscience, University of Queensland, St Lucia, QLD 4072, Australia; c.mcmeniman@uq.edu.au

Eight F_1 and two F_2 families of human body lice, *Pediculus humanus,* were bred to examine the inheritance of alleles in this species. Alleles at four autosomal microsatellite loci segregated in two ways in these lice: (i) in a Mendelian fashion i.e. diplo-diploidy, and (ii) in a non-Mendelian fashion. We interpret the latter as paternal genome elimination, where parental males transmit, exclusively, their maternal genome to their offspring (functional haplodipoidy). Further investigations of this extraordinary finding may provide insight into how haplodiploidy evolves in insects.

An *in vitro* larval immersion microassay for screening candidate Acaricides

WH White, PR Plummer, CJ Kemper, RJ Miller, RB Davey, JA Gutierrez, JA Meyer, CK Smith
Elanco Animal Health, 2001 W. Main St., op Code GL21, Greenfield, Indiana, USA; meyerje@lilly.com

Acaricide resistance in *Boophilus microplus* is rising dramatically in regions of the world where this ectoparasite is prevalent, posing significant economic burdens on cattle production and productivity in Central and South America, South Africa and Australia. While *Boophilus* has been eradicated from the United States, acaricide resistance will increase the threat of reintroduction into southern portions of the U.S. New chemical agents are needed that combine potent activity with novel modes-of-action not exhibiting cross-resistance to existing acaricide classes. Currently, none of the available *in vitro* tick bioassays offers the flexibility, speed, and sensitivity required to rapidly screen large numbers of compounds for candidate acaricides. We have optimized and characterized a larval immersion microassay (LIM) that offers superior sensitivity, the flexibility to accommodate multiple solvents and detergents, and a robust capability for screening compounds in a relatively short period of time using a minimal quantity of test article for evaluation. Dose-mortality studies were conducted against multiple ixodid ticks, including ug-resistant *B. microplus*, with representative formamidine, organophosphate, synthetic pyrethroid, pyrazole, macrocyclic lactone and carbamate acaricides. The rationale for using this method to screen chemical or natural product libraries and identify, characterize, and prioritize compounds for further development will be highlighted.

Incidence of bed bugs (Hemiptera: Cimicidae) in shared Accommodation In Sydney, Australia

PF Miller, BA Peters, N Ryan
Department of Health Sciences, University of Technology, Sydney, PO Box 123 Broadway NSW 2007, Australia; Peter.Miller@uts.edu.au

Bed bugs have remerged as significant pests in Australia and worldwide in the past ten years, The results of a survey of the incidence of bed bugs in shared accommodation in Sydney is presented. The survey examined the incidence of the bed bugs and the relationship of the infestation to a number of factors including, season, building construction and furnishings. It also examined control methods, their frequency and effectiveness. The results demonstrated widespread incidence of bed bugs with the majority of premises reporting an infestation in the previous 12 months and with many premises having multiple infestations throughout that period. Current control measures did not seem to be eliminating the problem as recurrence of the pest was common. A more comprehensive control strategy for bed bugs needs to be developed to manage this pest in shared accommodation.

Characterization of the enzymatic activities present in extracts of various mites.

MS Morgan, LG Arlian
Dept. of Biological Sciences, Wright State University, Dayton, OH 45435; Marjorie.morgan@wright.edu

Many of the previously-characterized allergens of house dust mites are known to be proteases and this enzymatic activity is thought to contribute to their allergenicity. Other astigmatid mites are also known to be allergenic but little or nothing is known about their enzymatic activities. The purpose of this study was to characterize the enzymatic activities present in extracts from 9 species of astigmatid mites, several of which have not previously been investigated. Extracts were prepared from 5 stored product mites (*Chortoglyphus arcuatus, Lepidoglyphus destructor, Blomia tropicalis, Tyrophagus putrescentiae, Acarus siro*), 3 house dust mites (*Dermatophagoides farinae, D. pteronyssinus, Euroglyphus maynei*) and one parasitic mite (*Sarcoptes scabiei*). ApiZym strips were used to screen for the presence of 19 individual enzyme activities. Digestion of 9 other substrates was also evaluated by spectrophotometric or electrophoretic methods. All mites exhibited some form of phosphatase, esterase, aminopeptidase and glycosidase activity although their substrate specificities varied considerably. Scabies mites did not possess detectable serine peptidase activity nor were they able to hydrolyze gelatin or casein while all other mites exhibited these activities. Storage mites possessed enzymes capable of degrading the widest range of substrates while scabies mites had the most limited proteolytic capacity.

Klinotactic orientation of the northern fowl mite to heat

JP Owen, BA Mullens, RT Cardé, KA Justus
Department of Entomology, University of California, Riverside, CA 92521; (bradley.mullens@ucr.edu)

The northern fowl mite (NFM) (*Ornithonyssus sylviarum*) is a cosmopolitan bird ectoparasite and a serious pest of the U.S. poultry industry. Mite infestations spread within a flock, even when direct bird-to-bird contact is prevented, and heat is a suspected orientation cue. NFM movement patterns were evaluated in a spatial heat gradient, as well as in an environment with temporal fluctuation of temperature (spatially uniform). Mites were filmed and the movement tracks were digitally analyzed for changes in velocity, angular shift and mean bearing. NFM significantly increased linear velocity when exposed to heat (35 °C) relative to control mites in ambient conditions (~27 °C). Mean track bearings were significantly associated with the position of the heat source in a spatial gradient, while track bearings of mites in ambient conditions were randomly directed. Temporal shifts in temperature from heated to ambient condition caused NFM to execute turns ≥ 90° within 5 seconds. Shifts in temperature from ambient to heated condition did not consistently cause NFM to execute turns ≥ 90°. These experiments indicate NFM orient to a heat source by comparing temperatures at different points in time (longitudinal klinotaxis) and executing turns based on internally stored (idiothetic) proprioceptive information.

Screening medicinal plant extracts for effects on *Aedes aegypti* (Diptera : Culicidae) and toxicity to a non target organism

S Promsiri, A Naksathit, M Kruatrachue, U Thavara
Department of Biology, Faculty of Science, Mahidol University, Rama VI Road, Bangkok 10400, Thailand; grans@mahidol.ac.th

A preliminary study was conducted to find out the effects of the extracts of 112 medicinal plant species, collected from the southern part of Thailand, on *Aedes aegypti*. Studies on larvicidal properties of plant extracts against the third and fourth instar larvae of *Ae. aegypti* showed fourteen species with high toxicity. Six plant species were comparatively more effective against the larvae at very low concentration. These extracts demonstrated no or very low toxicity to guppy fish (*Poecilia reticulata*). Three plants with promising larvicidal activity, *Mammea siamensis, Anethum graveolens* and *Annona muricata,* were used to study of the impact of the extracts on the life cycle of *Ae. aegypti*. The results showed that these plants affected the reproductive potential of surviving adults by reducing the number of eggs laid and egg hatchability. The first instar larvae were very susceptible to *A. muricata* and the second instar larvae were susceptible to *A. graveolens* while the third and fourth instar larvae were susceptible to *M. siamensis.* These extracts delayed larval development and inhibited adult emergence.

The prevalence rate of *Leishmania* infection among *Phlebotomus* collected from Abardejh of Varamin Iran

H Nekouie, M Assmar, MR Razavi
Department of Parasitology, Pasteur Institute of Iran; h_nekouie@yahoo.com

Cutaneous Leishmaniasis is a prevalent tropical parasitic disease, which is caused by Leishmania protozoa. The infection can be limited in immun-compitant person, but it could progress to a chronic and ulcerative disease in immuno-comprmised person. The reservoirs are carnivore and rodents and the vectors are Phlebotomus. Abardejh of Varamin is located in southeast of Tehran and there is a tropical ecosystem in its eastern border. There is a suitable condition by the Tamarisk and rodents exist for *Phlebotomus* activity. In this study we investigated the prevalence of Phlebotomus population in Abardejh district. The collected sandflies by funnel trap from rodents' barrows transferred to the department of Parasitology at Pasteur Institute of Iran .The sampling was continued during the spring and summer in periodicals dates. The collected sand flies were studied to define the genius and species before parasitological culture in NNN media. The data revealed that the maximum activities of Phlebotomus were in Jun and July months. The results indicated the high prevalence rate of infection among the sand flies. This could be a matter of debate because of human and agricultural environments are located closely to this district. Therefore application of chemical control, environmental sanitation seems to be required to control of tranfection from sand flies to man.

The molecular identification of closely related calliphorids (Diptera: Calliphoridae) of forensic importance.

LA Nelson, JF Wallman, M Dowton
"Institutes of Biomolecular Science and Conservation Biology, School of Biology, University of Wollongong, Wollongong NSW 2522;
lan51@uow.edu.au"

Blowfly larvae (Diptera: Calliphoridae) are one of the most useful groups of insects utilised during the investigation of human deaths because they are among the first colonisers of a cadaver. The identification of such larvae is a critical step when estimating the the postmortem interval (PMI), as the rate of larval development can vary substantially between species. Two blowflies that have the potential to feature in forensic investigations are *Chrysomya semimetallica* and *Ch. latifrons.* The identification of these species is hampered by their almost indistinguishable morphologies, even as adults. The species were differentiated on the basis of two highly variable regions of the ribosomal DNA genes – the internal transcribed spacer (ITS) sequences. The amplification of ITS2 from both species was readily accomplished, however only ITS1 from *Ch. semimetallica* amplified successfully. The ITS2 differences correspond to 1.22 % sequence divergence between the species. A rapid, cost-effective strategy for species identification would involve PCR amplification of the ITS regions, followed by restriction fragment length polymorphism (RFLP) analysis. Despite the differences within ITS2, no restriction sites were observed that could differentiate the two species. Assessment of this possibility in ITS1 will be achievable once the remaining data is obtained from *Ch. Latifrons*.

A global presence of *Wolbachia* in human lice?

GK Kyei-Poku, MA Perotti, P Coghlin, R Speare, DD Colwell, KD Floate, HR Braig
School of Biological Sciences, University of Wales Bangor, Bangor, Gwynedd, LL57 2UW, UK; bssc13@bangor.ac.uk

Wolbachia are intracellular bacteria of general interest. The profound effects on the reproductive fitness of their insect hosts have resulted in plethora of phenotypes, which still await a full characterisation. Infections of *Wolbachia* in lice affecting humans are of particular interest. Endosymbionts of lice have a great potential for the control of these insects. Previous research in Canada suggests that infections of *Wolbachia* occur in all species of lice (Anoplura, Mallophaga). Independent and concurrent research in Wales provides substantiating evidence. The current study represents the subsequent joint efforts to test for the ubiquity of *Wolbachia* infections in populations of human lice (i.e, head lice - *Pediculus humanus capitis*, body lice - *Pediculus humanus humanus*, pubic lice - *Pthirus pubis*) from different continents.

Field efficacy of a personal insect repellent based on essential oils from Australian native plants against the mosquito (Diptera: Culicidae) and the biting midge (Diptera: Ceratopogonidae)

BA Peters, PF Miller, JA Staton
Department of Health Sciences, University of Technology, Sydney, PO Box 123 Broadway NSW 2007, Australia; Bryce.Peters@uts.edu.au

Field trials were carried out in a wet tropical climate at separate sites in Cairns, Far North Queensland, Australia in Autumn 2002. One site consisted of a fresh water creek infested by mosquitoes and the other site a mangrove wetland infested by biting midges. Both studies were carried out during daylight hours and were conducted by periodically exposing human volunteers with bare lower legs (knee to ankle) to mosquitoes or biting midges over a four-hour period. Counts were made of mosquito landings over a five-minute period and biting midge landings over a three-minute period. Both legs of each volunteer were used to give five replicates of the repellent formulation and five replicates of the untreated control. Against mosquitoes, primarily *Verrallina carmenti* and biting midges, primarily *Culicoides ornatus*, the formulation significantly reduced the landing rate compared to untreated legs over the entire four-hour study period. This study demonstrated that this formulation provided protection against mosquitoes and biting midges for up to four hours after application.

Natural promastigote infection of *Phlebotomus caucasicus* in a new focus of visceral leishmaniasis in north west of Iran

Y Rassi, F Kaverizadeh, E Javadian
PO Box 6446,Tehran 14155, I.R. Iran Dept. of Medical Entomology &Vector Control, School of Public Health& Institute of Health Research, Tehran University of Medical Sciences

An investigation was carried out in Ahar County (a new focus of Visceral Lieshmaniasis) in order to determine the vector (s) of disease. This study was done in eastern Azarbaijan, North-west of Iran during the summer of 2003. Sand flies were collected using sticky papers, CDC light traps as well as aspirators. All of the collected sand flies were dissected in a op of normal saline for surveying of promastigote. Head and the two last abdomen segments of specimens were mounted in a op of Puri,s medium for species identification. Totally, 215 sandflies were collected including: *Phlebotomus kandelakii* (57.2%), *P.perfiliewi* (18.1%),*P.caucasicus* (11.2%), *P.sergenti* (7.9%), *P.papatasi* (3.3%) and *P(.adlerius)sp.*(2.3%). Only 1 out of 24 *P.caucasicus*(4.2%) was found naturally infected with parasites. This is the first infection report of *P.caucasicus* in this region. The ecology and some behavioural aspects of the vector will be discussed in details.

Application of a new *Aedes* surveillance method in Botucatu, Brazil.

LA Nogueira, LT Gushi, NG Madeira, PEM Ribolla
PO. Box 510, Parasitology, UNESP, 18618-000, Botucatu, Brazil; pribolla@ibb.unesp.br

In Brazil, infection by dengue virus has increased significantly in the last two decades, after the reintroduction of mosquito vector *Aedes aegypti*. Epidemiological surveillance remains the only way to prevent dengue outbreaks. Currently, the control program applied in *Aedes albopictus* and *Aedes aegypti* populations are larval surveys. An interesting alternative is the using of a new control strategy named PCI (Premise Condition Index). This model relates the property condition, like house condition, yard condition, and degree of shade; to the occurrence of *Aedes sp* oviposition. The present study is based on the application of PCI in properties located in the urban area of Botucatu. Ovitramps have been set in 105 spots all over the city and their properties qualified. Results from properties analysis by PCI showed that 64.7% ones with scores 8 and 9 (considered bad condition houses) were positive to *Aedes albopictus* while only 19% of properties with scores 3 and 4 (good condition houses) were positive. This analysis demonstrated the accuracy of PCI method, since major occurrence of *Aedes sp* has been observed in properties with highest scores. There is a positive correlation ($r=0.76$, $p<0.025$) between PCI and positive house percentage, showing the significance of the method.

Molecular population genetics of *Aedes aegypti* in Brazil using RAPD

KS Paduan, JP Araújo-Junior, PEM Ribolla
PO.Box 510, Parasitology, UNESP, 18618-000, Botucatu, Brazil; pribolla@ibb.unesp.br

Random amplified polymorphic DNA (RAPD) analysis technique has been used in studies of arthropod molecular taxonomy and in epidemiological studies of relatedness of geographic populations and vector movement. In Brazil, little is known about genetic structure among *Aedes aegypti* populations. We use RAPD to examine patterns of *Aedes aegypti* genetic structure in 11 populations from 6 Brazilian states. We found high genetic polymorphism (H_S = 0.38) and high levels of genetic differentiation exist both between population from different states (G_{ST} = 0.43) and between populations from cities in same state (G_{ST} = 0.41). These results indicate significant differentiation between *Aedes aegypti* populations in Brazil. There is a clear correlation between genetic structure and geographic localization showing that, if new populations are been introduced, they are not significant. Principal Component Analysis (PCA) of receive allele frequencies could separated populations in 3 different groups regarding geographic origin.

Biological characteristics of three domiciliated vectors of Chagas disease in Mexico.

PM Salazar-Schettino, M Cabrera, I de Haro, M Vences, M Bucio, A Ruiz, G Rojas.
Lab Biol Parásitos Fac Med UNAM Edif. A, 2º piso México CP 04510; azmar@servidor.unam.mx

Mexico has a great population of triatomine bugs actually are reported seven genera and 24 species of Triatoma genus. Due to this great amount and diversity, surveys were made for to know ecotopes and biology of three species of the Triatoma genus. The objective is to show laboratory and fields observations made in regions where Trypanosoma cruzi vectors predominate: Triatoma barberi recollected in Queretaro state, T. pallidipennis in Morelos and T. dimidiata in Veracruz. T. barberi is an exclusive species of Mexico, it prefers walls, T. dimidiata is found in floor and the middle of the wall downwards, both in beooms, and T. pallidipennis prefers floor and clothes, also wildlife. Life cycle is 523 and 510 for Triatoma barberi and T. dimidiata, respectively and for to T. pallidipennis is 171 days. T. barberi feeds and defecates at the same time, the others two species defecated among 10 and 30 minutes. Infection index percentage was is 56.6 for T. barberi, 29.0 for T. pallidipennis and 15.7 for T. dimidiata. Percentage of infective forms in bugs feces were 76, 26 and 15 for T. barberi, T. pallidipennis and T. dimidiata respectively. T. barberi is the best vector of T. cruzi in Mexico

Droneflies occurring from effluent of manure in Hokkaido, Japan (Diptera: Syrphidae)

H Sasaki, A Mikami
"Laboratory of Entomology, Rakuno Gakuen University, 582-1 Bunkyodai-Midorimachi, Ebetsu, Hokkaido 069-8501, Japan; h-sasaki@rakuno.ac.jp"

Three genera and 5 species of droneflies (Diptera: Syrphidae), namely *Eristalis (Eoseristalis) cerealis, Eristalis (Eoseristalis) roccica, Eristalis (Eristalis) tenax, Eristalinus (Lathyrophthalmus) tarsalis* and *Helophilus (Helophilus) virgatus*, occurred from the ovitraps using the effluent of manure as attractant and media in Hokkaido, Japan. These droneflies were reared in the laboratory and the specimens of each developing stages were examined their morphological characters by the binocular and scanning electron microscopes. The following differences between the species were observed:

Bioconversion with *Hermetia* to solve problems of manure accumulations and produce valuable feedstuff

DC Sheppard, GL Newton, GJ Burtle, CR Dove, W Watson, GC Rains, M Coulibaly
"University of Georgia, Tifton Campus, P. O. Box 748, Tifton, GA 31793, USA; Sheppard@tifton.uga.edu"

Black soldier fly, *Hermetia illucens* can eliminate many of the problems associated with large manure accumulations and with other putrescent wastes. The larvae consume fresh waste rapidly in managed systems and assimilate nutrients that otherwise might produce odors, pest flies and cause environmental pollution. Mature prepupae are self-collected for use as an animal feedstuff with about 42% protein and 35% fat. As a ration component, prepupae meal supported better fish growth than otherwise similar rations using fish meal. Data will be presented on this and other feeding studies with prepupae meal, amino acid and fatty acid profiles, elimination or reduction of several malodorous gasses, control of pest flies and reduction of waste dry matter by 50% or more and reduction in concentration of potentially polluting nutrients within that residue.

Prevalence of dengue virus in *Aedes* mosquitoes during y season by semi-nested reverse transcriptase-polymerase chain reaction (Semi-nested RT-PCR)

R Taksinvarajarn, P Tanayapong, S Pongratanaman, P Hansasuta, P Bhattarakosol, P Siriyasatien
Department of Parasitology, Faculty of Medicine, Chulalongkorn University, Bangkok, 10330 Thailand; fmedpsy@md.chula.ac.th

Dengue hemorrhagic fever remains a major health concern in Thailand. Much effort has focused on the prevention and control of the disease. Detection of dengue virus infection rate in mosquito would evaluate dengue control programs and predict the epidemics of dengue hemorrhagic fever. To determine dengue virus infection rate in mosquito by Semi-nested RT-PCR. A total of 400 mosquitoes were collected from Rom Kao Community representing a crowded community and another 9 non-crowded communities in Bangkok. Mosquitoes were then divided into 40 pools, each contained 10 mosquitoes. A total of 391 *Aedes aegypti* and 9 *Aedes albopictus* were screened for dengue virus. Mosquito infection rate in Rom Klao community is 2.5% of mosquito pool equal to that found in non-crowded communities. Both groups are found to be dengue virus serotype 3. Our study suggests a circulation of dengue virus serotype 3 in both crowded and non-crowed communities, the infection rates of which are indifferent during dry season.

Field evaluation of bifenthrin 10WP and bifenthrin 80g/L SC on dengue vectors at high-rise flats in Kuala Lumpur , Malaysia.

S Sulaiman, HF Othman, ZA Pawanchee, N Shaari
Department of Biomedical Science, Faculty of Allied Health Sciences, Universiti Kebangsaan Malaysia, Jalan Raja Muda Abdul Aziz 50300, Kuala Lumpur, Malaysia; salsul@medic.ukm.my

Bifenthrin 80g/L SC and Bifenthrin 10WP were evaluated against the sentinel sugar fed adults and 4th instar larvae of *Aedes aegypti* at 17 storey high-rise flats in Kuala Lumpur.The impact of both pyrethroid formulations on field populations of *Aedes aegypti* and *Aedes albopictus* larvae was monitored weekly using bottle containers.Both formulations of Bifenthrin showed adulticidal effects causing between 96% and 98% of *Aedes aegypti* mortality in the field compared to 18-19% in the control. However,both Bifenthrin formulations had not shown larvicidal effects when sprayed with ULV. This field trial indicated that both Bifenthrin formulations had potential for use in future dengue vector control programs.

Geographical range predictions of *Anopheles* mosquitoes in northern Australia using a genetic algorithm and data mining methods

AW Sweeney, NW Beebe, RD Cooper
IBID, University of Technology Sydney, Westbourne Street, Gore Hill, NSW 2065 Australia; Tony.Sweeney@uts.edu.au

An appreciation of the environmental factors which influence the geographical ranges of mosquito vectors of malaria is of considerable interest from both ecological and epidemiological viewpoints. GARP (the Genetic Algorithm for Rule-Set Prediction) was used for ecological niche modelling of *Anopheles farauti* ss, *Anopheles farauti* 2 and *Anopheles farauti* 3 in northern Australia. Models were developed using 41 environmental layers together with species locality datasets derived from systematic mosquito surveys in northern Queensland and the Northern Territory. For each species the predicted ranges included almost all presence records and excluded areas in which that species was not found in repeated collections. The datasets were analysed with CART (Classification and Regression Tree Analysis) and KnowledgeSeeker to investigate associations between environmental variables and the record/no-record collection sites for each species. The outputs were used for further model development with GARP to produce accurate range maps of *A. farauti ss* and *A. farauti* 3 using only 6 or 7 of the most significant environmental layers identified by decision-tree software. Further data mining analyses showed that the use of simulated absence data in lieu of no-record collection data may highlight significant environmental variables in datasets which do not have records for species absence.

A new pediculicide based on isopropyl myristate

T Foard, K Palma, RG Todd
"Insect Control & Research, Inc., 1330 Dillon Heights Avenue, Baltimore, MD 21228-1199, USA; inscontrolres@aol.com"

New pediculicides need to be effective, safe, and to act differently from other products so as to prevent or delay resistance. Isopropyl myristate (IPM) is approved for many cosmetic uses and is thus safe for topical use. IPM is not known to be neurotoxic to insects, unlike most other pediculicides. IPM in cyclomethicone was tested against body lice and their eggs (*Pediculus h. humanus*) as surrogates for head lice (*P. h. capitis*) by the ASTM methods. IPM gave 100% knockdown at +1 hour and 88.8% at +4 hours. 24-hour mortalities were: 15% IPM; 68.8%, 50% IPM; 97.1%, 100% IPM; 100%. Ovicidal action was slight, with mortalities under 20% The mode of action is unresolved, but is likely to be related to IPM's spreading and penetrating action. Symptoms were, however, similar to those from a neurotoxic synergized-pyrethrin pediculicide; Rid®. Toxicity was lower in lice exposed orally to IPM (56.0%) than by direct contact with a treated substrate (90.4%). Direct contact gave signs of desiccation, oral exposure did not. A cuticular route of action is indicated. An IND has been submitted to FDA and Phase II clinical trials start in April 2004.

Development of new microsatellite markers in the New World screw-worm *Cochliomyia hominivorax* (Diptera: Calliphoridae)

TT Torres, AML Azeredo-Espin
"PO Box 6010, Laboratório de Genética Animal, CBMEG – UNICAMP, 13083-875, Campinas, SP, Brazil; tttorres@unicamp.br "

Microsatellites are a highly informative class of DNA markers, consisting of tandem repeats of 2-6 bp distributed throughout eukaryotic genomes. Microsatellite loci stand out as codominant and multiallelic markers with high polymorphism and expected heterozygosity value. Due to these characteristics, they were the molecular markers chosen to continue our efforts to investigate the genetic variability and population structure of the New World screw-worm (NWS) *Cochliomyia hominivorax* (Coquerel). This species is one of the most important parasitic insect pests in Neotropics, causing myiasis and, consequently, significant losses to livestock industries in these regions. In order to generate new microsatellite markers for NWS, an enriched genomic library for microsatellite inserts was constructed. Of 56 clones inserts sequenced, 30 had a microsatellite and of these, 10 sequences with repeats of di-, tri-, tetra- and hexanucleotides were selected. Primer pairs were generated for the ten selected loci and eight of them were successfully amplified in NWS DNA samples. Polymorphism of each locus will be evaluated and the informative markers, in combination with ten polymorphic microsatellite markers previously described, should provide high resolution for assessing the fine-scale genetic structure in NWS.

Genetic structure and diversity in new world screw-worm *Cochliomyia hominivorax* (Diptera: Calliphoridae) populations from Uruguay revealed by microsatellite markers

TT Torres, AML Azeredo-Espin
"PO Box 6010, Laboratório de Genética Animal, CBMEG – UNICAMP, 13083-875, Campinas, SP, Brazil; tttorres@unicamp.br "

The New World screw-worm (NWS), *Cochliomyia hominivorax* (Coquerel), is one of the most important parasitic insect pests that cause invasive myiasis in warm-blooded vertebrates. Because of the substantial economic losses to livestock rearing caused by this pest throughout the neotropics, an international effort has been involved in a program to eradicate the NWS from endemic areas of Central and South America and to prevent invasions into screw-worm-free areas. It is crucial to characterize the genetic variability of target populations in order to maximize the effectiveness of the eradication program. Ten polymorphic microsatellite loci previously isolated from an enriched library constructed for *C. hominivorax* are currently being used to investigate the genetic variability and population structure across its current geographic distribution. Preliminary results obtained from Uruguayan populations indicated a considerably high genetic variability. Statistical analysis indicated that most of the genetic variation is contained within populations, while low levels of differentiation were found between them. The investigation into the genetic variability and population structure of NWS from Central and South American populations should provide fundamental information for future eradication strategies.

Isolation of microsatellite loci in the blowfly *Chrysomya chloropyga* (Diptera: Calliphoridae)

RA Rodrigues, TT Torres, AML Azeredo-Espin
"PO Box 6010, Laboratório de Genética Animal, CBMEG – UNICAMP, 13083-875, Campinas, SP, Brazil; tttorres@unicamp.br "

The species *Chrysomya chloropyga* (= *Chrysomya putoria*) (Wiedmann) is a synanthropic blowfly native from African regions. The adults feed and breed in carrion, feces, urban garbage and carcasses. Due to these biological features, *C. chloropyga* have great medical-veterinary importance acting as a vector of pathogens and is considered of potential forensic importance. This fly was probably introduced into Brazil around 1975 with the influx of Angolan refugees. Since then it has spread rapidly in Brazil and other countries of South America affecting the ecological scenario of the native Calliphoridae fauna. Genetic studies based on mitochondrial DNA revealed insufficient polymorphism at a fine scale. Since microsatellites are one of the most powerful markers for studying inter- and intrapopulation relationships, our goal is to develop a set of polymorphic microsatellite markers for *C. chloropyga*. A genomic library enriched for the motifs poli-AC/TG and poli-AG/TC was constructed. We are currently screening this library for microsatellite-containing clones. Of 54 clones inserts already sequenced, 26 had a microsatellite and 12 are useful sequences for designing primers. After polymorphism evaluation, these loci should contribute to population dynamics studies and for understanding the evolutionary context of the introduction of this species in the New World.

Survey of new world screw-worm *Cochliomyia hominivorax* (Diptera: Calliphoridae) for the presence of a point mutation associated with esterase-mediated organophosphate resistance

RA Carvalho, TT Torres, AML Azeredo-Espin
PO Box 6010, Laboratório de Genética Animal, CBMEG - UNICAMP, 13083-875, Campinas, SP, Brazil; tttorres@unicamp.br

The *Cochliomyia hominivorax* (Coquerel) is the main agent of primary myiasis in the South America, generating severe economic losses to livestock industry. In Brazil, its control has been done by the application of insecticides, but the inappropriate use of these chemical agents can select resistant flies. It has been shown in another species of the Calliphoridae family, *Lucilia cuprina*, that a Gly137®Asp substitution in the enzyme carboxylesterase (E3) converts its typical activity to an organophosphate (OP) hydrolase activity resulting in the development of OP resistance in this species. Preliminary efforts to isolate and characterize the E3 gene in *C. hominivorax* using primers previously described for *L. cuprina* resulted in a gene fragment of ~200 bp containing the site of the Gly137®Asp mutation. This region showed high similarity to the orthologous region in *L.*cuprina. The intron position is conserved, however its physical size and nucleotide sequence are not. The partial exon sequence differed from that in *L.cuprina* at 2 nucleotide sites, but no amino acid substitution was predicted. Further analysis will be conducted to determine the association of this point mutation OP resistance in *C.hominivorax* strains. This characterization should allow the identification of resistant individuals, enabling more effective control strategies.

Evaluation of prepared Thai plant-based repellents against mosquito bites under field condition

Y Trongtokit, Y Rongsriyam, N Komalamisra, P Krisadaphong, C Apiwathnasorn
"Department of Medical Entomology, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand; g4148061@student.mahidol.ac.th"

The experimental repellent products in the gel dosage form contained 20% clove oil (*Syzygium aromaticum*) and 10% clove plus 10% makaen (*Zanthoxylum limonella*) oil mixture were evaluated theirs efficacy against daytime- and nighttime-biting mosquito comparing with 20% deet (di-methyl benzamide) under field condition using a human bait method. One gram of the product was applied evenly from knee to the ankle of each leg. Shorts and shoes were worn to standardize the exposure area. Other exposed untreated parts of the body were protected against mosquitoes attack by wearing a jacket with hood and gloves, covering the thighs with a plastic sheet. For daytime-biting, 20% clove showed complete protection for 4.0 h and gave 95.7% repellency after 5 h application, whereas 10% clove plus 10% makaen oil mixture and 20% deet provided only 86.8 and 82.7% repellency after treatment, respectively against *Aedes aegypti*. For nighttime-biting, the 3 developing repellents yielded equally excellent (average 97.1% repellency for 5 h against the predominant *Culex quinquefasciatus* and *Mansonia uniformis* but they gave 89.0% repellency against *Cx. tritaeniorhynclus* and *Cx. gelidus*. This finding demonstrates that the repellency of 20% clove oil and 10% clove plus 10% makaen oil mixture in the gel dosage form are possible used against various different mosquito species.

Host grooming efficiency and its influence on the distribution of cat fleas, *Ctenocephalides felis*

MH Hsu, YL Yang, WJ Wu
27, Lane 113, Roosevelt Road, Section 4, Taipei 106, Taiwan; wuwj@ccms.ntu.edu.tw

Grooming is usually supposed to be the main factor to affect the final distribution of ectoparasites on hosts, that is, the distribution of ectoparasites can be changed when the grooming ability is refrained or can be different between those on the good and poor groomers. Therefore, in this study we compared the distribution of cat fleas, *Ctenocephalides felis* (Bouché)(Siphonaptera: Pulicidae), on the cat with good or poor ability of grooming and the cat wearing an Elizabethan collar or not. As expected, the results show that cat's grooming efficiency against fleas was significantly varied among individuals and greatly reduced by wearing an Elizabethan collar. However, the effect of grooming efficiency on the distribution of fleas on the host body is not significant. Regardless of cat's grooming efficiency, mean percentages of fleas detected at 24 or 96 hours after initial infestation were always highest on the neck (52 – 71.67%) among body regions (other regions ranging from zero to 30%). Fleas seem to prefer the anterior regions of cats including the head, neck, and front back. Moreover, male (60.17%) and female (61.18%) fleas have the same trend to move to the cat's neck.

Impact of anthelmintics on the growth of dung beetles and dung breeding flies in Japan.

N Yamashita, M Iwasa, S Shimano, N Yoshida , A Watanabe, A Mikami
National Agricultural Research Center for Tohoku, Arai, Fukushima, Fukushima, 960-2156 Japan; yama@affrc.go.jp

Most of anthelmintrics like an Ivermectin is excreted in the feces as a mixture of parent compound and metabolites. So, the use of anthelmintrics in livestock has potential impact on nontarget invertebrates, for example, dung beetles, flies, that depend on dung pats and contribute dung degradation in grassland. This study examined the impact of the anthelmintics residue on the dung degrading fauna in grassland. Dung samples were collected on 1, 3, 7, 14, 21, 28 and 35 day after pour on and bioassayed using the dung beetles and flies. Ivermectin residues attained maximal concentration from 1st to 3day after pour on followed by a linear decline to 35day. Dung pats collected 1 to 14days after treatment with ivermectin were lethal to larval development of native dung beetle, *Onthophagus lenzii* and native dung breeding flies, *Musca hervei*. Dung collected 1 to 3days after treatment was lethal to larval development and pupation of native dung beetle, *Aphodius elegance*. In field experiment using emergence trap, number of emerged flies were 3,655 (18families) in control dung and 2,234 (16 families) in treated dung.

Investigation of alternative insecticides for the treatment of bed nets and for indoor residual spraying to control *Anopheles* mosquitoes.

AL Yates, AN Asidi, M Rowland
The Gates Malaria Partnership, Disease Control and Vector Biology Unit, London School of Hygiene and Tropical Medicine, Keppel Street, London, WC1E 7HT, UK

There is an urgent need to investigate alternative insecticides for the control of pyrethroid resistant *Anopheles* mosquitoes, vectors of malaria. Resistance to DDT and pyrethroids among *Anopheles* (especially *gambiae* and *funestus*) species has been reported in western, southern, and eastern Africa. Alternative insecticides with novel modes of action remain may have potential for use on nets or indoor residual sprays. The Gates Malaria Partnership at LSHTM is working with WHO and industry to identify new actives. Bioassay tests were carried out using new insecticides including a phenylpyrazole (fipronil), an organophosphate (chlorpyrifos methyl, "Reldan"), an oxadiazine (indoxacarb) and a pyrrole (chlorfenapyr). Some of these compounds were tested in mixtures to investigate their possible synergistic interaction with pyrethroid insecticides. Laboratory studies with fipronil on netting have shown some irritant effect against *An. stephensi* and some synergisms between fipronil and deltamethrin. Different formulations of Reldan sprayed on various substrates (mud, plaster and wood) to investigate the efficacy of the formulations for indoor residual spraying (IRS) showed good residual performance up to 6 months especially on plaster. On the treated nets, Reldan performed well against wild populations of pyrethroid resistant mosquitoes. Indoxacarb and chlorfenapyr showed a slow acting effect in terms of mortality and KD but indoxacarb was better on netting when mixed with deltamethrin.

Evidence supports two cytologically different races of ***Anopheles pullus*** **in Korea**

CH Yu, W Choochote, A Jitpakdi, A Junkum, SJ Kim, SJ Park, GS Min
"Depart of Biological Science, Inha University, Incheon 402-751, Korea; chyu@inha.ac.kr"

Despite the medically-importance of anopheline mosquitoes as vectors of Korean vivax malaria, differentiation among Korean anopheline mosquitoes are obscure and difficult by traditional morphological taxonomic criteria. To verify the species status of two ambiguous species of *An. pullus* and *An. yatsushiroensis* (*An. pullus form yatsushiroensis*) mosquitoes from Korean, we established isofemale lines and investigated their genetic relationship by metaphase karyotypes, hybridization experiments, DNA sequence comparisons of rDNA ITS2 and mitochondrial COI and COII. Two isofemale lines showed different chromosomal shapes in sex chromosomes of X and Y, the reciprocal crosses between the two isofemale lines, however, provided viable progeny with completely synaptic salivary gland polytene chromosomes. DNA analyses also strongly supported the conspecificity of these isofemale lines. Based on these evidences, we conclude that two *An. pullus* forms which differ distinctively in morphological, cytological and ecological traits remain in interfertile status.

Incompatible hybridization between two sympatric species of *Anopheles sinensis* and *Anopheles pullus* (Diptera: Culicidae) in Korea.

CH Yu, W Choochote, A Jitpakdi, A Junkum, SJ Kim, MH Park, GS Min
"Depart of Biological Science, Inha University, Incheon 402-751, Korea; chyu@inha.ac.kr"

Hybridization tests of laboratory-raised, iso-female lines of *Anopheles sinensis* Form B and *An. pullus* Form A and B were conducted by induced copulation. The three iso-females line were established based on morphological characteristics of wild-caught, fully engorged females and three distinct types of metaphase karyotypes. They were *An. sinensis* form B (X, Y_2), *An. pullus* form A (X_1,Y_1) and form B (X_2,Y_2). The results of reciprocal and back crosses among *An. sinensis* and *An. pullus* indicated that *An. sinensis* was genetically incompatible with *An. pullus*, providing low viability of F_1-hybrid larvae with completely asynaptic of salivary gland polytene chromosomes, sex distortion of adults, abnormal development of ovarian follicles of F_1-hybrid females, and atrophy of accessory glands and testes of F1-hybrid males. The results strongly suggested that these two morphological species exhibited entirely reproductive isolation.

Bidirectional signalling and synaptogenesis: semaphorin1a and the transition from growth cone to synapse.

RK Murphey, TA Godenschwege
"Department of Biology, University of Massachusetts, Amherst, MA 01003; rmurphey@bio.umass.edu"

Target recognition during which a motile growth cone is transformed to a sedentary synapse is poorly characterized at the molecular level. We have demonstrated in the *Drosophila* giant fiber system that this transition is regulated in part by semaphorin1a (Godenschwege et al., 2003). Sema1a is a trans-membrane member of a family of proteins typically thought of as repulsive ligands that guide growth cone path finding. We have shown that Sema1a is required in both the pre- and postsynaptic cells for normal synapse formation and are using Sema1a as a point of entry to discover the signaling systems that regulate the transition from growth cone to synapse. In the pre-synaptic giant fiber Sema1a functions as a repulsive receptor and when Sema1a is over-expressed in the giant fiber synapse formation is disrupted. This gain-of-function defect can be enhanced by over expression of rac1 and suppressed by expression of the dominant negative rac1 suggesting that the repulsive function of sema1a is dependent on the small GTPases. We will elaborate on the role of rac1 as well other signaling systems that interact with semaphorin1a and are required for synaptogenesis . Finally, a model for the assembly of this giant synapse will be presented.

Bionomics of *Anopheles hyrcanus* in resurgent and endemic foci of malaria in Iran

MR Abai, H Vatandoost, AH Zahirnia, K Akbar-Zadeh, M Nazarai, MA Oshaghi, H Ashraf
School of Public Health & Institute of Health Research, Tehran University of Medical Sciences, P.O.Box: 6446-14155, Tehran Iran;
abaiiahm@sina.tums.ac.ir

An.hyrcanus group is reported from different parts of Iran. This species plays a role in malaria transmission in neighboring countries. The adult and larvae were collected from different parts of Iran using WHO's methods. This species is found in shaded part of rice-lands and irrigation canals and shaded stagnant water in Nikshahr and Pars-Abad and Poldasht districts. Its peak of activity occurs in midnight whereas s area three peaks of biting can be observed, mainly sunset and midnight according to locality. Light trap is able to collect the adult. This species tend to rest indoor when temperature is falling dawn. The peak of its activity is mainly in August. From the field study it was concluded that *An.hyrcanus* population found in different resurgent and malaria endemic area of Iran. Their seasonal activity, biting habitat, larval density, and abdominal condition is varied in different localities. It seems that in some area due to high population density and antropophilicity of this species it may play a role in malaria transmission. At the future, further molecular and biochemical studies will be done to confirm different sibling species of this species as in studied area.

Behavioral responses of *Culex* to oviposition site odors

SA Allan, UR Bernier, DA Carlson
USDA/ARS, CMAVE, PO Box 14565, 1600 SW 23rd, Gainesville, FL 32604, USA; sallan@gainesville.usda.ufl.edu

Culex mosquitoes, as important vectors of arboviruses in North America, are effectively sampled by gravid female traps baited with infusions such as hay infusion. Using several methods, a wide range of volatile compounds have been identified from hay and grass infusions and dairy effluent. The purpose of this study was to evaluate the behavioral responses of gravid *Culex* to these compounds as oviposition site attractants in a dual-port olfactometer assay. Responses obtained to individual compounds and then in binary and/or tertiary blends were compared to hay infusion. The efficacy of lures incorporating these mixtures were also evaluated in the olfactometer and compared to hay infusion standards. These results contribute to the development of standardized lures for gravid *Culex*.

Effect of fire on recovery and identification of entomological evidence at a homicide scene

GS Anderson
School of Criminology, Simon Fraser University, Burnaby, British Columbia, Canada, V5A 1S6;
ganderso@sfu.ca

Insects are valuable in determining elapsed time since death in a homicide. However, the killer may attempt to disguise the crime by setting fire to the crime scene. Experiments were conducted to determine the effect of arson on entomological evidence. Three freshly killed pigs (*Sus scrofa* L.) were placed in separate rooms in a house in Edmonton, Alberta. Extensive blow fly (Diptera: Calliphoridae) colonization occurred, and the remains were allowed to decompose to the advanced decay stage. At the time of the fires, large numbers of larval Calliphoridae, pupae and empty puparia, as well as teneral flies were present. Four successive simulated arson fires were set then extinguished. The first fire was ignited using gasoline poured on the carcass, the second used common household accelerants such as newspaper, the third was set in the basement and the final fire involved the entire house. After each fire was extinguished, the carcasses were examined for entomological evidence. In all, cases, enough entomological evidence was recovered after each fire, including the final destruction of the house, to allow an entomologist to analyze the evidence and to determine elapsed time since death. In several cases, live insects were recovered.

Novel strategies for arbovrius surveillance in response to WNV

CS Apperson
Department of Entomology, Box 7647, North Carolina State University, Raleigh, NC 27695-7647 USA; charles_apperson@ncsu.edu

The outbreak of West Nile virus (WNV) in 1999 in Queens, New York USA was an unprecedented public health event on the North American continent. Albeit, the epidemic has stimulated development of only a few novel vector/virus surveillance tools. The VecTest® is the best-known novel technology resulting from the outbreak of West Nile virus. This lateral flow or dipstick test is used to detect West Nile virus antigen in homogenized mosquitoes. The VecTest has also been used successfully to detect viral antigens in extracts of cloacal swabs taken from moribund WNV-infected birds. Another more recent diagnostic test, the RAMP West Nile Virus Test, detects WNV antigen in mosquitoes and birds. This test is based on latex particles that are tagged with fluorescent antibodies to WNV. Sentinel animals have been used to detect the occurrence of WNV. The virus is highly lethal to some birds, such as American crows and blue jays. Field surveillance of WNV activity involves a strategy of systematically collecting and testing dead corvids for WNV infection. Counts of dead corvids have also been used to estimate the intensity of local transmission of WNV.

Weather station ambient temperature corrections in forensic entomology

MS Archer
"The Victorian Institute of Forensic Medicine, 57-83 Kavanagh St, Southbank VIC 3006, Australia,
melaniea@vifm.org"

Weather station data is used by forensic entomologists to estimate ambient temperatures at body discovery sites. Correlation data from sites may also be collected to correct for site and station differences. This experiment tested the accuracy over time of retrospective weather data correction using linear regression between stations and sites. Temperatures were logged at six hypothetical body discovery sites during a seven day period for which a hypothetical body lay *in situ*, and a further four correlation periods. The accuracy of weather data for hypothetical body *in situ* periods improved after correction in 22 of 24 correlations, however, mean predicted body *in situ* temperatures for sites differed significantly between correlation periods. Predicted temperatures generally rose with time after body removal, which correlated with rising site temperatures accompanying seasonal change. Therefore, practitioners should be cautious in making correlations if weather patterns during correlation differ greatly from those while the body was *in situ*.

Biometrics and behavior in mosquito repellent assays

DR Barnard, RD Xue
"USDA-ARS-CMAVE, P. O. Box 14565, Gainesville, Florida 32604 U.S.A., dbarnard@gainesville.usda.ufl.edu"

Biotic and environmental factors influence the outcome and interpretation of repellent bioassays. Mosquito-related test factors include larval nutrition, carbohydrate availability, age/parity of females, blood engorgement status, and diel blood-feeding patterns. Environmental/human subject-relevant factors are light, temperature, humidity, repellent dose and exposure time, absorption, penetration, evaporation, abrasion, and/or washing of repellent from skin (by perspiration), and the innate repellency of human/animal test subjects. In laboratory tests, cage configuration is critical. With small cage/modular-types of test apparatus (<1000 cm^3), treatment effects may be confounded with "edge effects", because of the position of a feeding port or module, whereas tests repeated using the same human subject comprise pseudo-replication. In large cage (>1000 cm^3) tests, complete protection times are based on the responses of mosquitoes in the upper extreme of the frequency distribution for repellent tolerance, rather than on the average population response; large cage techniques are not useful for determining the Estimated Median Dose (ED_{50}), or other percentiles of interest. Variation in repellent assays can be minimized by rearing and testing mosquitoes in a standardized environment, by choosing appropriate sample sizes, by selecting a biologically-relevant assay method, and by careful and diligent oversight of test proceedings.

Vector and viral genetic determinants of epidemic dengue and dengue hemorrhagic fever in Mexico

B Beaty, N Gorrochoteguí-Escalante, K Bennett, I Salazar-Sanchez, S Lozano-Fuentes, K Olson, I Fernandez-Salas, M De Lourdes Muñoz, J Farfan-Ale, M Lorono-Pino, B Blitvich, C Blair, W Black.
Department of Microbiology, Immunology and Pathology, Colorado State University Fort Collins, CO 80523.

To elucidate vector determinants of dengue transmission in Mexico, ~1,600 *Ae. aegypti* collected from throughout North America and individually phenotyped for dengue 2 (DEN2) virus midgut and disseminated infections. DNA from each of these mosquitoes was archived for association mapping of candidate genes that condition vector competence. Dramatic differences in vector competence in the *Aedes aegypti* populations were demonstrated, and vector competence was correlated with dengue seroprevalence. Studies to reveal the genetic basis of *Aedes aegypti* vector competence identified two candidate genes (Early Trypsin and Abundant Trypsin) that condition dengue virus infection of vectors. RNAi silencing of the Early Trypsin gene resulted in reduced vector competence of *Aedes aegypti*. To determine the epidemiological relevance of these genes, a population genomics approach using association mapping was used to reveal the statistical relationship between genetic polymorphisms and vector competence phenotype in these genes. An association was found between the *Abundant Trypsin* and DEN2 disseminated infection rates DEN2 infection phenotypes in these American *Aedes aegypti* populations. Such information is important in risk assessment for epidemic dengue and DHF/DSS. During these studies, a new DEN2 virus of the American-Asian genotype was introduced in Yucatan State, causing an epidemic of DHF/DSS. This virus is being compared with other DEN2 viruses, which have previously circulated in the Yucatan State, for its ability to infect, replicate in, and be transmitted by *Aedes aegypti* and for its epidemic potential.

Chemical analysis and laboratory bioassays of host odors to identify compounds that attract and inhibit the attraction of mosquitoes

UR Bernier, SA Allan, DA Carlson
USDA-ARS, Center for Medical, Agricultural, and Veterinary Entomology, Gainesville, FL 32608, ubernier@gainesville.usda.ufl.edu

Using various sampling techniques and gas chromatography/mass spectrometry (GC/MS), a comprehensive chemical profile of host odors can be obtained. The differences in chemicals emanated by different hosts may provide a clue to the structures of compounds used by anthropophilic mosquitoes, compared to those used by zoophilic mosquitoes, for host location. Screening of candidate compounds is accomplished in our laboratory by using a triple-cage dual-port olfactometer. Bioassays of single compounds and blends of compounds have resulted in the development of attractive synergistic binary blends for anthropophilic mosquitoes. Further improvement to the blends has resulted in a three-component blend that is more attractive than some human individuals in laboratory bioassays. During the development of these attractive odor blends, some compounds were observed to inhibit the host-seeking capability of mosquitoes, possibly my masking the attractive odors. Inclusion of these compounds (attraction-inhibitors) in attractive blends, results in a substantial decrease in the ability of mosquitoes to locate the attractive odor source in the olfactometer. Laboratory bioassays are being used to develop a system that demonstrates the possibility of concealing a host with attraction-inhibitors and driving mosquitoes to choose an attractant blend over a live human or animal host.

Sexual dimorphism of antennal gene expression in the malaria vector *Anopheles gambiae*

H Biessmann, RW Justice, S Dimitratos, MF Walter, DF Woods
"Developmental Biology Center, University of California, Irvine, CA 92697, USA, hbiessma@uci.edu, "

To obtain a better understanding of the olfactory processes that allow mosquitoes to identify human hosts, a molecular study has been performed to identify and characterize molecules in the olfactory signaling pathway of the African malaria vector *Anopheles gambiae*. cDNA libraries from antennae of females and males were established, from which a collection of cDNAs encoding odorant binding proteins (OBPs) and other novel antennal proteins were isolated and characterized, representing various families of putative carrier proteins with homologues in other insects. Using filter array hybridizations and quantitative RT PCR, regulation and gender specificity of expression of these genes was investigated. Although male and females appear to express the same olfactory genes, significant differences in steady state levels of some of these putative carrier protein genes were detected between the sexes and after blood feeding in females. Results of microarray experiments of gender-specific expression of olfactory carrier proteins and receptors will be reported. Our ultimate goal is to identify and characterize molecules in the odor reception pathway of this mosquito vector species with the intent of facilitating the development of better methods to interfere with the mosquito-host interaction.

Study of decomposition rates of pig carcasses and viability of *Calliphora vicina* in the UK climate

AP Brandt
Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, a.brandt@nhm.ac.uk

The estimation of post mortem interval (PMI) in a country such as the UK which experiences fluctuating temperatures, both seasonally and daily, is considerably more complicated than in those countries with fairly constant temperatures. In order to assess the effects of the different seasons on decomposition rates and insect species composition, piglet carcasses were put out at The Natural History Museum in Central London. Significant differences were recorded from carcasses put out at different times of the year, and between those laid outside on a roof, and those inside the building, where insects had limited access to the carcasses. Although oviposition by the primary invaders occurred at the same time on both the indoor and outdoor carcasses, the rate of development of *Calliphora vicina* on the outdoor carcasses was significantly slowed down due to the cold temperatures experienced, thus limiting the decomposition rate considerably. Further laboratory based studies were carried out to assess the effect of cold temperatures on the different life stages of *Calliphora vicina*.

Molecular basis of resistance to pediculicides

"WG Brogdon, G Groner, AE Lenhart, RA Wirtz"
Entomology Branch F42, DPD, NCID, Centers for Disease Control and Prevention, 4770 Buford Highway NE, Atlanta, Georgia 30341, USA, wgb1@cdc.gov

Head and body lice develop resistance to pediculicides through mutations of insecticide target sites, such as the voltage-gated sodium channel, and increased activity of detoxification enzymes such as oxidases and esterases. The difficulties of conducting bioassays on field-collected lice make molecular analysis of insecticide resistance an especially attractive option. Here are described the molecular details of resistance that has appeared in lice together with a discussion of ongoing work to develop methods to detect and assess these mechanisms through molecular analysis. A useful approach to measuring all of these mechanisms is fluorometric PCR. This method allows detection of resistance mechanisms based on point mutations at the insecticide target site, resistance gene amplification, or increased expression of resistance genes. Knowledge of resistance gene sequence is a prerequisite in the development of these methods. Our knowledge to date of louse resistance gene sequences is summarized. The same molecular methods that serve to detect resistance are also central to the determination of population genetic relationships of the resistance alleles. We discuss our present state of knowledge of louse molecular markers and the louse genome as they relate to insecticide resistance.

Environmental change and lyme disease risk

JS Brownstein, D Fish
Yale School of Medicine, 60 College St., New Haven, CT 06520-8034, USA, john.brownstein@yale.edu

An understanding of the influence of environmental change on Lyme disease in North America is a fundamental component in assessing changes the spatial distribution of human risk. Because disease risk may be influenced both by large-scale climate change and local-scale landscape modification, we developed a multi-scale approach to dissecting the influence of environment. First, we used a climate suitability model for the tick vector *Ixodes scapularis* to examine the potential effects of global climate change on future Lyme disease risk in North America. The model reveals a significant expansion of *I. scapularis* north into Canada and central United States as well as a retraction of the vector from southern United States. With higher resolution remotely sensed data, we evaluated the impact of local-scale landscape structure on both entomologic risk and human exposure. Landscape fragmentation resulting from suburban development was compared to both human and tick surveillance data from Connecticut and showed that landscape mosaic plays a significant role in defining disease risk. In spite of higher tick densities, human incidence of Lyme disease was found to be lower in fragmented contexts. The synthesis of such environmental models will allow for improved predictions of Lyme disease emergence.

Influence of the structure of host-odor plumes on the orientation maneuvers of flying mosquitoes

RT Cardé, T Dekker
"Department of Entomology, University of California, Riverside, CA 92521, United States of America, ring.carde@ucr.edu"

Host finding in mosquitoes is typically subdivided into two sequential stages: attraction at long range that is induced by host-released odors, principally assumed to be carbon dioxide. Orientation at close range is assumed to be regulated by the interactions of carbon dioxide with other host odors, humidity, heat, and visual cues. In our work with *Aedes aegypti* in a wind tunnel, upwind fight along the carbon dioxide plume required the sequential encounter with filaments of carbon dioxide, as would normally occur in a plume diffusing in wind. A single brief encounter with a filament of carbon dioxide odor induced a surge toward upwind. A relatively homogeneous cloud of carbon dioxide, in contrast, activated flight, but did not stimulate upwind movement. Conversely, orientation to human skin odor seems to require a longer term encounter than occurs with exposure to an odor filament. The threshold for response to skin odor is itself modulated by an encounter with carbon dioxide: a brief exposure to carbon dioxide lowers the threshold of response to skin odor by five-fold. Together the interactions of carbon dioxide and skin odor explain several features of host orientation, and provide support for the hypothesis of sequential stages of odor utilization.

Development of lure for the dengue mosquito

RR Coler, A Mafra-Neto, T Dekker
"2060 Chicago Ave, Suite C2, Riverside, CA 92507 – USA, rcoler@iscatech.com"

Instead of proceeding with the traditional isolation and identification from hosts of individual mosquito attractants, ISCA Technologies, Inc. created compositions which mimic the skin of the specific vertebrate hosts. Most mosquitoes apparently exhibit some level of host 'preference', i.e., they do not feed indiscriminately on any vertebrate host. In some studies host-feeding patterns within a closely related species complex is odor mediated and was attributed to differential response to CO_2 and other skin odors. The actual bait, created through a process patented by ISCA, provides the parasitic arthropod (host seeking *Aedes aegypti*) a much more complete "olfactory sensation" associated to a specific "host" (human) than any other attractants on the market. Traps lured with this bait containing artificial "sensory correct" profiles of human hosts trigger rapid responses from females *Ae aegypti* inducing the full set of host seeking and feeding behaviors, from activation to imbibing. The current ISCA prototype trap has proven to be superior to the Fay-Prince and Wilton traps and other commercial traps set-up in competitive laboratory trap tests. Laboratory studies indicate the capture rate of this prototype baited with this new lure closely approximates the rates obtained from human biting counts for the same mosquito density.

2-Oxocarboxylic acids elicit landing responses from female *Anopheles gambiae*

TP Healy, MJW Copland, A Cork, A Pyrzyborowska, JM Halket
"Natural Resources Institute, Central Avenue, Chatham Maritime, KENT 4TB, UK, a.cork@gre.ac.uk "

Landing and probing responses were elicited from female *Anopheles gambiae* in wind tunnel bioassays by 2-oxocarboxylic acids. The most significant responses were elicited by 2-oxopentanoic acid although 2-oxo-butanoic, 2-oxo-3-methylbutanoic, 2-oxo-3-methylpentanoic, 2-oxo-4-methylpentanoic and 2-oxo-hexanoic acids also elicited responses. 2-Oxo-propanoic (pyruvic), 2-oxo-octanoic, 2-hydroxy-propanoic (lactic) and 2-hydroxy-pentanoic acids were inactive. The response to 2-oxopentanoic acid was dose and temperature dependent with 30 µg and body temperature (34^{o}C) eliciting the most significant responses. Responses decreased over time but this was thought to be due to evaporation. Chemical analysis of a suitably derivatized human sweat sample confirmed the presence of pyruvic, 2-oxo-3-methylbutanoic, 2-oxo-3-methylpentanoic and (*E*)-oxo-4-methylpentanoic acids. The three methyl-branched acids, previously identified in human body fluids, are metabolically linked to the amino acids valine, leucine and isoleucine *via* a reversible trans-amination. However, the most active compounds, 2-oxopentanoic and 2-oxohexanoic acid were not identified in human sweat. Taken together the research suggests that C_4-C_6 2-oxocarboxylic acids represent a class of compounds that provide female *An. gambiae* with close range, host-specific odour cues.

Distribution of blood feeding within the subgenus *Inseliellum* (Diptera: Simuliidae)

CA Douglas
Department of Biological Sciences, University of Alberta, Edmonton, Canada T6G 2E9, d.craig@ualberta.ca

Simulium (*Inseliellum*) *buissoni* in Nuku Hiva, Marquesas Islands, Polynesia, has been referred to as the "scourge of the Pacific". It is a sufficiently serious blood feeder on humans that it resulted in the administrative centre of the Marquesas being moved from Nuku Hiva, south to Hiva Oa. *Simulium buissoni* is also a serious bird biter and attempts to eradicate this black fly were made in the early 1990's. *Simulium* (*I.*) *gallinum,* distributed on other Marquesas Islands, however, feeds only on birds. Distribution of blood feeding within *Inseliellum* will be discussed in light of a reconstructed phylogeny for the subgenus. Also discussed will be the "Miracle of the Nono" from the 1930's, where it is reputed that serious biting of humans by black flies on the southern Marquesas Islands, ceased ostensibly, overnight.

Evolution of blood-feeding behavior in black flies (Diptera: Simuliidae)

CC Douglas
Centre for Biodiversity and Conservation Biology, Royal Ontario Museum, 100 Queen's Park, Toronto, Ontario, CANADA, M5S 2C6, dcurrie@zoo.utoronto.ca

Phylogenetic-, paleontological-, and host specificity data are combined to reveal patterns of blood feeding behavior among black flies. The fossil record reveals that simuliids originated before the radiation of birds and mammals, suggesting that other warm-blooded hosts were exploited by the earliest members of the family. Ornithophily probably evolved independently in the Prosimuliini and Simuliini, with numerous, independent, reversals to mammalophily in the latter tribe. Although host-switching events in black flies have been predominantly from ornithophily to mammalophily, there is a least one example of the reverse among certain members of the *Simulium* (*s.str.*) *slossonae* species-group. Obligatory autogeny (i.e., females that lack biting mouth parts), is a derived trait that evolved numerous times independently from both mammalophilic and ornithophilic progenitors. Such non-bloodsucking species, which constitute only about 2.5% of the world species, live predominantly in high latitude or high altitude environments. Tarsal claw morphology has utility for inferring host preference among anautogenous black flies; however, the current practice of coding claws as either "simple" or "bifid" does not exploit the full panoply of variation present in this character system. Detailed comparative studies are needed in order to identify useful characters for species recognition and phylogenetic studies.

Landscape epidemiology of malaria in Tumkur (Karnataka), India, as monitored by satellite remote sensing

RC Dhiman
Malaria Research Centre (ICMR), 22 Sham Nath Marg, DELHI-110054, India, dhiman1@vsnl.com

Study was conducted in selected villages of 3 Primary Health Centres of Tumkur (Karnataka)with varying endemicity to find out the landscape elements critical to malaria endemicity at village level using satellite remote sensing.. Ground data on the presence of breeding habitats, monitoring of larval density, adult *Anopheles culicifacies* (malaria vector) from indoor resting sites and ecological features within 1.5 km radius from the centre of each village were generated in 2001 and 2002. Data of Indian Remote Sensing satellite with 23.8 metre and 5.8 metre resolution respectively were procured for the dates of ground survey and analyzed for generation of images and statistics of land use features within a buffer zone of 1.5 km around each village. Delineation of tanks, streams, ponds, marshy areas, the main breeding habitats of *An. culicifacies* was possible by Remote sensing by merging LISS III and PAN products. The breeding habitats in the vicinity of human settlements within 500 metres were found more productive for *An. culicifacies.*

Quantification of land use features revealed that extent of water bodies, permanent vegetation cover, less barren/scrub and rocky areas were associated with high malaria endemicity. Identification of villages into high/low risk of malaria is possible leading to village level stratification for development of village specific selective and cost effective spraying strategy for integrated vector management programme for targeting malaria control.

Aedes aegypti behavior in manipulated domestic environments in Thailand

JD Edman, LC Harrington, TW Scott
"Center for Vectorborne Diseases, School of Veterinary Medicine, University of California, Davis, CA 95616, jdedman@ucdavis.edu"

Aedes aegypti, a low-density mosquito, lives in or near human dwellings, feeds frequently and specifically on people, and efficiently transmits dengue viruses. Field experiments with wild mosquitoes are risky in endemic areas and population augmentation to increase sample sizes causes ethical concerns. We circumvented both issues by screening the entire house and yard of rented homes in order to safely conduct relatively natural behavioral experiments using females collected in the village as pupae. Host size, location, and orientation effects on feeding were studied using 4 rotated subjects. Released mosquitoes (~25%) were recovered using pack-pack aspirators and the origin of their blood meals scored by DNA fingerprinting. There was strong correlation between host size and feeding with the largest individuals consistently feeding the most mosquitoes. *Ae. aegypti* fed most often on people inside house but body orientation appeared unimportant. Timing of oviposition and the impact of container size on egg number were evaluated in various sized jars lined with germination paper. Papers were changed at regular intervals and eggs counted. Most eggs were laid in late afternoon. Larger diameter containers consistently received more eggs whether located inside or outside. Indoor females preferred containers without preexisting eggs.

Behavioural responses of gravid *Aedes aegypti* (Diptera: Culicidae) to synthetic oviposition attractants identified from grass infusions volatiles.

AE Eiras, IM Silva, RA Roque, IM Matosinhos, M Geier
Federal University of Minas Gerais, Belo Horizonte, Brazil, alvaro@icb.ufmg.br

Grass infusions have been used as oviposition attractants and/or stimulants for enhancing ovitrap efficacy. However, the infusion procedures are very time-consuming and extremely labour-intensive. Thus, the volatiles released from grass infusions that attract gravid mosquitoes *Aedes aegypti* to ovitrap were identified by coupled gas chromatography-electroantennogram detection (GC-EAD), coupled gas chromatography-masspectometry (GC-MS), electroantennography (EAG) and field trapping. Six candidate compounds were identified and evaluated in the field and in laboratory. Electrophysiological studies showed that antennas of gravid mosquitoes are sensitive to all synthetic compounds but only few individual compounds elicited behavioral responses within a dual port olfactometer. Laboratory and field studies showed that the lures and dispensers are still attractive after 30 days old in the environment. Video recording analysis of the behavior response of gravid *A. aegypti* to adult mosquito trap (MosquiTRAP^{â}) baited with the oviposition lure (Atr*Aedes*^{â}) showed that chemical and physical structures of odor plumes have great influence on the trap catch performance. At the moment, the MosquiTRAP^{â} and the Atr*Aedes*^{â} are being evaluated for *A. aegypti* national monitoring program in Brazil.

Laboratory and field evaluation of mosquito repellents in Australia

SP Frances
Australian Army Malaria Institute, Gallipoli Barracks, Enoggera, Brisbane, Queensland, 4051, Australia, steve.frances@defence.gov.au

This paper will review laboratory and field studies conducted in Australia and Papua New Guinea to evaluate mosquito repellent formulations. The response of *Anopheles* spp. in the field to *N,N*-diethyl-*3*-methylbenzamide (deet) is variable, and several species are tolerant of current formulations. In contrast, deet repellents are quite effective in providing protection against Culicine mosquitoes in this region. Additional studies on the laboratory and field response of mosquitoes to a comparatively new active ingredient, (1-methyl-propyl 2-(2-hydroxyethyl)-1-piperidinecarboxylate), known as picaridin, will also be presented.

Role of defensin in tick-pathogen interaction

K Fujisaki, N Tsuji, B Battsetseg, D Boldbaatar, T Miyoshi
Obihiro, Hokkaido 080-8555 Japan, fujisaki@obihiro.ac.jp

Antimicrobial peptides are major components of host innate immunity, a well-conserved, evolutionarily ancient defensive mechanism. Infectious disease-bearing vector ticks are thought to possess specific defense molecule that have been acquired in the process of their evolution against the transmitted pathogens. We found a parasiticidal peptide evolved from a common ancestral peptide resembling spider and scorpion toxins from *Haemaphysalis longicornis*, the obligatory vector for *Babesia* parasite transmission. This protein, named longicin, displayed bactericidal and fungicidal properties resembling those of defensin homlogues from invertebrates and vertebrates. Longicin showed a remarkable ability to inhibit the proliferation of merozoites, an erythrocyte-blood stage of equine *B. equi*, by killing the parasites. Longicin was localized at the surface of the parasites, as demonstrated by confocal microscopic analysis. In an *in vivo* experiment, longicin induced significant inhibition of parasitemia in animals infected with the zoonotic and murine *B. microti*. Our findings suggest that longicin is a promising candidate for designing antibabesia therapeutics.

Attractive host odours for mosquitoes: the blend ratio makes the difference

M Geier, A Rose, A Eiras
"Institut für Zoologie, Universität Regensburg, Universitätsstr. 31, 93040 Regensburg, Germany,
martin.geier@biologie.uni-regensburg.de"

Mosquito species differ with respect to their host preferences, and some discern not only different species of vertebrate hosts but also different individuals of a given species. Olfactory cues derived from the hosts determine to a large extend the host choice, and it is an intriguing question how these insects accomplish the necessary fine odour discrimination. Emanations from vertebrate hosts consist of complex blends. Attention has focused on the identification of kairomones that guide mosquitoes to their hosts. Here we show that odour blends rather than their single constituents attract the anthropophilic yellow fever mosquito *Aedes aegypti* (L.). Highly attractive blends consist of L-(+)-lactic acid, ammonia, and distinct fatty acids which were essential to maximise the attractiveness of the blend. The mosquitoes' responses, however, depended markedly on the ratio of these compounds. In a direct competition bioassay a distinct blend ratio turned out to be as attractive as an average human hand. When added to natural human skin emanations some compounds also altered significantly the attractiveness of the host. The data show that the blend ratio of a few distinct compounds is crucial for the attraction of mosquitoes to human hosts.

Specific monitoring tools for anthropohilic mosquitoes

M Geier, A Rose, C Baptista, SA Richie, A Eiras
Institute of Zoology, University of Regensburg, Universitätsstr. 31, 93053 Regensburg, Germany, martin.geier@biologie.uni-regensburg.de

For a better estimation of the risks of mosquito-transmitted disease epidemics, it is vital to quickly assess the density of the host seeking mosquito population. A simple, specific, and effective trapping tool would overcome some of the disadvantages of the currently used methods to estimate the density of mosquito populations. We introduce an new monitoring suction trap with an attractive lure for anthropohilic mosquitoes. The lure releases a cocktail of volatiles that also emanate from human skin. The attractiveness of the mixture strongly depends on the mixing ratio of the compounds. Release rates and blend ratio can be optimised to suit a number of anthropophilic mosquitoes. Although CO_2 is not essentially necessary for the effectiveness of the new attractant, it enhances the catching rate of the blend.
The design of the trap combines the generation of a specific plume shape for an optimum effectiveness of the attractants with visual cues to enhance the catch of the attracted mosquitoes. The trap is optimised for the new attractive blend, easy to produce and simple to use. It can be applied indoors as well as outdoors and is currently tested in the laboratory and in the field in Brazil, Asia, Australia and Europe with a range of mosquito species.

Spatio-temporal risks for lyme borreliosis: examples from Switzerland

L Gern, JL Perret, F Jouda, O Rais
"Institut de Zoologie, University, Rue Emile Argand 11, 2007 Neuchâtel. Switzerland, lise.gern@unine.ch"

Lyme borreliosis causes health problem for populations in endemic areas in the Northern hemisphere. In the present study, the density of questing *Ixodes ricinus* ticks and their infection with *Borrelia burgdorferi* sensu lato (sl) was examined in areas located North and South of the Alps in Switzerland. From 1999 to 2001 free - living *I. ricinus* ticks were collected on a monthly basis by flagging vegetation in these areas. Density of questing ticks varied greatly between studied areas. *Borreliae* were observed in ticks collected in all investigated sites. However the prevalence of infection differed significantly among areas. Infection prevalence varied from 9% to 40% in nymphs and from 17% to 51% in adults. Adult ticks were significantly more infected (35%) than nymphs (20%). There was no correlation between nymphal density and infection prevalence as well as between adult density and infection prevalence, but there was a correlation between density of ticks and density of infected ticks. During the spring peak of questing tick density, a range of 2-69 infected ticks per 100 m^2 was observed. Five *Borrelia* species were identifed: *B. garinii*, *B. burgdorferi* sensu stricto, *B. afzelii*, *B. valaisiana* and *B. lusitaniae*.

Forensic entomology and artificial intelligence: which is the relation?

L Gomes, CJ Von Zuben
Departament of Zoology, UNESP, Av. 24A, 1515, Zip Code: 13506-900, Rio Claro, SP, Brazil, leugomes@yahoo.com.br

Blowflies of genus *Chrysomya* are so important in forensic entomology to indicate the Post Mortem Interval (PMI). Moreover, the larvae of these insects have an aggregation behaviour when are feeding of the tissues in human and animal corpses which each one influence the other one during this process of feeding and post- feeding, and still after, during the post- feeding larval dispersal searching for pupation sites. The results of this influence is a self-organization in this process which is studied in computer programs (Cellular Automata) using the data from this behaviour and the program produced from these data to be applied in the development of programs of Artificial Intelligence and improve the performance of navigation systems in robots by the environment. These studies were done with about 10,000 larvae of *Chysomya megacephala* and *Chrysomya albiceps* in arenas simulating the environment conditions. Therefore, the study of some biological systems just as the studies in Forensic Entomology could be so important to develop programs in Artificial Intelligence.

Natural repellents against malaria vectors – an evolving operational research agenda in southern Africa

JM Govere, DN Durrheim
"World Health Organization Afro, 95 Park Lane, Harare, Zimbabwe, goverej@who.co.zw"

Personal protection against biting mosquitoes is an important malaria prevention strategy. Insecticide-impregnated bednets and indoor residual house spraying, the main strategies for malaria vector control, provide protection only against indoor feeding and indoor resting malaria vectors. Furthermore, the development and spread of antimalarial drug resistance and insecticide resistance in vector mosquitoes has reawakened interest in repellent use for malaria control. However, currently available synthetic repellents are not affordable to the majority of people living in malaria-endemic countries. Results of qualitative enquiry in Mpumalanga province, a rural malaria-endemic area of South Africa bordering Mozambique lead to identification of three plants, *Lippia javanica* (fever tea), *Pelargonium reniforme* (rose geranium) and *Cymbopogon excavatus* (lemon grass), traditionally applied for preventing mosquito bites. We report on the laboratory and subsequent field evaluation of *Anopheles arabiensis* repellency using water and alcohol leaf extracts from the three plant species. Efficacy results for *L. javanica*, a pleasant-smelling shrub that is locally abundant during the malaria season suggest its utility as a cost-effective personal repellent.

Role of tick lectins in pathogen transmission

L Grubhoffer, V Kovar, P Kopacek
Institute of Parasitology, Academy of Sciences of the Czech Republic, University of South Bohemia, Branisovska 31, 370 05 Ceske Budejovice, Czech Republic, liborex@paru.cas.cz

Tissue specific lectin/haemagglutinin activities of both soft and hard ticks have been investigated. Some tick lectins are proteins with binding affinity for sialic acid, various derivatives of hexosamines, and different glycoconjugates. Most tick lectin/haemagglutinin activities are blood meal enhanced, and could serve as molecular factors of self/non-self recognition in defence reactions against bacteria or fungi, as well as in pathogen/parasite transmission. Dorin M, the plasma lectin of *Ornithodoros moubata*, is the first tick lectin purified so far from tick haemolymph, and the first that has been fully characterized. Partial characterization of other tick lectins/haemagglutinins has been performed mainly with respect to their carbohydrate binding specificities and immunochemical features. Few papers have been published on tick lectins so far, and therefore more data is needed to complete the mosaic of knowledge of their structural and functional properties in terms of their role in pathogen transmission. (Supported by the Grant Agency of the Czech Republic No. 206/03/1323.)

A three dimensional pharmacophore model for discovery of new insect repellent compounds

RJ Gupta, AK Bhattacharjee, W Dhenanetra
Office of the Director, Research Plans and Programs, US Army Medical Research and Materiel Command, Fort Detrick, MD. Department of Medicinal Chemistry and Department of Entomology, Walter Reed Army Institute of Research, Washington, DC.

In pursuit for a better understanding of insect repellent property of molecules we have generated a three-dimensional pharmacophore model using 3D-Catalyst from a training set of eleven diverse insect repellent compounds including DEET. Protection time data for repellent activity of the training set were taken from an earlier published study. Three hydrophobic sites and a hydrogen-bond acceptor site in the molecule appear to be critical for potent insect repellent activity. Calculated stereoelectronic properties such as molecular electrostatic potentials on DEET and some of these molecules in the training set are consistent with our observation. The pharmacophore shows a fairly good correlation (correlation=0.9) between protection time afforded by the compounds in the training set and their predicted protection time. The validity of the pharmacophore model goes beyond the list in the training set and is found to map well on a variety of other insect repellents. By mapping this model on a potent insect repellent compound we have generated a three-dimensional shape based template. A search of in-house database using the pharmacophore template resulted in the discovery of new potential candidate repellent compounds.

Making the case: frequently-contested aspects of forensic entomology evidence

R Hall
"Research, 205 Jesse Hall, Univ. Missouri, Columbia, MO USA, hallr@missouri.edu"

As forensic entomology evidence is introduced at trial, there are a few predictable aspects that frequently are at the heart of controversy regarding either admissibility or weight. Essentially all of these relate to the argument that, whereas forensic entomology is "good science" generally and applied in the present instance by a qualified expert, that as applied to the facts of the case at bar, the opinion under consideration is not based on reliable data (standards of the U.S. Federal Rules of Evidence or various state codifications thereof). Of those objections related to such "reliable data," the most common related to forensic entomology center around the use of remote temperatures. Few homicide victims are located proximate to weather stations, and fewer still decompose while investigators make measurements. Consequently, in virtually all instances, it is necessary to analyze the thermal development of insect species in the context of temperature data obtained during routine operations of weather stations that typically are located at some distance remote from the site where the decedent was found. Whether these data are analyzed as accumulated degree-days (ADD) or degree-hours (ADH), the same objections are continually raised in court: that the data do not accurately reflect conditions at the decomposition scene (because of uncertainty due to distance, differences in altitude, eccentricities of air flow, cooling effects of adjacent water bodies, heating effect of bright sunlight, or similar concerns). Generally, such objections can be forestalled by simple temperature measurements verifying concordance between the weather stations and body site. Related weaknesses include arithmetic errors in tabulating thermal units, misapplication of ADD to calculate ADH, failure to understand how ADD/ADH are applied in the context of existing dipteran developmental data, failure to consider base temperatures below which development essentially ceases, failure to consider the possible effects of "maggot mass," or putative failure to consider the effect of unique drying conditions on corpses. The forensic entomologist should analyze cases in the context of such potential arguments and be prepared to defend conclusions. Curiously, allegations regarding possible misidentification of insect species are seldom raised.

Blood feeding behavior of west nile virus mosquito vectors in Northeastern USA

LC Harrington, KM Mullen
Department of Entomology, Cornell University, Ithaca, NY 14853, lch27@cornell.edu

Control and prevention strategies for West Nile virus (WNV) can only be optimized once the most important human vectors have been identified. Although enzootic vectors of WNV have been identified, the epizootic human and horse-feeding vectors are not clear. A three-year study was conducted to investigate the host-feeding patterns of mosquitoes in areas where humans are active and avian reservoirs are nearby. Resting collections, using specially designed vegetation aspirators, were conducted in Upstate New York and New York City. After identification to species, engorged abdomens were analyzed using antibody sandwich ELISA to identify host blood sources. Blood meals also were tested with the precipitin method against antisera for 20 different species of mammals, birds, and reptiles. More than one host in a blood meal was detected in a small number of samples. These results provide a picture of the temporal and geographic variation in feeding patterns of mosquito species commonly included in surveillance programs as well as those that have not been considered important vectors of pathogens in the Northeast USA. The greatest frequency of human blood feeding was found in *Ochlerotatus triseriatus, Oc. aurifer, Aedes cinerius, Oc. fitchii/stimulans, Culex restuans, Cx. salinarius, Cx. territans, Ae. albopictus* and *Oc. japonicus.*

Going global: Taking molecular forensic entomology the next step

ML Harvey, IR Dadour, MW Mansell, MH Villet
Centre for Forensic Science, University of Western Australia, Mailbag M420, Nedlands, 6009, Australia, mharvey@cyllene.uwa.edu.au

In recent years, the importance of DNA-based techniques for application to the identification of insects, particularly blowfly larvae (Calliphoridae: Diptera) has been widely established. Research has frequently been locality specific, considering the distinction of different species within isolated populations or groups of populations within a small area. While small scale studies are beneficial in development of protocols for accurate molecular identification of insects in specific localities, a global approach to molecular study of forensically significant species facilitates consideration of such issues as species status. This study considers genetic variation in the cytochrome oxidase I (COI) encoding region of mitochondrial DNA (mtDNA) from calliphorids collected throughout Southern Africa and Australia. Alternate regions of DNA are explored for their value in providing an insight to intraspecific variation within several cosmopolitan species. Flies from New Zealand, the United States, Thailand, Taiwan, Brazil and Italy are considered, in addition to Australian and southern African individuals. The study indicates the potential of DNA to provide not only a means of more efficient and accurate identification of insects, but also to analyse the genetic processes occurring within some species, and potential applications and pitfalls for forensic entomology.

The potential for traditional plant-based insect repellents & fumigants as a means of reducing malaria in remote areas

N Hill, S Moore, M Cameron, Z Zhang, X Min
"Disease Control & Vector Biology Unit, London School of Hygiene & Tropical Medicine, Keppel Street, London, WC1E 7HT, UK, nigel.hill@lshtm.ac.uk "

Insect repellents and mosquito coils are widely accepted as beneficial for travelers in regions of vector-borne disease transmission. However, their efficacy at preventing malaria has never been established and is one reason why such methods have never been extended into disease control programmes. Isolated communities in remote regions are often at increased risk of malaria due to problems in provision of even basic malaria control programmes. For example, *P. falciparum* cases in China are increasing dramatically among minority peoples living in the border regions of Laos, Myanmar and Vietnam, or among migrant forest workers in the Bolivian Amazon. In such areas, particularly where there is an abundant floral habitat such as the SE Asia rainforests or the Amazon, there often remains dwindling historical knowledge of traditional plant-based anti-mosquito measures. By working with such communities it may be possible to identify and develop a means of disease control at the individual, household or village level. Such methods, if effective, could be both cheap and sustainable if local plant species are identified as having repellent, fumigant or insecticidal properties which could be exploited. Surveys of plant use among 25 minority peoples in China are reported and the potential for malaria control assessed.

Incidence, prevalence, and seasonality of *Choanotaenia* and *Raillietina* poultry tapeworms in arthropod and vertebrate hosts

NC Hinkle, L Luong, EG Platzer
Department of Entomology, University of Georgia, Athens, GA, USA, NHinkle@uga.edu

Confined animal production facilitates arthropod transmission of disease agents by increasing host-vector interactions, fostering sustained exposures, and providing optimal habitat. Poultry tapeworms, *Choanotaenia infundibulum* and *Raillietina cesticillus*, infest domestic and wild fowl throughout the world. Research at the University of California demonstrated that two insect species collected from caged laying hen operations, the hide beetle, *Dermestes maculatus*, and the house fly, *Musca domestica*, were naturally infected with tapeworm cysticercoids. Tapeworm incidence and prevalence fluctuated independently of host populations, with no distinct seasonal pattern. Extrinsic incubation was shown to be temperature-dependent, with development to infective cysticercoids requiring only 5 days at 33C. As husbandry practices change to optimize facilities for food animal productivity, conditions conducive for arthropod populations simultaneously develop. As intensive production increases, infestation rates can be expected to climb as well.

The sonic web trap for management of stomoxys calcitrans around horses

TL Tam, JA Hogsette, SH TenBroeck
USDA-ARS, CMAVE, P O BOX 14565, Gainesville, Florida, 32604, USA, jhogsette@gainesville.usda.ufl.edu

The Sonic Web (SW) is a trap that is attractive to nuisance flies, particularly the stable fly, *Stomoxys calcitrans*. The trap has a sound component, the heartbeat of a dog, as well as a visual component that draw flies to the trap where they are captured on a replaceable sticky surface. Traps were first evaluated in pairs to determine the role played by the sound. Traps were placed approximately 100 m apart on a horse farm and trap 2 always captured more stable flies than trap 1. The fewest flies were captured when sound was either off or on in both traps. The most flies were captured when sound was on in trap 1 and off in trap 2. Results indicated that several traps could be used in tandem with the sound turned on in only one key trap with spacing at 100-m intervals. SW traps captured significantly more stable flies that the standard Olson trap. When SW traps were placed along the 4 sides of a paddock containing a horse, traps intercepted 90% of the flies entering the paddock before they fed on the horse. SW traps could be an important part of an integrated stable fly management program.

Issues in the control of sheep lice (*Bovicola ovis*)

PJ James
Department of Primary Industries and Fisheries, Animal Research Institute, LMB No 4, Moorooka, QLD, 4105 Australia, peter.james@dpi.qld.gov.au

Sheep lice are among the three main parasitic diseases of sheep in Australia. Historically sheep lice have been controlled by government regulation and the application of chemical insecticides. However, where regulatory powers still exist they are now seldom exercised and there is increasing sensitivity to the use of chemicals in major wool markets, amongst woolgrowers and in society at large. Woolgrowers face continuing cost of production pressures and the effectiveness of some widely used products has been compromised by the development of resistance. These constraints necessitate a more integrated approach to control. Barriers to change include poor knowledge of the biology of *B. ovis*, difficulty in detecting lice in the early stages of an infestation, lack of availability of alternative control methods and sociological factors. These issues are explored and parallels awn with human head lice control.

Regulation of head lice treatments in Australia

SI James
88 Wakley Crescent, Wantirna South VIC 3152 Australia, dsjames@bigfoot.com

Head lice treatments in Australia are regulated by the Therapeutic Goods Administration (TGA) via a two-tiered system. Head lice treatments containing herbal ingredients identified as "low risk" (e.g. melaleuca oil) require **listing** on the Australian Register of Therapeutic Goods (ARTG) These products do not undergo efficacy evaluation prior to listing, although sponsors are required to hold evidence to support label claims. Treatments making "high" level claims, or containing ingredients such as malathion, permethrin or pyrethrins require **registration** on the ARTG, involving evaluation of safety, efficacy and quality of the goods. However, a number of currently registered products were available before the onset of the listing/registration process in 1991. Products available before this time may not have been evaluated, although the potential for the TGA to request evaluation of these "grandfathered" products exists. The regulation of head lice treatments in Australia was reviewed in 2002/2003. A number of recommendations resulted from the review including specific recommendations about label claims and the level of evidence required to support registration or listing of a new head lice treatment product. The recommendations take into account the practical requirements of sponsors and the limitations of the current two-tiered regulation system.

A new device for recording host-seeking rhythms of mosquitoes using a photoelectric sensor

H Kawada, M Takagi,
"Department of Vector Ecology & Environment, Institute of Tropical Medicine, Nagasaki University, Nagasaki, Nagasaki 852-8523, Japan,
vergiss@net.nagasaki-u.ac.jp"

A new automatic device capable of recording the host-seeking behavior of mosquitoes was designed using a photoelectric sensor. The host-seeking rhythms of several mosquito species were recorded in the laboratory. The use of CO_2, in addition to heating and contrast of black and white color, was essential to the functioning of the present recording device. The diel rhythms of non-blood fed *Aedes albopictus, Ae. aegypti, Culex quinquefasciatus, Cx. tritaeniorhynchus*, and *Anopheles stephensi* females recorded by the device corresponded closely with the flight activity levels, as measured by human landing counts and light traps, observed in the field for the same species. This simple automatic recording device also proved to be useful for evaluating the natural host seeking behavior of field-collected mosquitoes.

Astounding success in controlling *Aedes aegypti* in Vietnam using a new strategy

BH Kay, VS Nam
"Australian Centre for International and Tropical Health and Nutrition at the Queensland Institute of Medical Research, Brisbane, Australia and National Institute of Hygiene and Epidemiology, Hanoi, Vietnam, brianK@qimr.edu.au"

From 1989, Vu Sinh Nam and Brian Kay have worked together with a team of collaborators including John Aaskov and Truong Uyen Ninh to deliver community based *Aedes aegypti* control using predacious copepods, the programs being managed by the Australian Foundation of Peoples of Asia and the Pacific. The four elements of the new strategy are (1) vertical and horizontal approaches to build up community understanding, (2) quantitative sampling methodologies designed to prioritize control, (3) inoculation of locally acquired *Mesocyclops* into large water storage containers, and (4) vector control activities at community level. By 2003, *Aedes aegypti* has been eliminated from 42 of 46 communes in north and central Vietnam, involving the protection of some 400,000 people. This is a world first achievement as no insecticide was used. The implications of this model are exciting as this approach is applicable to many countries where water has to be stored for survival.

Seasonal studies on the influence of clothing and wrapping on carcass decomposition and arthropod succession

JA Kelly, TC van der Linde, GS Anderson
Department of Zoology and Entomology, University of the Free State, P.O. Box 339, Bloemfontein, 9300, South Africa, kellyja@telkomsa.net

Six pig (*Sus scrofa* L.) carcasses, three wrapped and clothed carcass and three wrapped and naked, were sampled i) daily ii) after five days and iii) after ten days. Two more carcasses, one naked and not wrapped, and one clothed but not wrapped were sampled daily as controls. Differences in decomposition between the clothed or wrapped carcasses included the distribution and size of maggot masses and significant delay in drying out of the carcasses for all seasons. The maggot masses were primarily dominated by *Chrysomya marginalis* (Wiedemann) and *C. albiceps* (Weidemann), in autumn and summer. *Chrysomya chloropyga* (Weidemann) and *Calliphora vicina* Robineau-Devoidy in winter, with *C. chloropyga* and *C. albiceps* in spring. There was no delay in oviposition except in winter where a five day delay occurred on the wrapped carcasses. Extremely high internal temperatures in the warmer seasons caused significant maggot mortality on the wrapped carcasses. The predation of *C. marginalis* maggots by *C. albiceps* maggots was observed in autumn. In summer, maggot masses of these species were observed in separate groups. The coleopteran community was dominated by *Thanathopilus micans* L. larvae, succeeded by *Dermestes maculatus* De Geer, larvae. Adult *D. maculatus* and *Necrobia rufipes* De Geer, were present on the carcasses throughout all seasons.

Ectoparasites and arthropod-borne parasites of brown rat, *Rattus norvegicus*, in Ahvaz, southwest Iran

EB Kia, Z Telmadarraiy, H Vatandoost, A Farahnak, MM Homayouni, M Satvat, M Jedari, F Kasiri
School of Public Health & Institute of Health Research, Tehran University of Medical Sciences, P.O.Box: 6446-14155, Tehran, Iran, eshratkia@yahoo.com

Arthropods play an important role in the transmission of infectious agents to human and animals, such as rodents. Ahvaz, southwest Iran, is encountered with high density of rodents, especially *R. norvegicus*. In this study, 72 *R.norvegicus* were captured from different sites of Ahvaz, using live traps. Their ectoparasites were collected and identified. Thin and thick blood smears were prepared. After dissection of rats, their different organs were examined for any endoparasites, applying specific techniques. In general ectoparasites comprised 2 species of flea, *Xenopsylla astia* and *X. nubica*, 1 species of louse, *Polyplax spinula* and 1 species of mite *Laelaps nuttalli*. Among endoparasites, 9 species utilize arthropods as vector or intermediate host in their indirect life cycles. These included 1 species of protozoan parasite, *Trypanosoma lewisi* and 8 species of helminth parasites. The potential risk of each of these identified species to the health of human and animals will be discussed.

Applications of GIS and remote sensing for surveillance and control of mosquito borne diseases

Uriel Kitron
University of Illinois, Urbana , IL 61801, USA, ukitron@uiuc.edu

The risk of transmission of mosquito borne diseases depends on the spatial distribution of vector species in relation to the distribution of human hosts and, in case of mosquito-borne zoonoses, the distribution of vertebrate reservoir hosts. These distributions and temporal changes in these spatial patterns depend on environmental and climate/weather conditions. Satellite imagery provides means to gather vast amount of landscape/landcover and meteorological data that are proximate determinants of vector distribution and risk of disease transmission. Geographical information systems allow for the integration of environmental, entomological, epidemiological and demographic data and provide a framework for surveillance and control on scales ranging from local health departments and mosquito control districts to national and international programs. Products of applications of these tools and quantitative analysis of spatial data include data management tools, disease risk maps, and decision making tools for location and time of interventions. Examples from studies in the U.S. Israel, Trinidad and Kenya will be presented, including malaria cases in relation to *Anopheles* larval sites in Trinidad and Israel, dengue and dengue haemorrhagic fever in Trinidad, eastern equine encephalitis outbreaks in Michigan, USA, and La Crosse encephalitis transmission and the effect of introduction of *Aedes albopictus* in Illinois, USA.

Suppression of dengue transmission by application of integrated vector control measures at sero-positive GIS-based foci: Demonstration of a cost-effective model

P Kittayapong, S Yoksarn, U Chansang, C Chansang, A Bhumiratana
Center for Vectors and Vector-Borne Diseases and Department of Biology, Faculty of Science, Mahidol University, Rama 6 Road, Bangkok 10400, Thailand, grpkt@mahidol.ac.th

A serological survey of approximately 2,000 primary school children from six schools in Chachoengsao, Thailand, was performed at the end of the peak dengue transmission period. GIS analysis of sero-positive cases was carried out to determine transmission foci in high IgG-IgM positive villages. Vector control implementation was conducted in the foci and also within 100 meters around the foci, including schools attended by children in the treated areas, with collaboration from local public health and school authorities. Vector control measures included source reduction by routine garbage pickup organized by local government, the use of locally made screen covers, a combination of local Bti and *Mesocyclops*, and locally made lethal ovitraps. Implementation of vector control measures in the foci was continued until the end of the rainy season. Vector control efficiency was monitored using both entomological and serological parameters. Results showed a significant reduction of dengue vectors in treated areas when compared to untreated areas. Despite overall higher dengue incidences in the second year when compared to the first year, IgG-IgM positive students in the treated areas decreased from 13.46% to 0% while those from untreated areas increased from 9.43% to 19.15%.

Novel Mosquito Traps: Do They Really Work

Daniel L Kline

"USDA-ARS, CMAVE, 1600 SW 23rd, Gainesville, FL, USA, dkline@gainesville.usda.ufl.edu"

A diversity of commercial traps for mosquito control have become available during the past five years. Most are marketed to homeowners. Many models have been evaluated in a large outdoor screened enclosure against two species (*Aedes aegypti* and *Ochlerotatus taeniorhynchus*) of laboratory reared mosquitoes to determine their relative efficacy. Several models were selected for field testing against natural populations. Ongoing research is trying to answer the question: Can mosquitoes be trapped out? Different management strategies are being evaluated, e.g. control potential on isolated islands versus urban/suburban residential settings. In urban/residential settings traps are being evaluated as a protective barrier around a city block and in individual yards. Preliminary results indicate that protective trap barriers provide excellent control (>90%) on isolated islands, but only moderate (50% reduction) control in urban/suburban areas. A single trap in a single yard provided no measurable mosquito control.

The mode of action of deet, SS220, and Bayrepel® arthropod repellents against *Aedes aegypti*, *Anopheles stephensi*, and *Phlebotomus papatasi*

JA Klun, A Khrimian, M Debboun
"USDA, ARS, 10300 Baltimore Ave. Beltsville, MD, 20705, USA, klunj@ba.ars.usda.gov"

Laboratory bioassays were conducted with human subjects using six-celled K&D modules and the known arthropod repellents, N,N-diethyl-3-methylbenzamide (Deet), (1S, 2′S)-methylpiperidinyl-3-cyclohexene-1-carboxamide (SS220) and 2-(2-hydroxyethyl)-1-piperidine carboxylic acid 1-methylpropyl ester (Bayrepel) against *Aedes aegypti* (Linnaeus), *Anopheles stephensi* Liston mosquitoes and the sand fly, *Phlebotomus papatasi* which are vectors of human diseases. When five females of each species were simultaneously exposed to one half repellent-treated (4.8×10^{-2}μmol/cm^2) and one half untreated skin beneath the opening of a 3x4 cm cell, they bit exclusively on untreated skin. When treated and untreated skin was covered with cloth to preclude tactile contact with skin surfaces, the insects bit only through cloth covering untreated skin. The tests proved that each species was exquisitely capable of avoiding the compounds in their close-range feeding behavior and this was accomplished by olfactory chemical sensing. When cloth, untreated and repellent treated, was placed over the skin all species avoided the compounds and fed through the cloth only where repellent was absent. In the presence of any the three repellents within a cell, biting responses were reduced by about 50% relative to controls. Thus, besides inhibiting feeding on repellent-treated skin, the compounds also exhibited spatial-repellent activity.

Key issues in advancing the sterile insect technique for african malaria vectors

BGJ Knols, B El-Sayed, MQ Benedict, C Malcolm, H Bossin, A Robinson
International Atomic Energy Agency (IAEA), A-2444, Seibersdorf, Austria; Tropical Medicine Research Institute, Khartoum, Sudan

Pilot projects that assessed the feasibility of the sterile insect technique (SIT) against Anopheles mosquitoes were conducted in El Salvador in the 1970s. Though on a relatively small scale, these trials demonstrated that sterility could be induced in a wild mosquito population through releasing (chemo) sterilized males. Since then, major scientific advances merit a renewed look at SIT and its applicability in the African context. We describe the R&D phase currently underway in Sudan and Austria, to develop appropriate mass-rearing systems and sterilization procedures. The salient features of such releases, also in relation to the use of transgenic approaches, will be discussed. These include colonization and mass rearing, (genetic) sexing, mosquito fitness and release mechanisms.

The influence of burning on the decomposition and insect succession of pig carcasses

JH Kolver, TC van der Linde, MW Mansell
"Department of Zoology and Entomology, University of the Free State, P.O. Box 339, Bloemfontein 9300, South Africa, KolverJH.sci@mail.uovs.ac.za"

Recent casework raised the question whether burning has an influence on the decomposition and insect succession of bodies. This was investigated by dousing three pig carcasses with different volumes of petrol and burning them to different degrees (Slight = 1.5L Medium =5L, Heavily = 10L). The insect succession onto these carcasses was compared to a control carcass. The control carcass decomposed at the fastest rate with the heavily burnt carcass at the slowest rate. Adult insects comprised the following: At the control carcass Diptera (60.8%), Coleoptera (29.9%) and Hymenoptera (8.8%). At the slightly burnt carcass Coleoptera (55.8%), Diptera (38.6%) and Hymenoptera (5.4%). The dominant orders at the medium burnt carcass were Coleoptera (38.5%), Diptera (33.3%) and Hymenoptera (28%). At the heavily burnt carcass Coleoptera (51.4%) and Diptera (28.6%) were dominant. Hymenoptera (18.7%) did not have a direct influence on decomposition, since they functioned as predators. *Chrysomya albiceps* was the dominant Calliphoridae species at the control and medium burnt carcasses and *Chrysomya marginalis* at the slightly and heavily burnt carcass. Representative samples of larvae collected during decomposition revealed that *C. albiceps* larvae preferred to feed underneath the carcasses, with *C. marginalis* larvae feeding mostly inside and at the top of the carcasses.

The study of excito-repellency phenomenon of *Anopheles stephensi* exposed to nets impregnated with cyfluthrin

H Laddoni, H Alipur, MR Abai
"Department of Medical Entomology, School of Public Health, Tehran University of Medical Sciences; ladani@tumssph.com"

The excito-repellency phenomenon is occurred in the vector population following the application of definite insecticides. Based on the field observation, in relation to residual spraying operation, the excito-repellency phenomenon may led to behaviouristic changes of the mosquitoes as diversion either to new hosts or other unsprayed shelters. This occurrence may lead to failure in control program. At these conditions, the mosquitoes leave the sprayed houses to either unsprayed or outdoor shelters before picking up the lethal dose. The result of this investigation will be useful for planning of the control program in the country. For the first time, the standard design of excito-repellency (ER) test box was made of aluminum. The laboratory test was carried out with cyfluthrin treated nets against *An.stephensi* (Beech strain). The result showed that the tendency of the mosquitoes to long resting on the netting of exposure chamber was decreased at high dosage of insecticide, and tried to leave the exposure chamber toward the exit trap. The mean of the feeding rate was least at higher dosage in comparison of lower one.

Human behaviors and environmental factors elevating the risk of exposure to *Ixodes pacificus* nymphs in a hardwood forest

RS Lane, DB Steinlein, J Mun, M Peribañez-Lopez
"Division of Insect Biology, 201 Wellman Hall, University of California, Berkeley, California 94720, U.S.A., blane@nature.berkeley.edu"

The nymph of the western black-legged tick, *Ixodes pacificus*, has been implicated as the primary vector of the Lyme disease spirochete, *Borrelia burgdorferi*, in northwestern California. In 2002 and 2003, six human behaviors and environmental factors were evaluated as potential risk factors for acquiring nymphal ticks in a dense woodland in this region. The prevalence of *B. burgdorferi* and the causative agents of human anaplasmosis (*Anaplasma phagocytophilum*) and human monocytic ehrlichiosis (*Ehrlichia chaffeensis*) also were determined in nymphs that had been collected from subjects or by dragging leaf litter. Time-adjusted tick-acquisition rates demonstrated that sitting on logs was the riskiest behavior followed, in descending rank, by gathering wood, sitting against trees, walking, stirring and sitting on leaf litter, and sitting on litter. The number of ticks acquired appeared to be unrelated to the type of footwear worn. Nymphal ticks were active throughout the daytime over a wide range of micrometeorologic conditions. Overall, about 3-4% of nymphs were infected with *A. phagocytophilum* and *B. burgdorferi*, regardless of the collection method, versus none with *E. chaffeensis*. Co-infection with *B. burgdorferi* and *A. phagocytophilum* was detected for the first time in this life stage of *I. pacificus*. The public health implications of these findings will be discussed briefly.

Genetically Modified Mosquitoes: A Real World View

G.C. Lanzaro

The concept of controlling mosquito-borne diseases via the development and implementation of genetically modified strains has been under serious consideration since the early 1990's. Although this idea has been met with great enthusiasm in some quarters there remains substantial skepticism in others. The general concept and progress toward the development of such a strategy will be presented. Numerous roadblocks to the development of a GM mosquito plan remain, including (i) lack of gene drivers, (ii) lack of robust effector molecules and mechanisms to manipulate their expression, (iii) poor efficiency of transgenesis, (iv), and (v) no consideration of logistical problems associated with implementation in the field. These will be presented and prospects for overcoming them discussed. Aspects of the ecology and population genetics of targeted species will be discussed as they relate to the successful release and establishment of GM mosquitoes in nature.

Reverse chemical ecology: chemical prospecting of mosquito attractants and repellents

WS Leal, Y Ishida, A Cornel
" Department of Entomology, University of California-Davis, Davis CA 95616, USA, wsleal@ucdavis.edu"

For a few decades, chemical ecologists have been utilizing insect antennae as the sensing element or biodetector, in electroantennogram (EAG) and gas chromatography-electroantennographic detection (GC-EAD) assays for the identification of minute amounts of pheromones and other semiochemicals. The "molecular" equivalent of these electrophysiology-based "short cut bioassays" is the screening of attractants and repellents based on their binding affinities to odorant-binding proteins (OBPs). OBPs assist hydrophobic semiochemicals to cross an aqueous barrier in the insect sensilla (sensillar lymph) and reach odorant receptors (ORs). Both OBPs and ORs contribute to the high specificity of the insect olfactory system by forming two layers of filters. Although binding per se does not necessarily imply a physiological function, test compounds that do not bind to OBPs can be eliminated from further behavioral studies as they will never "see" the receptors. Reverse chemical ecology is a protein-based approach that requires the full identification of OBPs, cDNA cloning, functional expression of OBPs, and binding assays. In this presentation, we will discuss the latest development of a NIH-funded project* aimed at the development of better attractants and repellents for *Culex* species, the principal vectors of West Nile Virus.* NIH-National Institute of Allergy and Infectious Diseases (1U01AI058267-01).

Developing methodologies for a fungal biopesticide against *Boophilus* microplus, the cattle tick

DM Leemon, NN Jonsson, DJ Merritt
Animal Research Institute, Locked Mail Bag No 4, Moorooka, QLD, 4105, Australia, diana.leemon@dpi.qld.gov.au

The Queensland department of primary industries and fisheries has been investigating fungal biopesticides for livestock ectoparasites as part of a wider strategy to reduce the reliance upon chemicals in livestock industries. Fungal biopesticides have been available for the control of agricultural and horticultural pests for over thirty years and methodologies and accepted protocols for the development of these fungal biopesticides are now well established. Current work with the cattle tick has shown that livestock pests present additional challenges, some of which are due to the inability to conduct *in vitro* assays on obligate parasites, the cost of *in vivo* experiments using animals and the different environments the fungus must operate in when invading the parasitic and free-living phases. In addition, the development of formulation and application methods suitable for penetrating an animal's hair coat and delivering a lethal dose of spores to ticks present further challenges. Solutions to these problems have sometimes been obvious and straightforward but mostly have been arrived at slowly and painstakingly. We have concluded that the development of methodologies for fungal biopesticides of livestock ectoparasites is a multidisciplinary exercise requiring a thoughtful balance of appropriate *in vitro* bioassays with on-animal investigations.

Increased densities of vector mosquitoes in anthropogenic environments in the Kapiti region in New Zealand and potential ecological mechanisms as to why

PT Leisnham
"Department of Public Health, Wellington School of Medicine & Health Sciences, PO Box 7343, Wellington South, New Zealand, leipa321@student.otago.ac.nz"

Landuse changes, including deforestation, agriculture and urbanisation, have coincided with increases in mosquito-borne diseases worldwide. Anthropogenic environmental changes can alter mosquito populations by modifying the characteristics of breeding habitats, but we still poorly understand the ecological mechanisms involved. Mosquito breeding habitats were sampled in native forest, pastureland and urbanland in the Kapiti region, New Zealand, and 17 environmental characteristics were measured of each. Higher immature mosquito densities were collected from mainly artificial containers in urbanland and pastureland compared to mainly ground pools in native forest. Nine environmental variables were significantly different between landuses but none of these were significantly related to mosquito density. Principal components analysis partitioned environmental data into seven ecological types. One ecological type was significantly related to both landuse and mosquito density, and positively associated with ammonia, bacteria and dissolved organic carbon (DOC), and negatively associated with nitrate and predatory damselfly larvae. The findings of this study support those from prior surveys in warmer climes of greater vector disease risk in anthropogenically-modified environments because of compromised ecosystem integrity. Unlike most previous field-based work, this study also suggests important mechanisms involved; pinpointing mainly bacteria, DOC, nitrate and damselfly larvae as acting in combination to regulate vector mosquito density.

The final word on the genetic, evolutionary and taxonomic relationship of *Pediculus humanus* and *P. capitis*

NP Leo, JM Hughes, SC Barker
Department of Microbiology and Parasitology, University of Queensland, Brisbane 4072, Australia, N.Leo@imb.uq.edu.au

Body lice are thought to have diverged from head lice when humans began to wear clothes. This recent evolutionary divergence and incomplete lineage sorting has complicated assessments of whether head lice and body lice are separate species. We used microsatellite markers to test lice from hosts that were infested with head and body lice simultaneously, to see if the head and body lice had interbred. Our results showed that head and body lice had not interbred on a host. Assignment tests revealed that lice that had migrated among hosts always moved from head to head, and body to body, but never between heads and bodies. We conclude that head and body lice are separate species. We speculate that head lice are descended from the lice of neanderthals and modern humans, and that body lice are descended from the lice of modern humans that left Africa about 100,000 ya.

The search for natural repellents from human beings against mosquitoes

JG Logan, MA Birkett, LJ Wadhams, AJ Mordue (Luntz), JA Pickett
Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire AL5 2JQ, james.logan@bbsrc.ac.uk

Blood sucking insects are differentially attracted to human beings. This is likely to be caused by differences in the semiochemical profiles of individual human hosts. Despite substantial research into insect-human interactions, the responsible semiochemicals have not yet been identified. An explanation for this difference is that unattractive individuals either lack attractant chemical compounds or may produce compounds that 'mask' the activity of attractants. A special air entrainment technique was developed and used to collect volatile chemicals from human volunteers, and the extracts analysed by gas chromatography (GC), coupled GC-electroantennography (GC-EAG) and GC-mass spectrometry (GC-MS). For the first time electrophysiological responses of female yellow fever mosquitoes, *Aedes aegypti* to volatiles from air entrainment extracts were recorded, and a number of electrophysiologically active compounds were identified. Previous behavioural studies have confirmed the differential attractiveness of volunteers to biting insects. A quantitative and qualitative analysis of compounds within the extracts, from individuals known to be differentially attractive to biting insects, has revealed significant differences in chemical profiles. The identification of behaviourally active compounds could lead to new and improved control technologies, whereby 'masking' compounds could potentially be incorporated into new, safe and natural repellents against biting insect pests.

Anopheles arabiensis at the edge of its distribution in northern state, Sudan

CA Malcolm, BB El Sayed, ML Hickson, RS Azrag, AME Hassan, B Knols, MQ Benedict, AS Robinson
"Biological Sciences, Queen Mary, University of London, London E1 4NS, UK, c.a.malcolm@qmul.ac.uk"

Northern state, Sudan is mainly desert, rainfall is rare and most life is found close to the Nile. *Anopheles arabiensis* is the only anopheline and malaria vector found in the area in recent decades. It is present along the Nile downriver to about 200 km south of the Egyptian border, where poor terrain and control efforts prevent its spread further north. Initial results are presented from field and molecular studies to determine the population structure and dynamics of the species and related environmental factors. The receding Nile following the flood contributes most to sustaining *A. arabiensis*. Larval breeding sites can be found on low lying riverbank, ied-up inlets, or channels around islands, through most of the year. Land use is mainly associated with irrigation, but this does not appear to contribute greatly to anopheline numbers, however the extent of human presence and activities do increase the potential for anopheline breeding. Upriver from the fourth cataract and downriver from the third cataract, the terrain is rocky desert and less suitable for both humans and mosquitoes. The *An. arabiensis* population is thus semi-isolated within an approximately 700 km corridor a few kilometres wide and breaks down further into pockets depending on particular river features.

Control of biting midge (Ceratopogonidae) attack on residents of a marine canal estate in Redcliffe (Australia) by residual barrier treatment of Bistar 80SC® to ornamental garden plants in house yards

D McGinn, M Asnicar, C Perel, M Brown
Griffith University, Brisbane 4111 Queensland Australia, mosquitosi@iprimus.com.au

Biting midge (Ceratopogonidae) breeding in marine sediments associated with engineered canals in a residential community in Redcliffe Australia have been responsible for considerable biting attack and nuisance. Limitations on approved applications of larvicides in breeding sites has historically restricted control to personal protection, midge screening and education of residents. In October 2003 – Feb 04, Redcliffe City Council funded a trial to test the efficacy of Bistar 80SC® (FMC Chemicals Pty Ltd) as a 0.1% AI (Bifenthrin) residual application to ornamental garden vegetation and dwelling external walls. Eight paired randomised treated and untreated premises were assessed for differences in biting midge exposure. The assessment was undertaken using CO_2 and Octenol baited light traps placed in treated and untreated yards. A self administered questionnaire scoring individual household daily experience of biting midge activity was also used. Untreated control premises received a placebo application of water alone to control bias in the resident questionnaire. Analysis of difference in light trap collections between treated and untreated showed a 76.4% reduction in midge (primarily *Culicoides molestus*) from treated premises. Resident survey results indicated occupants of treated premises experienced generally favourable biting midge conditions while residents from untreated homes experienced fluctuating exposure and discomfort corresponding to lunar emergence cycles.

Aerial efficacy assessment of Anvil 10+10 against *Anopheles quaimaculatus*

MV Meisch, DA Dame, JR Brown
319 Agri. Bldg. Fayetteville, AR, 72701, USA, meisch@uark.edu

Aerial ULV applications of Anvil 10+10 were conducted against caged, field-collected *Anopheles quaimaculatus* adults using Beecomist® 360A rotary atomizers. Standard and optimized applications were conducted at 0.62 fl oz (0.0036 lbs a.i.) per acre using stacked passes 3,500 ft and 5,000 ft upwind of the target site. Efficacy of Anvil 10+10 and impact of wind velocity at flight altitude (150 ft) were assessed by bioassay and analysis of collected droplets.

The potential role of aquatic insects in the transmission of buruli ulcer disease in Africa

RW Merritt, ME Benbow, R Kimbirauskas
Dept. of Entomology, Michigan State University, East Lansing, MI, USA, merrittr@msu.edu

Buruli ulcer is the third most frequent mycobacterial disease in humans, next to tuberculosis and leprosy, often causing serious skin ulcerations, bone deformities, and disability. Unlike TB and leprosy, Buruli ulcer has emerged dramatically since the 1980's, with increasing numbers of cases being reported from at least 31 countries, mostly in tropical and subtropical areas, including Africa. Although poorly understood, the epidemiology of Buruli ulcer associates the resurgence with people who live and/or work close to wetlands, especially slow flowing (riverine) or stagnant water bodies (marshes, swamps), often created as a result of some human environmental disturbance. The disease is not known to be contagious between humans, and epidemiological studies have not yet established natural reservoirs or modes of transmission. However, it was recently demonstrated experimentally that *M. ulcerans* could survive and multiply exclusively within salivary glands of aquatic bugs (Naucoridae: *Naucoris* sp.) and they were able to transmit *M. ulcerans* to mice by their bites, suggesting a possible mechanism for human infection. The organism has been found in samples of water, biofilm and detritus. A possible trophic scenario for the natural mode of transmission of *M. ulcerans* is presented based on preliminary work in Ghana by the authors.

Efficacy of a Spinosad Suspension Concentrate Formulation for Controlling Chewing and Sucking Lice on Cattle Under Field Conditions

C Jones, LL Smith, DE Snyder, DE Hutchens, Z Cui, D Mowrey, LD Firkins, AJ Paul, JA Meyer
"2001 West Main Street, Greenfield, Indiana, 46140, USA, meyerje@lilly.com"

Field studies were conducted with cattle in Wisconsin and Illinois between January and April, 2000, to determine the efficacy of 0.04% spray and 2 mg/kg pour-on treatments of a spinosad suspension concentrate formulation against chewing and sucking lice. Positive control substances included in the study were Co-Ral® EC (5.8% coumaphos) and CyLence™ Pour-on (1% cyfluthrin). Animals in the negative control group remained untreated. All lice species were visually sampled on each animal at weekly intervals after treatment, for eight weeks. Individual louse counts were summed over each examination site for each species. A repeated measures analysis using a mixed model (SAS PROC MIXED), was conducted for data pooled across both study sites. Both spinosad treatments and CyLence™ Pour-on provided excellent efficacy (98-100%) against *Bovicola bovis* over the entire study period; Co-Ral® EC efficacy opped below 90% from Weeks 6-8. The efficacy of the spinosad spray treatment against *Linognathus vituli* was >93% for the entire study and >88% for the spinosad pour-on treatment. Co-Ral® EC was >90% efficacious against *L. vituli* during Weeks 1-7, while CyLence™ Pour-on only exceeded 90% for Weeks 3-7. *Solenopotes capillatus* were found only at the Wisconsin site; all treatments were highly efficacious throughout the study period.

The effect of human age on dengue seroconversion risk in Iquitos, Peru

SL Minnick, AC Morrison, TW Scott
Entomology Dept, University of California Davis, 1 Shields Ave, Davis, CA 95616, USA, slminnick@ucdavis.edu

Basic models of infectious disease often assume that force of infection is independent of host age. This assumption has been shown to be violated for many directly transmitted diseases, but has rarely been examined in vector-borne systems, such as dengue. Data from DNA fingerprinting studies of mosquito bloodmeals indicate that the biting rate of *Aedes aegypti* increases with human age. If risk for dengue infection increases with human age, models assuming an age-independent risk will underestimate the proportion of the population that needs to be vaccinated in order to eliminate disease transmission. A cohort of approximately 3,000 schoolchildren and their families in Iquitos, Peru were followed for up to 5 years (1999-2003) with blood samples collected at 6-month intervals. Sera were tested for dengue virus antibodies by the plaque reduction neutralization test. The effect of human age on risk for dengue seroconversion was evaluated using a multiple logistic regression model, which also included area of residence within the city. Preliminary analysis suggests that risk increased with age and was highest in the southern region of the city. Estimates of age-specific forces of infection can be used to design an optimal immunization program.

Oviposition Site Selection by Mosquitoes in Response to drought

Allie Mokany
School Of Botany And Zoology, Anu, Canberra, Act, 0200, Australia, allie.mokany@anu.edu.au

Mosquitoes are vectors of many important medical and veterinary diseases. Although outbreaks of mosquito borne disease can be correlated to changes in precipitation in the very short term, precipitation rarely corresponds to mosquito abundance in the long term. Here, I present the results of a field based mesocosm experiment designed to test how water level and drought influence the oviposition behaviour of two species of mosquitoes. I used two water levels (high and low) and two drought treatments (normal and drought). Water for the drought treatments was obtained from ponds that had experienced ying for a period of a month prior to experimentation. The two mosquito species differed markedly in their oviposition response. The egg laying behavior of *Ochlerlatatus notoscriptus* was significantly greater in the drought treatments regardless of water level. However, the egg laying behavior *Anopheles annulipes* showed the opposite response with significantly more larvae present in the high water treatments regardless of whether the treatment water was normal or in drought. My results provide supportive evidence that mosquitoes may show population outbreaks following drought years and that this framework may provide a reliable way of predicting year-to–year variation in mosquito abundances based on individual species oviposition response.

Tests on a new bait for strike flies (Diptera: Calliphoridae)

Michael C. Morris
"57 Cornford St, Karori, Wellington, New Zealand, nezumi1@ihug.co.nz."

A bait consisting of sulphur-containing volatile compounds encapsulated in a caesin-based slow release matrix was tested for its efficacy in catching sheep strike flies (Diptera, Calliphoridae). The fresh bait was significantly more effective than a liver/sodium sulphide mixture in trapping a major strike fly (*Lucilia sericata*) and a minor strike fly (*Chrysomya rufifacies*) on a sticky trap. The bait also trapped significantly more gravid flies of these species. The bait efficacy wore off after 17 days under ambient conditions. The bait was also less effective than the liver mixture when used in Western Australia traps. This may be due either to its loss of effectiveness with age, or to differences in the responses of flies when landing close to the bait on a sticky trap and when searching for the exact location of an odour source in a Western Australia trap. Ways of improving the bait efficacy are discussed.

Aedes aegypti surveillance in Iquitos, Peru: a 4- year test of the pupal/demographic survey

AC Morrison, H Astete, A Getis, K Gray, M Sihuincha, J Stancil, J Olson, P Blair, TW Scott
"Proyecto Dengue, University of California, Davis, Department of Entomology, Calle Nauta 898, Iquitos, Peru, aegypti@terra.com.pe"

We present results from 4 years of pupal/demographic surveys of a circuit of ≈ 6,000 houses surveyed >10 times in the Amazonian city of Iquitos, Peru. We compare traditional larval indices with pupal and adult mosquito indices. We evaluated *Aedes aegypti* production from different container classes, including those based on water management practices overtime and space. A total of 289,941 water-holding containers were characterized, of which 7.3% were positive for *Ae. aegypti*. Although, temporal and geographic variations were detected for all variables examined, consistent production patterns were observed for the lid status (lids: 32% wet containers, 2% pupal production), container location (outdoor: 43% wet containers; 85% pupal production) and method by which the container was filled with water (rain filled: 15% wet containers; 88.3% pupal production). Based on these patterns and additional targeting of containers with highly variable pupal counts we propose a targeted control strategy for Iquitos that would reduce *Ae. aegypti* populations below published but untested threshold values for Iquitos.

Screening medicinal plant extracts for effects on *Aedes aegypti* (Diptera : Culicidae) and toxicity to a non target organism

S Promsiri, A Naksathit, M Kruatrachue, U Thavara
Department of Biology, Faculty of Science, Mahidol University, Rama VI Road, Bangkok 10400, Thailand, grans@mahidol.ac.th

A preliminary study was conducted to find out the effects of the extracts of 112 medicinal plant species, collected from the southern part of Thailand, on *Aedes aegypti*. Studies on larvicidal properties of plant extracts against the third and fourth instar larvae of *Ae. aegypti* showed fourteen species with high toxicity. Six plant species were comparatively more effective against the larvae at very low concentration. These extracts demonstrated no or very low toxicity to guppy fish (*Poecilia reticulata*). Three plants with promising larvicidal activity, *Mammea siamensis*, *Anethum graveolens* and *Annona muricata,* were used to study of the impact of the extracts on the life cycle of *Ae. aegypti*. The results showed that these plants affected the reproductive potential of surviving adults by reducing the number of eggs laid and egg hatchability. The first instar larvae were very susceptible to *A. muricata* and the second instar larvae were susceptible to *A. graveolens* while the third and fourth instar larvae were susceptible to *M. siamensis*. These extracts delayed larval development and inhibited adult emergence.

The mosquito burden in Kenya

HN Njiru
"HEADS Alliance P. O. Box 1905, 60100-Embu Kenya, hndwiga@yahoo.com "

Kenya is a tropical country with a climate favourable for diverse insect life – both the harmful and the useful alike. Embu District experienced a malaria outbreak between January and February 2001 where more than 300 people were admitted at the main health facility in the District, 70 lives were lost. Malaria is endemic in Embu district with a morbidity of 60% and mortality of 25%. Expectant mothers and children are affected most with slide positivity of 30% and 45% respectively. Annually, each household spends around US$ 65 on malaria control and funeral expenses. Larval densities range from 30-40% with peak densities in March, April and May. Despite this, 25% of the community cannot positively identify mosquito as the malaria vector. Only 12% can correctly name the five main symptoms of malaria (fever, chill, sweating, anorexia, joint pains). The ministry of health has issued guidelines on uniform treatment and community sensitisation. Consistent use of bednets, chemoprophylaxis and indoor residual spraying are being encouraged. Plans are underway to start biological adult and larval control. This paper discusses the mosquito burden from the perspectives of larval density, host prevalence index, mortalities and morbidities, bed occupancy and the economics of vector control

Tick vector-pathogen interrelationships

PA Nuttall, M Labuda
"NERC Centre for Ecology & Hydrology, Polaris House, North Star Avenue, Swindon SN2 1EU, U.K., pan@ceh.ac.uk"

The interrelationships between tick-borne pathogens, their tick vectors and diverse vertebrate hosts, are represented by a triangle of parasitic interactions. The interactions are between (i) tick-pathogen, (ii) pathogen-host, and (iii) tick-host. In (i) the pathogen interacts with its vector, infecting and replicating within tick cells or extracellular spaces. The ability of a particular tick species to act as a vector depends on whether the pathogen can survive and overcome several 'barriers' within the tick. However, this is a simplistic view of the tick vector-pathogen interrelationship as both (ii) and (iii) influence the success of (i). This triangle of interactions is focused at the skin site of tick feeding - the initial site at which pathogens gain access to either their host or vector. For pathogens, the skin-feeding site is an ecologically privileged niche, profoundly modified by the pharmacological activities of bioactive tick saliva molecules. Exploitation of this niche is known as saliva-activated transmission (SAT). Tick saliva molecules that promote SAT have not been identified but appear to differ for different tick vector-pathogen interrelationships. Identifying the SAT factors and their mode of action offers new insights for controlling ticks and tick-borne diseases.

Argentina: veterinary forensic entomology as a potential tool against rustling

A Oliva
Av. A. Gallardo 470 – C1405DJR – Buenos Aires – Argentina, aoliva@macn.gov.ar

Cattle rustling entails economic loss to cattle owners and danger to their safety, marketing of uninspected meat and hides and loss to the State from unpaid taxes. In 2003, the Faculty of Veterinary Medicine (Tandil, Buenos Aires province, Argentina) incorporated forensic entomology to a course of legal veterinary medicine aimed at fighting rustling. Preliminary field experiments showed a large proportion of hemisynanthropic insects, most of them Neotropical, which may represent the autochthonous necrophagous fauna, now displaced by synanthropic introduced species in urban environments. Colonization and development times proved longer in the arid climate of Tandil than at Buenos Aires city, where most published data were gathered. Field experiments whith bovine bodies and parts are required. Hitherto, bovines have been avoided as a model because of the added complication of the ruminant digestive tract. Since most countries with rustling problems also have a pattern of introduced species displacing the original necrophagous fauna in city environments, they might benefit from knowledge obtained through these studies.

Arboviruses, mosquitoes, and RNA interference

KE Olson, EA Travanty, I Sanchez-Vargas, KM Keene, BD Foy, BJ Beaty, CD Blair
Arthropod-borne and Infectious Diseases Laboratory, Department of Microbiology, Immunology and Pathology, Colorado State University, Fort Collins, Colorado 80523, kolson@colostate.edu

The identification of critical arbovirus-vector interactions reveals new insights into vector competence. For instance, flavivirus and alphavirus replication in mosquitoes triggers a natural RNA interference (RNAi) response; however, viral counterdefenses probably allow RNAi evasion and establishment of persistent infections. We can enhance RNAi to dengue virus type 2 (DENV2) in *Aedes* species by administration of double-stranded (ds) RNA derived from the DENV2 genome, either by direct transfection of dsRNA, transient expression from a Sindbis virus (SINV) transducing system, or stable transformation with a plasmid that expresses a hairpin-forming transcript. RNAi is sequence-specific, is maintained by low concentrations of effector RNA, blocks accumulation of intracellular viral RNA, and results in the appearance of 21-25 nt siRNA homologous to the mRNA target. We have identified genes from the Dicer and Argonaute families in 2 mosquito genera and have used RNAi to knock down their expression to determine which genes have a role in virus resistance. We have evidence that DENV2 and some strains of SINV establish persistent infections in mosquitoes by suppression of RNAi, and are investigating mechanisms. We are identifying viral-encoded suppressors by site-specific mutations in infectious cDNA clones. Our work suggests that persistent infections in mosquitoes result from a balance between host RNA silencing and viral counterdefenses and provides new strategies for tipping the balance in favor of the vector host.

Endosymbionts and sex ratios in the human head louse

MA Perotti, HR Braig
School of Biological Sciences, University of Wales, Bangor, Gwynedd, LL57 2UW, UK, bssc13@bangor.ac.uk

At the turn of the 19th century the first observations of a female-biased sex ratio in broods and populations of head lice had been reported. A study by Buxton in 1938 on the sex ratio of lice on prisoners in Ceylon is still today the subject of reanalyses. However, in the last sixty years no data have been collected, especially on more normal levels of infestations. Here we report a female bias of head lice in a survey of 480 school children in Argentina. This bias is independent of lice intensity. These lice as well as lice from pupils in Britain were carrying several, related strains of the endosymbiotic bacterium *Wolbachia*, one of the increasing number of intracellular sex ratio distorters. No lice without *Wolbachia* were detected. Similar *Wolbachia* strains are also present in the pig louse suggesting that this endosymbiont might have marked influence on the biology of the whole order. The sex ratio distortion in head lice that has been reported world wide is stable over time; that is a remarkable deviation from the stability of frequency-dependent selection of Fisher's sex ratio.

Blood Feeding in *Cnephia* (Diptera: Simuliidae): Molecular Phylogeny

KP Pruess
University Of Nebraska, Lincoln, NE 68583-0816, U.S., kpruess@unlnotes.unl.edu

Five species of *Cnephia* were studied, three non-biting, one a mammal feeder, and one a bird feeder. Of the non-feeding species, *C. eremite* is Holarctic in distribution and specimens were examined from both Canada and Sweden. *Cnephia pallipes* is a Palearctic non-feeder and *C. dacotensis* a temperate Nearctic non-feeder. *Cnephia pecuarum* is an economically important large mammal feeder in south-central U.S. and *C. ornithophilia* a widely distributed bird feeder in southern and eastern North America. Sequence was obtained from the complete mitochondrial CO-II gene (687 bp) and partial EF1-alpha nuclear gene (1030 bp). Molecular data is discussed in relation to conventional wisdom about relationships among species based on cytological and biological information, geographic distribution and genetic diversity within species. Molecular data strongly support *Cnephia* as a monophyletic clade in the tribe Simuliini. Speciation hypotheses were not fully concordant between molecular and conventional data.

Onchocerciasis in Central America: Ecology & Control

MA Rodríguez-Pérez,
Centro de Biotecnología Genómica-IPN, PO Box 152, Reynosa 87710, Tamaulipas, México, mroiguez@ipn.mx

Detection of O. volvulus larvae in vector populations of black flies is of prime importance in the assessment of the effectiveness of ivermectin control programs. Detection of larvae is attained by dissection of individual flies or by PCR (amplification of an Onchocerca 150 bp repeated sequence, followed by hybridization of the PCR products with a species-specific DNA probe) from pools of flies. The PCR was compared with dissection method to estimate the infection rate (p) and the mean larval load (any larval stage) per parous fly (m) in a local vector population. Both methods produced statistically similar estimates, thus PCR is an alternative and efficient method for entomological surveillance. Sample sizes required to estimate m from p for fixed levels of precision were calculated using Mexican and Guatemalan data, assuming that k (an aggregation parameter from the larval distribution among parous flies) is known. Optimal sampling and PCR was used to evaluate the impact of ivermectin on m, p and transmission potentials in Mexico. The data suggest that substantial progress towards the goal of suppressing transmission has been accomplished. In southern Chiapas, entomological estimates decreased in comparison with the baseline data, but PCR positivity was still detectable. In northern Chiapas and Oaxaca, with no baseline data, there was an absence or near absence of infected and infective flies.

Malaria vectors, *Anopheles hyrcanus* group (Culicidae, Diptera): morphological comparisons and molecular analysis

LM Rueda, RC Wilkerson, C Li, HC Kim, TA Klein, GH Song, D Strickman
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA, ruedapol@msc.si.edu

Anopheles hyrcanus group consists of at least 30 species, with several species including *Anopheles sinensis, lesteri, pullus*, that are known or potential malaria vectors. The morphological diagnostic features and molecular identities of malaria vector *hyrcanus* group species are determined. Larvae, pupae and adults of selected species were described mophologically, and their ITS2 and DNA sequences from our laboratory and GenBank were compared.

Distribution and bionomics of malaria mosquito vectors, *Anopheles (Anopheles)* in Japan, Korea and other parts of Asia

LM Rueda, TA Klein, HC Kim, J Pecor, M Iwakami, M O'Guinn B Prendergast, M Mogi, T Toma, I Miyagi, RC Wilkerson
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA, ruedapol@msc.si.edu.

Mosquito specimens of *Anopheles (Anopheles)* from collections conducted in Japan (2002-03), Korea (1999-2003), Philippines (2002), HongKong (2001), mainland China (2001-03) were identified using morphological and molecular techniques, and recorded. Larval, pupal and adult rearings of field collected samples were conducted for morphological and molecular analysis. Detailed locations of various collection sites and habitats were characterized for known and potential malaria vectors of different countries. Habitats of vectors include ricefields, irrigated ditches, temporary and permanent pools, ponds, streams, others.

Dengue mosquito vectors, *Aedes* and *Ochlerotatus*: morphological identifications and distribution

LM Rueda
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA, ruedapol@msc.si.edu

The diagnostic morphological features of mosquito vectors of dengue viruses are compared for various *Aedes (Diceromyia, Stegomyia)* and *Ochlerotatus (Finlaya, Gymnometopa)* species found in four regions of the world, namely Oriental Region, Pacific and Australian Region, Afrotropical Region, and the Americas. Morphological characters are indicated to separate both larvae and adults of the vector species of each region. The distribution and bionomics of *Aedes* and *Ochlerotatus* vector species are included.

New and resurgent arboviral disease threatening humans in Australia

RC Russell
Department of Medical Entomology, University of Sydney and ICPMR, Westmead Hospital, Westmead, NSW 2145, Australia, rrussell@usyd.edu.au

Australia has a range of indigenous arboviruses and an introduced few that are of public health concern; all are mosquito-borne. Endemic encephalitogenic viruses (Murray Valley Encephalitis, Kunjin) are annually active and responsible for occasional cases in the northwest but, despite widespread vector distribution, only rare activity and no epidemics in the southeast since 1974. The most common arboviruses, Ross River annually infecting many thousands nation-wide causing polyarthritis, and Barmah Forest (a similar syndrome) on the increase and responsible for outbreaks of hundreds regionally, have a spectrum of coastal saline and inland freshwater vectors. The most important exotics are the returning dengue viruses with outbreaks of hundreds confined to Queensland by vector distribution but with virus endemicity and vector spread threatening, and the recently introduced Japanese Encephalitis virus causing only a few deaths in northern Queensland but with virus persistence and its affinity for a local vector threatening. Environmental factors drive arbovirus activity by influencing vector populations, which vary with virus and circumstance, although little is known of the role of reservoir hosts. Tourism and development activities that increase human/vector/virus contact, and climate changes that promote vector and virus proliferation, threaten to exacerbate the disease threat to the public health.

Repellents for integrated tsetse management

RKSaini, A Hassanali
International Center of Insect Physiology and Ecology (ICIPE), P.O. Box 30772 Nairobi, KENYA, rsaini@icipe.org

ICIPE is in the forefront in identifying potent repellents, both synthetic analogues of natural tsetse repellents and natural repellent blends from un-preferred animals like waterbuck and zebras. One potent synthetic repellent for savannah tsetse species, developed by molecular optimization studies, acts as an olfactory antagonist of a key phenolic kairomone, which flies use to locate the host for feeding (Saini & Hassanali; patent application). This repellent substantially reduce tsetse challenge (> 80%) and feeding efficiency (>80%) on cattle. A prototype dispenser which is placed around the neck of an animal has been developed. Field trials indicate that the repellent can provide effective protection to cattle but all animals in a herd need to be protected or else significantly higher infection occurs in unprotected animals. Experiments are ongoing to evaluate how repellents can be integrated with other existing tsetse control techniques. A 'push-pull' strategy that deploys repellents (to 'push') and baited traps / targets (to 'pull') to enhance suppression rates is being evaluated. A variant of this may involve the use of a proportion of cattle with 'pour on' insecticides as live baits. A business plan for commercial production and distribution of repellent products is also being developed.

Mitochondrial genome organization of lice is highly variable

R Shao, C Covacin, SC Barker
Department of Microbiology and Parasitology, The University of Queensland, QLD, 4072, Australia, r.shao@uq.edu.au

Mitochondrial (mt) genome organization is extremely conserved in mammals, vertebrates and most arthropods, e.g., humans and frogs have the same mt genome organization; so have fruit flies and water fleas. We have sequenced the entire mt genomes of the wallaby louse (Phthiraptera: Amblycera) and the pigeon louse (Ischnocera), and part of the mt genomes of the human louse (Anoplura) and four other amblyceran lice. Unlike most arthropods, the mt genome organization of these lice is highly variable. Lice share only 1-2 gene boundaries with fruit flies. No gene boundaries were shared among lice of the three suborders. Mt genome organization differs even among three genera within the suborder Amblycera. Changes in the mt genome organization of lice include gene translocation, inversion, separation of rRNA genes and loss or multiplication of non-coding regions. In addition to lice, we found mt genome organization was variable or highly variable in other two hemipteroid orders, Psocoptera (psocids) and Thysanoptera (thrips), but is strictly conserved in the order Hemiptera (bugs). We speculate that the changes in the mt genome organization in lice, psocids and thrips may be related to their life-history traits such as small body size, small colony size, and high degree of inbreeding.

Kinetics of *Borrelia burgdorferi* infection in larvae of refractory and competent tick vectors.

CAG Soares, CM Rangel-Lima, KS Brandt, NS Zeidner, J Piesman, CB Beard
"1- CDC, NCID/DVBID/BZB, Fort Collins-CO, 80521, USA. CDC/APHL EID Fellowship Program; 2- Lab. Genética Molecular de Eucariontes e Simbiontes, Dept. Genética – I.B., UFRJ, Rio de Janeiro, RJ, Brazil. soares@biologia.ufrj.br."

Borrelia burgdorferi is the causative agent of Lyme disease and is transmitted by the tick *Ixodes scapularis*. The ticks, *Amblyomma americanum* and *Dermacentor variabilis*, represent non-competent or semi-competent species for this spirochete. The present work assesses *B. burgdorferi* acquisition by the larvae of these three species of ticks, detailing the dynamics of the spirochete colonization in these refractory species. *B.burgdorferi* counts were assessed by qPCR using primers and probe for the spirochete *flaB* gene. Larvae were fed on infected mice and the spirochete loads were determined after 3 to 4 days of feeding and up to 28 days post-feeding. Analyses of pools of 10 larvae indicate that *A.americanum* is very refractory to *B.burgdorferi*, with no detection of spirochete DNA during or post-feeding. *I.scapularis* supports high loads of spirochetes (10^3-10^4/larvae). In *D.variabilis*, *B.burgdorferi* uptake was reduced. However, these ticks supported spirochete growth up to the fourth day post-infection, when the ratio of spirochetes increased from 1/300 to 1/7 of the counts in *I.scapularis*. After this time point, *D.variabilis* no longer supports spirochete growth, but *B.burgdorferi* DNA was still detected after molting. These results indicate inappropriate conditions for *B.burgdorferi* colonization and uptake, or the presence of anti-*Borrelia* factor(s) in non-permissive tick species.

West Nile virus activity in the USA and regional differences in vectors and transmission dynamics

HM Savage
Centers for Disease Control, P.O. Box 2087, Fort Collins, CO 80522, USA

In the USA, West Nile virus (WNV) was first detected in New York City in 1999. By the fall of 2003, WNV had spread south and west to 45 states. During 1999–2003, 13,405 human cases of WNV disease were reported. Principal enzootic and epidemic vectors of WNV in the USA are *Culex (Culex)* mosquitoes. In the Northeast and upper Midwest, *Cx. pipiens* L. including form molestus, *Cx. salinarius* Coquillett and *Cx. restuans* Theobald are the most important vectors. In the South, *Cx. quinquefasciatus* Say and *Cx. salinarius* are the most important vectors. In Florida and the southern portions of LA, MS, and AL, *Cx. nigripalpus* Theobald is a potential vector. In the Rocky Mountain and High Plans states, *Cx. tarsalis* Coquillett and *Cx. pipiens* are the primary vectors. In the arid Southwest, *Cx. tarsalis* is the primary vector with *Cx. quinquefasciatus* playing a role in urban areas. Across much of the mid-latitudes, *Cx. pipiens* and *Cx. quinquefasciatus* hybridize and both taxa and hybrids are important vectors. California will experience WNV disease in the future and important vectors are likely to be *Cx. tarsalis* and members of the *Cx. pipiens* complex, with *Cx. stigmatosoma* Dyar and *Cx. erythrothorax* Dyar being focally important. Important avian host vary with regional abundance, however, the house sparrow (*Passer domesticus*) appears important in virus transmission throughout the USA.

Aedes aegypti **genomics**

DW Severson, DL Knudson, BM Soares, BJ Loftus
137 Galvin Life Sciences, University of Notre Dame, Notre Dame, IN 46556, USA, severson.1@nd.edu

"We have initiated a genome project for *Aedes aegypti* that will ultimately lead to complete sequence information. We are sequencing both ends of genomic DNA Bacterial Artificial Chromosome (BAC) clones and random cDNAs representing a variety of tissues, and physically mapping selected BAC clones. BAC clone end-sequencing is completed and the data are available at GenBank. We plan to sequence and analyze both ends of ~80,000 cDNAs derived from normalized libraries produced from 4 specific mRNA sources and one library enriched for full-length sequences. Individual libraries are in various stages of construction, with one competed (*Brugia malayi*-infected) and 29,824 ESTs generated, and sequencing of a second (*Plasmodium gallinaceum*-infected) nearly completed. The third library (females exposed to a dengue virus) has just been completed and we are in the process of constructing libraries from 1) fat body and 2) combined developmental stages. We have incorporated all sequences from our genome project with gene sequences available in GenBank into an *A. aegypti* Gene Index available at TIGR (www.tigr.org/tdb/tgi/aegi/). We have recently (2/13/2004) been notified that NIH-NIAID has selected *A. aegypti* for full genome sequencing. We anticipate this will include an 8X coverage that should provide a high quality genome assembly. "

Measures of *Aedes aegypti* density and the risk of dengue virus transmission.

TW Scott, AC Morrison, H Astete, A Getis, K Gray, M Sihuincha, J Stancil, J Olson, P Blair, JW Jones, R Sithiprasasna, S Koenraadt, M Mammen.
"Department of Entomology, University of California, Davis, CA, 95616, USA. twscott@ucdavis.edu "

In two large, cohort-based prospective studies we are defining entomological risk and characterizing its relationship to human dengue infection. Based on results from more than 5 years of field research in the Amazonian city of Iquitos, Peru we are determining the appropriate scale (spatial and temporal) at which to measure entomological risk and dengue virus transmission. A new research program in Khamphaeng Phet, Thailand is an extension of the Iquitos project and will explicitly link in time and space various measures of entomological risk to human dengue infections

Mitochondrial genome organization of lice is highly variable

R Shao, Ms Cath Covacin and Associate SC Barker
Department of Microbiology and Parasitology, The University of Queensland, QLD, 4072, Australia, r.shao@uq.edu.au

Mitochondrial (mt) genome organization is extremely conserved in mammals, vertebrates and most arthropods, e.g., humans and frogs have the same mt genome organization; so have fruit flies and water fleas. We have sequenced the entire mt genomes of the wallaby louse (Phthiraptera: Amblycera) and the pigeon louse (Ischnocera), and part of the mt genomes of the human louse (Anoplura) and four other amblyceran lice. Unlike most arthropods, the mt genome organization of these lice is highly variable. Lice share only 1-2 gene boundaries with fruit flies. No gene boundaries were shared among lice of the three suborders. Mt genome organization differs even among three genera within the suborder Amblycera. Changes in the mt genome organization of lice include gene translocation, inversion, separation of rRNA genes and loss or multiplication of non-coding regions. In addition to lice, we found mt genome organization was variable or highly variable in other two hemipteroid orders, Psocoptera (psocids) and Thysanoptera (thrips), but is strictly conserved in the order Hemiptera (bugs). We speculate that the changes in the mt genome organization in lice, psocids and thrips may be related to their life-history traits such as small body size, small colony size, and high degree of inbreeding.

Simuliid taxonomy in relation to transmission of human onchocerciasis and mansonelliasis in Brazil.

AJ Shelley, SBL Luz, M Maia-Herzog, APA Luna Dias, LM Hernández.
Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, ajs@nhm.ac.uk.

Mansonelliasis was recorded as widespread in the southern Amazon over 50 years ago and human onchocerciasis 35 years ago in a discrete area in the northern Amazon region of Brazil. Incrimination of the simuliid vectors that transmit the filarial parasites responsible for these diseases has only been possible during the last three decades, largely due to the logistical difficulty in collecting species in these regions and the complex taxonomy of members of the *Simulium amazonicum* group to which several belong. This has been caused by the morphological similarity between vector and non vector species of the group. The use of digital image analysis has facilitated the morphological definition of species in the group, recently augmented by cytological and molecular studies. Our current classification of the group based on these techniques is presented together with distribution maps of vector species that suggest that disease dispersal to non endemic areas may be occurring as infected individuals migrate from the disease foci as rural areas of the Amazon are developed.

Polymerase chain reaction-based differentiation of members of the *Anopheles culicifacies* complex

OP Singh, G Goswami, Nutan Nanda, K Raghavendra, D Chandra, SK Subbarao
Malaria Research Centre (ICMR), 22 SHAM NATH MARG, Delhi-110054, India, singh@mrcindia.org

Anopheles culicifacies, the principal vector of malaria in India, is responsible for over 65% of total malaria in India and is a complex of 5 cryptic species designated as species A, B, C, D, and E. These members are morphologically indistinguishable at any stage of life and can be identified by examining species-specific inversions in polytene chromosome and mitotic karyotype of Y-chromosome of male progeny. In an attempt to develop a simple alternative to cyto-taxonomy, we have developed an Allele-Specific Polymerase Chain Reaction (ASPCR) assay targeted to D3 domain of 28S ribosomal DNA, which unambiguously differentiates *An. culicifacies* species A and D from species B, C, and E. The assay was evaluated using chromosomally-identified specimens of *An. culicifacies* originating from different geographical regions of India representing different sympatric associations and was found to be specific. The culicifacies-specific primers used in the assay did not cross-react to other anophelines as tested against all members of *An. fluviatilis* complex (species S, T, and U), *An. minimus* (species A), *An. stephensi* and *An. subpictus*. The search of genomic database using culicifacies-specific primers sequences revealed that these primers are specific to *An. culicifacies* only. The possible use of this diagnostic assay in disease vector control programme for discrimination of vector species from non-vector will be discussed.

Invasive species impacts, bee and wasp injuries in New Zealand

L Villa, DP Slaney, P Weinstein
"Ecology and Health Research Centre, Dept. of Public Health, Wellington School of Medicine & Health Sciences, University of Otago, PO Box 7343, Wellington South, New Zealand, slaney@wnmeds.ac.nz"

The continued global modification of the environment by human activities has resulted in broad scale ecological disruptions, including the introduction of exotic invasive species. In New Zealand over the last two centuries, two exotic species of bees and four exotic species of wasps of public health concern have become established. In 1990 it was reported that NZ had the highest recorded densities of wasps in the world. In order to establish the prevalence of sting injuries in NZ, we analysed NZ health statistics data and carried out retrospective questionnaire based population surveys. The incidence of bee and wasp sting related hospitalisations remained similar over the twelve-year period from 1988-1999, with an average of 3.1/100,000/year, higher than that reported for the USA but lower than Australian hospitalisation rates. While, results from the questionnaires indicated a high prevalence of sting injuries 1,300/100,000/month (based on a six-month period), significantly higher than that reported in other countries. We estimate that the degree of under-reporting in NZ health statistics from sting injuries could be as great as 53-fold. New Zealand's unique environment (leading to high densities of wasps) and New Zealander's outdoor lifestyle may explain the high prevalence of sting injuries.

Insecticides don’t kill lice but formulations of insecticides do!

JA Staton
Technical Consultancy Services Pty Ltd PO Box 1022, Rockdale, NSW, 2216, Australia, john@techconsult.com.au

Head lice treatment preparations are labelled according to the qualitative and quantitative content of their active ingredients. A recent review of this group of products by the Medicines Evaluation Committee of Australian Therapeutic Goods Administration concluded that "There is a paucity of good quality information on the effects of different formulations on the efficacy of head lice products". This presentation will review the available evidence and identify some of the issues which may impact on dosage form design of head lice preparations.

Potency and avidity of tick paralysis antitoxin in Australia

BF Stone
"University of Queensland, School of Molecular and Microbial Sciences, St Lucia, QLD 4072, Australia, b.stone@uq.edu.au"

Tick paralysis due to the Australian paralysis tick, *Ixodes holocyclus* is a potentially-lethal syndrome affecting domestic pets, livestock and humans along the east coast of Australia mainly during late spring and early summer. There is no vaccine available at present. Prevention in animals largely depends on acaricidal treatment. Treatment of paralysis is based on a commercially-available antiserum, raised in hyperimmune dogs by progressive and cumulative antibody stimulation by repeated infestation with adult female ticks. This serum constitutes a specific, antitoxin widely used by veterinarians and to a limited extent by physicians to treat cases of tick paralysis. Standardisation at the minimum arbitrary level of 500 antitoxin units per ml is legally required. Variability occurs in potency and particularly in avidity (the well-known relative variability on dilution to neutralise an active toxin [in this case, holocyclotoxin] *in vivo* and *in vitro*). A modified method using dilution of antitoxin as opposed to the earlier method of dilution of toxin, may be used to study this variability. This variability will be discussed and possible explanations proposed.

Global expression profiling of the major detoxification enzyme families in the major African malaria vector *Anopheles gambiae*

C Strode, JP David, J Hemingway, J Vontas, H Ranson
Vector Research Group, Liverpool School of Tropical Medicine, Pembroke Place, Liverpool, L3 5QA, UK. cpcs@liverpool.ac.uk

Vector control programs based on the use of insecticides, whether it be by residual house spraying or treated bed nets, are being challenged by the emergence of insecticide resistance. For example, there is wide scale resistance to pyrethroids in mosquitoes from West Africa, which are the major insecticides used in malaria control. One reason for this is the increased detoxification of insecticides by three major enzyme families; glutathione *S*-transferases, cytochrome P450 monooxygenases and the carboxylesterases. The recent publication of the complete genome sequence of the major malaria vector *Anopheles gambiae,* has allowed us to construct a highly specific 'detoxification chip', which contains fragments of all the genes putatively implicated in insecticide resistance in this mosquito. We have used microarray technology to monitor the expression of genes in insecticide-susceptible and resistant mosquito strains to pin-point the genes responsible for resistance. Furthermore, to generate a more detailed profile, their expression has also been assessed in the various life stages of the mosquito and in male and female insects. The detoxification chip is an excellent tool to provide a platform with which to go on and determine the function of these enzymes.

Odour blends in the host-seeking behaviour of the malaria vector *Anopheles gambiae*.

YT Qiu, RC Smallegange, A Galimard, M Jawara, JJA van Loon, TA. van Beek, W Takken
Laboratory of Entomology, Wageningen University, PO Box 8031, 6700 EH Wageningen, The Netherlands, willem.takken@wur.nl

The mosquito *Anopheles gambiae* is the most important malaria vector in Africa primarily because of its strong anthropophilic behaviour. We have studied factors affecting host-seeking behaviour of this mosquito, notably the olfactory cues with which human hosts are being detected. Responses of the mosquitoes to human skin emanations were studied with electrophysiological and behavioural essays. We demonstrated that important olfactory stimuli for *An. gambiae* are ammonia, L-lactic acid and several aliphatic carboxylic acids. EAG and single sensillum recordings demonstrated significant dose-responses in olfactory cells of grooved peg and trichoid sensilla. Behavioural responses were observed with single and mixed odours in an olfactometer. *An. gambiae* always responded to ammonium, although as a single component ammonium could not compete with the natural odours from human skin. Ammonia was an essential synergist to cause activity of lactic acid and/or carboxylic acids. Laboratory results were complemented by field studies in West Africa, where it was found that wild *An. gambiae* were attracted to a synthetic blend of volatiles from a distance. The same blend of odours that caused high attraction in the olfactometer, attracted most mosquitoes to odour-baited traps. The results are discussed with consideration for the development of olfaction-based technologies for malaria control.

Novel mosquito repellents derived from essential oils of plants in Thailand

"A Tawatsin, U Thavara, J Bansiddhi, P Wongsinkongman, T Boonruad, N Komalamisra, MS Mulla "
National Institute of Health, 88/7 Tiwanon Rd., Nonthaburi 11000, Thailand, apiwat@dmsc.moph.go.th

Mosquito-borne diseases, such as dengue, malaria and filariasis are serious public health problems in many countries, especially in the tropical regions of the world. These diseases are caused by pathogens that are transmitted to man through mosquito biting only, thus personal protection from mosquito bites is then considered as one of the strategies to prevent them. Efforts to develop alternatives to replace chemical repellents have been increasingly considered, including extracting and evaluating plant products for repellent activity. The development and use of locally available plant products showing repellent activity thus avails an alternative strategy for prevention of mosquito-borne diseases. In this study we evaluated and reported repellent effects of essential oils extracted from plants against 4 mosquito vectors: *Aedes aegypti*, *Ae. albopictus*, *Anopheles dirus* and *Culex quinquefasciatus* under laboratory conditions using human volunteers. The essential oils were extracted from various parts of 22 plant species, belonging to 10 families, and the oils were prepared as 10% solution in absolute ethanol and some additives. The essential oils showing high degree of repellency were subsequently formulated as topical repellents and tested against day- and night-biting mosquitoes under field conditions. The results obtained from both laboratory and field evaluations will be presented.

Evaluation and development of cockroach repellents derived from essential oils of plants

U Thavara, A Tawatsin, J Chompoosri, P Asavadachanukorn, MS Mulla
National Institute of Health, 88/7 Tiwanon Rd., Nonthaburi 11000, Thailand, usavadee@dmsc.moph.go.th

Cockroaches are common insects found throughout the world, especially in the tropical regions. They are generally recognized as not only household pests but also pose a high health hazard to humans. Various aspects of cockroach control including chemical and non-chemical methods have been researched on an ongoing basis. Repellents against cockroaches are considered as one of alternatives to eliminate cockroaches from dwellings and other harborage places. Attempts have been made to find and develop cockroach repellents derived from plant extracts. We evaluated 20 essential oils extracted from various plants such as basil, black pepper, eucalyptus, galanga, guava, kaffir lime, etc., for repellency against two cockroach species: the American cockroach (*Periplaneta americana*) and the German cockroach (*Blatella germanica*). The experiments were carried out against adult cockroaches in the laboratory. It was found that the tested essential oils provided various degrees of repellency against cockroaches, ranging from 40 to 100%. The essential oil extracted from kaffir lime leaves showed excellent activity, manifesting 100% repellency against both cockroach species. The essential oils providing high degrees of repellency (>80%) were subsequently formulated as cockroach repellents and tested against cockroaches in the field. Data from both laboratory and field tests will be presented.

Recent trends in louse control in the USA

RG Todd
"Insect Control & Research, Inc. 1330 Dillon Heights Avenue, Baltimore, MD 21228-1199, USA inscontrolres@aol.com"

Since the advent of permethrin resistance among head lice (*Pediculus h. capitis*) in the 1990's in the USA, the hegemony of permethrin and synergized-pyrethrin products has given way to a more diverse array of louse control products. Many of the new products use 'natural' ingredients since consumers are anxious to avoid applying insecticides to their chilen, but efficacy is often questionable. Products for nit removal, for repelling lice and for louse detection are all available. The synergized-pyrethrins and permethrin-based products still have a dominant position. New active ingredients and novel technologies have been, and are, being evaluated for louse control – information on most are not yet publicly available. Products now on the market are discussed. FDA requirements are summarized Market size and product market-share are estimated. Future trends are predicted.

The *Simulium ochraceum* (species complex) (Diptera: Simuliidae) and its distribution in relation to onchocerciasis transmission in Latin America.

LM Hernández Triana, AJ Shelley, APA. L Dias, M Maia-Herzog
"Department of Entomology, The Natural History Museum, Cromwell Road, SW& 5BD, London, UK. luih@nhm.ac.uk."

Simulium ochraceum is the primary vector of the disease in Central America and it could be responsible for sporadic transmission of the disease in mainland Ecuador. It consists of three cytotypes which probably have different biting behaviour and susceptibility to the parasite. The morphological variation of this species along its distribution range and its rôle in onchocerciasis transmission are here discussed. The female of *S. ochraceum s.l.* is recognised by thorax orange with 1+1 white pruinose, sub-median cunae (light source anterior). Within the complex, variation in the length of white pruinose vittae and coloration of postnotum and legs occur. *Simulium ochraceum s.l.* shows marked differences in its biting behaviour, being anthropophilic in Central and South America and largely zoophilic in the Caribbean Islands. It bites man occasionally in Brazil and Venezuela. The use of integrated taxonomic techniques is suggested to discover the meaning of morphological variations in terms of cytotypes. The host capacity of *S. ochraceum s.l.* is low because of the presence of cibarial teeth, but it is an efficient vector in hyperendemic areas for the disease. Other factors affecting the vector capacity of this species in the transmission of onchocerciasis in Latin America are discussed.

Emergence of epidemic dengue in Kerala State, southern India, with an account of establishment and dominance of the vector mosquito *Aedes albopictus* (Skuse)

BK Tyagi, J Hiriyan, SC Tewari, V Thenmozhi
Centre for Research in Medical Entomology (ICMR), 4-Sarojini Street, Chinna Chokkikulam, Madurai 625 002, TN, India; bk_tyagi@sify.com

Dengue (including dengue hemorrhagic fever and dengue shock syndrome) has emerged as a major health hazard in India in recent decades as it is being increasingly reported in epidemic proportions from even States hitherto largely *terra incognito* for epidemic dengue, e.g. Kerala State in south India. Several focal outbreaks of dengue fever have been reported from Kerala in recent years, originating in the sylvatic and mountainous terrains of Kottayam, Idukki and Ernakulam, and spreading to coastal districts. The enormity of problem is gauged from the fact that the incidence hiked steeply from merely 14 cases and 4 deaths in 1997 to 3377(241-fold increase) and 66 (>16-fold increase) by November, 2003. While the principal dengue vector, *Aedes aegypti*, was insignificantly prevalent in density mostly along the coastal belt urban areas, *Ae. albopictus* has dominated in prevalence (71.2%), followed by *Armigeres subalbatus* (20.7%), *Aedes aegypti* (4.4%) and *Culex uniformis* (1.5%) amongst all the 22 species under seven genera occurring in the State. Twice the dengue virus had been detected in *Ae. albopictus* adults reared from the field-collected immatures from Western Ghat region. *Aedes aegypti* is, however, yet to be incriminated from Kerala State.

The truth is out there: application of new technology for the understanding and surveillance of mosquito-borne arboviruses

AF van den Hurk, SA Ritchie, BL Montgomery, AT Pyke, GA Smith, JS Mackenzie
"Department of Microbiology and Parasitology, School of Molecular and Microbial Sciences, University of Queensland, St Lucia, QLD, 4072, Australia, anew_hurk@health.qld.gov.au"

Since 1995, Japanese encephalitis virus (JEV) has emerged as an annual threat to northern Australia. To monitor for future incursions of JEV, a sentinel pig programme was established in the Torres Strait and on Cape York Peninsula. While this system has been successful in detecting the virus, it is not ideal: deployment of the pigs is expensive, dangerous to handlers, and, as pigs are the primary amplifying hosts of JEV, they could serve as a source of virus. We outline the development of a mosquito-based sentinel system for the detection of JEV activity in remote areas of northern Australia. This approach is based on application of new generation mosquito traps, such as the propane-powered Mosquito Magnet™, for collection of mosquitoes, and a real time TaqMan RT-PCR for specific detection of viral RNA. In a field trial of the system, it was demonstrated that a single JEV-infected mosquito could be detected in pools of <5000 mosquitoes, maintained for <14 days in tropical conditions. Since 2002, 10 mosquito pools have been positive for JEV at the same time sentinel pigs have seroconverted to the virus. The relative efficacy of the mosquito-based system for detection of JEV and other arboviruses will be discussed.

The New Year's party that went terribly wrong – A case study on the influence of wrapping on decomposition of a body.

TC van der Linde
Department of Zoology & Entomology, University of the Free State, P.O. Box 339, Bloemfontein 9300 South Africa, vdlindet.sci@mail.uovs.ac.za

In this study, an example of unusual disposal of remains is presented with comments on the changes in the resulting patterns of arthropod invasion. A young female disappeared the night of 31st December 2001, after a New Year's party. The evening of 12th January 2002 a suspect was arrested and the body was found. The body was in an advanced stage of decomposition, almost skeletonized. The insects present were late third instar *Chrysomya albiceps* larvae, a few adult *Dermestes maculates* and a few adult Piophilidae. These insects did not correspond to the stage of decomposition. Diptera pupae were also expected. The question arose whether the body might have been kept for a few days, excluding insects, before disposal. It was later established that the body was wrapped in a cotton sheet before it was left in the field. The crime scene was reconstructed, using two pig carcasses, the one wrapped in a sheet and the other unwrapped. Decomposition and insect succession of the two carcasses were monitored and compared. The insects present on the carcasses were the same, but the wrapping of the carcass slowed down the decomposition process, although colonization of the two carcasses occurred at the same time.

The colonization of buried remains at different depths

M Turchetto, S Vanin
Department of Biology, University of Padova, via U. Bassi 58/b, I-35121 Padova, Italy, stefano.vanin@unipd.it

A body exposed in the environment represents a trophic resource for necrophagous organisms. Faunal succession and free access to the corpse are influenced by environmental factors and by the state of the body remains. Instead, in the case of buried corpses, few organisms are able to reach and process these remains. To study which insect species are responsible for underground degradation, we performed experiments by burying some boxes with meal at different soil depths. Two experimental areas in NE Italy were chosen: one in a hilly landscape without agricultural activities, the other in a zone with high human exploitation. In these sites both grassland and deciduous forest were tested. The buried boxes were collected at different times and insect specimens were identified. Diptera belonging to 8 families were found: Stratiomyidae, Phoridae, Sphaeroceridae, Piophilidae, Anthomyiidae, Muscidae, Sarcophagidae and Calliphoridae. The most abundant being the Phoridae, with *Diplonevra funebris* the most abundant species (80% of the total). Calliphoridae and Sarcophagidae were present only in the non-buried boxes. Several Coleoptera were also collected: Staphylinidae were found at all the depths, both as adults and larvae, while Silphidae and Dermestidae were collected only in the non-buried boxes.

Bionomic of ***Anopheles stephensi*** **Liston in a malarious area, Hormozgan province, southern Iran, 2002**

H Vatandoost, MA Oshaghi, MR Abaie, M Shahi, F Yaghoobi, M Baghaii, AA Hanafi-Bojd, G Zamain
School of Public Health & Institute of Public Health Research, Tehran University of Medical Science,
P.O.Box: 6446-14155, Tehran, Iran. e-mail:hvatandoost@yahoo.com

A total of 25000 malaria cases has been reported from Iran. From which Hormozgan province has a higher API comprising 30% of total cases. *Anopheles stephensi* is an important malaria vector in Iran. This species has two activity peaks, one in spring and another in autumn in the region. Mosquitoes of this species prefer to rest and feed indoors. Larval habitats are quite different. All three known biological forms of this species; type, intermediate, and *Mysorensis* occur in the province. Insecticides susceptibility tests showed susceptibility to bendiocarb, propoxur, malathion, fenitrothion, deltamethrin, permethrin, cyfluthrin and lambdacyhalothrin, but resistant to DDT and low level of tolerance to dielin. Larvicidal activity of malathion, fenitrothion, temephos and chlorpyrifos at diagnostic dose exhibited susceptibility to all larvicides except to fenitrothion. The irritability tests to pyrethroid insecticides showed a high level of irritancy to permethrin and lambda-cyhalothrin, but low irritancy to cyfluthrin and deltamethrin.

Identification of Australian carrion-breeding blowflies using multiple gene regions

J Wallman, M Dowton, R Leys, L Nelson
Institute for Conservation Biology, School of Biological Sciences, University of Wollongong, NSW, 2522, Australia, jwallman@uow.edu.au

"Carrion-breeding blowflies have well recognised forensic importance. Their period of development on a corpse can help indicate the time elapsed since death. The applied importance of these flies makes their reliable identification a necessity. Mitochondrial DNA markers may help identify immature blowflies whose identity is difficult or impossible to confirm morphologically. DNA recognition of Australian blowflies poses a special challenge, because their relatively recent speciation makes it necessary to focus on highly variable gene regions for their molecular separation. Thirty-four blowfly species from southern and north-eastern Australia were included in our study, representing almost all species currently known or suspected to be carrion-breeders. Phylogenetic analyses of DNA sequences from the mitochondrial genes COI, COII and ND4 were conducted using parsimony, maximum likelihood and Bayesian methods. In general, these genes provide a powerful tool for the identification of the immature stages of Australian carrion-breeding blowflies. However, in some cases mtDNA sequence divergence is very low, even though statistical support for the separation of individual specimens may be high. Since this leaves open the potential for misidentifications, we have also investigated the applicability of variable nuclear gene markers, the ITS1 and ITS2 regions, to the molecular identification of very closely related species."

Emerging Vectors in Urban Wetland Ecosystems

WE Walton
Dept. of Entomology, Univ. Of California, Riverside, CA, 92521, USA, william.walton@ucr.edu

The use of constructed treatment wetlands for water quality improvement, water reclamation, wetland habitat supplementation, and other goals is increasing worldwide. Man-made wetlands can provide a cost-effective alternative to conventional water treatment facilities for municipal wastewater and are one of several technologies being used to improve the water quality of urban/suburban storm water runoff. A drawback of man-made wetlands used to treat municipal and storm water in areas of rapid human development is the juxtaposition of developmental sites for pathogen-transmitting and pestiferous mosquitoes with human development and peridomestic reservoirs of the causative agents of disease. Management practices and design features thought to be important for water quality improvement often enhance mosquito production. Vector control activities can be impeded by the management practices used to fulfill simultaneously the diverse goals for multipurpose constructed wetlands. The production of native mosquito species which are known to be vectors of the causative agents of disease remains a concern at man-made wetlands and at many best management practices for treating non-point pollutants in the urban environment. The introduction of novel pathogens and vectors into urban landscapes containing treatment wetlands creates new challenges for agencies charged with protecting public health.

The response of mosquito populations to conservation, rehabilitation and construction of urban wetlands at Sydney Olympic Park, NSW, Australia.

CE Webb, KJ Willems, PH Johnson, RC Russell.
Department of Medical Entomology, University of Sydney and ICPMR, Westmead Hospital, Westmead NSW 2145, Australia;
cameronw@icpmr.wsahs.nsw.gov.au

Homebush Bay once contained diverse, yet degraded, estuarine and freshwater wetlands that were either removed or rehabilitated in conjunction with the Sydney Olympic Park urban redevelopment. In addition, extensive freshwater wetlands were constructed for water storage, waste-water treatment, wildlife conservation and aesthetic enhancement. Over 50 mosquito species belonging to 8 genera have been identified from the area, and the potential increases in nuisance biting and public health risks following redevelopment have been a major concern for local authorities. Poor tidal flushing of the estuarine wetlands resulted in unusually large populations of the saltmarsh mosquito, *Ochlerotatus vigilax*, a known virus vector and biting pest, but populations have declined following the commencement of pesticide application and wetland remediation programs. *Culex annulirostris* and *Coquillettidia linealis* are two freshwater pest/vector species that were abundant but declined with the redevelopment. Although the constructed freshwater wetlands were designed to minimise mosquito populations, they have become more productive with increasing vegetation density. Additionally, domestic species *Ochlerotatus notoscriptus* and *Culex quinquefasciatus* are expected to increase with the further residential development. This presentation will provide commentary on the response of mosquito fauna to changes in estuarine and freshwater habitats influenced by the Sydney Olympic Park urban development.

Using vector-borne disease outbreaks to guide ecosystem interventions.

A Cook, A Jardine, P Weinstein
M431, School of Population Health, The University of Western Australia, 35 Stirling Highway, Crawley, WA, 6009, Australia, philipw@sph.uwa.edu.au

There is close association between ecosystem health and human health, exemplified by disease outbreaks that result from ecosystem disruptions. Historical examples include the massive mortality from yellow fever and malaria during construction of the Panama Canal, and more recently the emergence of Lyme disease in ecosystems with decreased biodiversity. In order to decrease the burden from such vector-borne diseases, it is necessary to identify disrupted ecosystems for early remediation. Human health is generally subject to the most widespread and comprehensive surveillance compared to other proposed 'indicators of ecosystem health'. Thus we suggest that human disease outbreaks are one of the most useful and practical bioindicators of the health of an ecosystem. Indeed, many subtle ecosystem disruptions are often only identified as a result of detailed epidemiological investigations following an anomalous increase in human disease incidence detected by routine surveillance mechanisms. Outbreak data can act as a pivotal warning system for ecosystem disruption and can be used to identify interventions for preservation of ecological (and ultimately human) health. Using this approach, appropriate strategies for intervention and remediation can be introduced at an earlier stage than would be possible based solely on environmental monitoring, thereby improving ecosystem health and human health concurrently.

Genotyping human and other vertebrate DNA from maggot gut contents: practical considerations

JD Wells, JG Linville, J Hayes
Dept Biology, West Virginia U, Morgantown, WV 26506, USA, jdwells@mail.wvu.edu

Genetic analysis of maggot gut contents may aid a death investigator. We performed experiments aimed at defining procedures and conditions that will allow such an analysis to succeed. Calliphorid larvae were fed on beef, pork, rat, dog, cat, sheep, rabbit, deer, and human tissues. Larvae were then harvested at a range of developmental stages. Conventional forensic DNA typing procedures were performed on larval gut DNA extracts. The effects of maggot development, specimen preservation technique, larval starvation, and transfer of a feeding larva to a new food type, on recovery of the correct food genotype were examined. PCR amplification involved new cytochrome b primers specifically for vertebrate and not insect DNA, and a commercial STR kit. 20% bleach destroyed surface contamination without interfering with the analysis of internal tissues. Larvae manually removed from food or naturally postfeeding were unsuitable for this analysis after 24 hr off the food. For larvae transferred between food types, both the original and second food genotype could be recovered 46 hr following transfer if specific primers were used. Our methods failed with formalin-preserved specimens. However for all other preservation strategies STR and mtDNA types were obtained from at least some specimens after six months of storage.

Cellular and molecular immunology of the tick-host interface: implications for pathogen transmission

SK Wikel
"Center for Microbial Pathogenesis, School of Medicine, University of Connecticut Health Center, 263 Farmington Avenue, MC3710, Farmington, CT, 06030, USA; swikel@up.uchc.edu"

Complex immunologic interactions occur at the tick-host interface. Tick feeding stimulates host innate and specific acquired immune responses to limit blood meal acquisition. In response to host defenses, tick saliva contains molecules that counteract host immunity. Tick infestation suppresses lymphocyte proliferation, polarizes/modulates cytokine responses, reduces adhesion molecule/integrin expression, modifies antigen presentation, and inhibits cytokine action. The cellular and molecular bases for these phenomena are being defined and multiple diverse pathways for achieving the same end point of immunomodulation are being characterized. The earliest stages of specific T-lymphocyte responses are being analyzed. Genomic and proteomic approaches are used to identify the molecules responsible for modulation of host immune defenses. Tick salivary gland gene expression is being characterized during the first few hours of feeding, and salivary gland molecules of interest are being cloned, expressed and their biological activities identified. Emerging from these studies is a picture of a web of interactions essential for successful blood feeding and transmission of infectious agents that is far more complex than initially envisioned.

Genomics and the development of vaccines against ticks and tick borne disease

P Willadsen, M Hope
"CSIRO Livestock Industries, 306 Carmody Rd., St Lucia, Queensland, Australia, 4067; Peter.Willadsen@csiro.au"

Whole genome sequences of major tick borne disease organisms are available or in progress. Sequencing of the first tick genome will commence soon. Host microarrays allow the dissection of the response to tick or pathogen infestation in a novel way. However, analysis of this deluge of information remains problematic. The rate-limiting step in vaccine development typically remains the assessment of candidate antigens and delivery systems in animals. Genomic information to be useful must be filtered to select a small number of candidates from a plethora of choices. Experience with *Boophilus microplus,* other tick species as well as *Anaplasma marginale* suggests that few highly effective antigens have yet been discovered and the reason for the efficacy of those remains obscure. Other, often less efficacious antigens identified to date fall principally into a few biochemical classes while many other potential antigen classes remain unexplored. The effective use of genomic information will demand a greatly enhanced understanding of the biology of vaccination than is currently available.

cDNA cloning, characterization and preliminary vaccine effect analysis of two *Rhipicephalus haemaphysaloides haemaphysaloides* cathepsin L-like cysteine proteinases

J Zhou, L Chen, Y Zhou, H Gong
"Shanghai Institute of Animal Parasitology, Chinese Academy of Agricultural Sciences, 3 Lane 345, Shilong Road, Shanghai 200232, China; zjlzc@online.sh.cn"

Two cathepsin L-like cysteine proteinase genes were cloned from the tick, *Rhipicephalus haemaphysaloides haemaphysaloides*, named as RhcA and RhcB. The full length of RhcA is 1168bp, encoding a 332 amino acid residue polypeptide; the full length of RhcB is 1153bp, encoding a 335 amino acid residue polypeptide. The consensus amino acid motifs presence in both deduced amino acid sequences and both genes show high sequence homology to other cathepsin L-like cysteine proteinase genes, so they were identified as members of the cysteine proteinase gene family. Expression analysis by RT-PCR revealed that RhcA and RhcB were expressed differently in different stages of tick development. Western blot proved the anti-saliva serum can recognize the *E.coli* expressed recombinant proteins. The immunization test of recombinant against tick infestation showed the two molecules exhibited partially vaccine effects in attachment rate and engorgement rate of adults. GenBank accession No. AY336797 and AY336798 are for RhcA and RhcB respectively

Seasonal studies on the influence of clothing and wrapping on carcass decomposition and arthropod succession.

JA Kelly, TC van der Linde, GS Anderson.
Department of Zoology and Entomology, University of the Free State, P.O. Box 339, Bloemfontein, 9300, South Africa, kellyja@telkomsa.net

Six pig (*Sus scrofa* L.) carcasses, three wrapped and clothed carcass and three wrapped and naked, were sampled i) daily ii) after five days and iii) after ten days. Two more carcasses, one naked and not wrapped, and one clothed but not wrapped were sampled daily as controls. Differences in decomposition between the clothed or wrapped carcasses included the distribution and size of maggot masses and significant delay in ying out of the carcasses for all seasons. The maggot masses were primarily dominated by *Chrysomya marginalis* (Wiedemann) and *C. albiceps* (Weidemann), in autumn and summer. *Chrysomya chloropyga* (Weidemann) and *Calliphora vicina* Robineau-Devoidy in winter, with *C. chloropyga* and *C. albiceps* in spring. There was no delay in oviposition except in winter where a five day delay occurred on the wrapped carcasses. Extremely high internal temperatures in the warmer seasons caused significant maggot mortality on the wrapped carcasses. The predation of *C. marginalis* maggots by *C. albiceps* maggots was observed in autumn. In summer, maggot masses of these species were observed in separate groups. The coleopteran community was dominated by *Thanathopilus micans* L. larvae, succeeded by *Dermestes maculatus* De Geer, larvae. Adult *D. maculatus* and *Necrobia rufipes* De Geer, were present on the carcasses throughout all seasons.

Ectoparasites and arthropod-borne parasites of brown rat, *Rattus norvegicus*, **in Ahvaz, southwest Iran**

EB Kia, Z Telmadarraiy, H Vatandoost, A Farahnak, MM Homayouni, M Satvat, M Jedari, F Kasiri
School of Public Health & Institute of Health Research, Tehran University of Medical Sciences, P.O.Box: 6446-14155, Tehran, Iran, eshratkia@yahoo.com

Arthropods play an important role in the transmission of infectious agents to human and animals, such as rodents. Ahvaz, southwest Iran, is encountered with high density of rodents, especially *R. norvegicus*. In this study, 72 *R.norvegicus* were captured from different sites of Ahvaz, using live traps. Their ectoparasites were collected and identified. Thin and thick blood smears were prepared. After dissection of rats, their different organs were examined for any endoparasites, applying specific techniques. In general ectoparasites comprised 2 species of flea, *Xenopsylla astia* and *X. nubica*, 1 species of louse, *Polyplax spinula* and 1 species of mite *Laelaps nuttalli*. Among endoparasites, 9 species utilize arthropods as vector or intermediate host in their indirect life cycles. These included 1 species of protozoan parasite, *Trypanosoma lewisi* and 8 species of helminth parasites. The potential risk of each of these identified species to the health of human and animals will be discussed.

Applications of GIS and remote sensing for surveillance and control of mosquito borne diseases

U Kitron
University of Illinois, Urbana, IL 61801, USA, ukitron@uiuc.edu.

The risk of transmission of mosquito borne diseases depends on the spatial distribution of vector species in relation to the distribution of human hosts and, in case of mosquito-borne zoonoses, the distribution of vertebrate reservoir hosts. These distributions and temporal changes in these spatial patterns depend on environmental and climate/weather conditions. Satellite imagery provides means to gather vast amount of landscape/landcover and meteorological data that are proximate determinants of vector distribution and risk of disease transmission. Geographical information systems allow for the integration of environmental, entomological, epidemiological and demographic data and provide a framework for surveillance and control on scales ranging from local health departments and mosquito control districts to national and international programs. Products of applications of these tools and quantitative analysis of spatial data include data management tools, disease risk maps, and decision making tools for location and time of interventions. Examples from studies in the U.S. Israel, Trinidad and Kenya will be presented, including malaria cases in relation to *Anopheles* larval sites in Trinidad and Israel, dengue and dengue haemorrhagic fever in Trinidad, eastern equine encephalitis outbreaks in Michigan, USA, and La Crosse encephalitis transmission and the effect of introduction of *Aedes albopictus* in Illinois, USA.

Suppression of dengue transmission by application of integrated vector control measures at sero-positive GIS-based foci: demonstration of a cost-effective model

P Kittayapong, S Yoksarn, U Chansang, C Chansang, A Bhumiratana
Center for Vectors and Vector-Borne Diseases and Department of Biology, Faculty of Science, Mahidol University, Rama 6 Road, Bangkok 10400, Thailand, grpkt@mahidol.ac.th

A serological survey of approximately 2,000 primary school chilen from six schools in Chachoengsao, Thailand, was performed at the end of the peak dengue transmission period. GIS analysis of sero-positive cases was carried out to determine transmission foci in high IgG-IgM positive villages. Vector control implementation was conducted in the foci and also within 100 meters around the foci, including schools attended by chilen in the treated areas, with collaboration from local public health and school authorities. Vector control measures included source reduction by routine garbage pickup organized by local government, the use of locally made screen covers, a combination of local Bti and *Mesocyclops*, and locally made lethal ovitraps. Implementation of vector control measures in the foci was continued until the end of the rainy season. Vector control efficiency was monitored using both entomological and serological parameters. Results showed a significant reduction of dengue vectors in treated areas when compared to untreated areas. Despite overall higher dengue incidences in the second year when compared to the first year, IgG-IgM positive students in the treated areas decreased from 13.46% to 0% while those from untreated areas increased from 9.43% to 19.15%.

Novel mosquito traps: can they control moquitoes

DL Kline
USDA-ARS, CMAVE,1600 SW 23rd , Gainesville, FL, USA, dkline@gainesville.usda.ufl.edu

A diversity of commercial traps for mosquito control have become available during the past five years. Most are marketed to homeowners. Many models have been evaluated in a large outdoor screened enclosure against two species (*Aedes aegypti* and *Ochlerotatus taeniorhynchus*) of laboratory reared mosquitoes to determine their relative efficacy. Several models were selected for field testing against natural populations. Ongoing research is trying to answer the question: Can mosquitoes be trapped out? Different management strategies are being evaluated, e.g. control potential on isolated islands versus urban/suburban residential settings. In urban/residential settings traps are being evaluated as a protective barrier around a city block and in individual yards. Preliminary results indicate that protective trap barriers provide excellent control (>90%) on isolated islands, but only moderate (50% reduction) control in urban/suburban areas. A single trap in a single yard provided no measurable mosquito control.

The mode of action of deet, SS220, and Bayrepel® arthropod repellents against *Aedes aegypti*, *Anopheles stephensi*, **and** *Phlebotomus papatasi.*

JA Klun, A Khrimian, M Debboun
USDA, ARS, 10300 Baltimore Ave. Beltsville, MD, 20705, USA, klunj@ba.ars.usda.gov

Laboratory bioassays were conducted with human subjects using six-celled K&D modules and the known arthropod repellents, N,N-diethyl-3-methylbenzamide (Deet), (1S, 2'S)-methylpiperidinyl-3-cyclohexene-1-carboxamide (SS220) and 2-(2-hydroxyethyl)-1-piperidine carboxylic acid 1-methylpropyl ester (Bayrepel) against *Aedes aegypti* (Linnaeus), *Anopheles stephensi* Liston mosquitoes and the sand fly, *Phlebotomus papatasi* which are vectors of human diseases. When five females of each species were simultaneously exposed to one half repellent-treated (4.8×10^{-2}µmol/cm^2) and one half untreated skin beneath the opening of a 3x4 cm cell, they bit exclusively on untreated skin. When treated and untreated skin was covered with cloth to preclude tactile contact with skin surfaces, the insects bit only through cloth covering untreated skin. The tests proved that each species was exquisitely capable of avoiding the compounds in their close-range feeding behavior and this was accomplished by olfactory chemical sensing. When cloth, untreated and repellent treated, was placed over the skin all species avoided the compounds and fed through the cloth only where repellent was absent. In the presence of any the three repellents within a cell, biting responses were reduced by about 50% relative to controls. Thus, besides inhibiting feeding on repellent-treated skin, the compounds also exhibited spatial-repellent activity.

Key issues in advancing the sterile insect technique for African malaria vectors

BGJ Knols, B El-Sayed, MQ Benedict, C Malcolm, H Bossin, A Robinson
International Atomic Energy Agency (IAEA), A-2444, Seibersdorf, Austria; Tropical Medicine Research Institute, Khartoum, Sudan; CDC, Atlanta, USA; Queen Mary University, London, UK;

Pilot projects that assessed the feasibility of the sterile insect technique (SIT) against Anopheles mosquitoes were conducted in El Salvador in the 1970s. Though on a relatively small scale, these trials demonstrated that sterility could be induced in a wild mosquito population through releasing (chemo)sterilized males. Since then, major scientific advances merit a renewed look at SIT and its applicability in the African context. We describe the R&D phase currently underway in Sudan and Austria, to develop appropriate mass-rearing systems and sterilization procedures. The salient features of such releases, also in relation to the use of transgenic approaches, will be discussed. These include colonization and mass rearing, (genetic) sexing, mosquito fitness and release mechanisms.

The influence of burning on the decomposition and insect succession of pig carcasses.

JH Kolver, TC van der Linde, MW Mansell
Department of Zoology and Entomology, University of the Free State, P.O. Box 339, Bloemfontein 9300, South Africa, KolverJH.sci@mail.uovs.ac.za

Recent casework raised the question whether burning has an influence on the decomposition and insect succession of bodies. This was investigated by dousing three pig carcasses with different volumes of petrol and burning them to different degrees (Slight = 1.5L Medium =5L, Heavily = 10L). The insect succession onto these carcasses was compared to a control carcass. The control carcass decomposed at the fastest rate with the heavily burnt carcass at the slowest rate. Adult insects comprised the following: At the control carcass Diptera (60.8%), Coleoptera (29.9%) and Hymenoptera (8.8%). At the slightly burnt carcass Coleoptera (55.8%), Diptera (38.6%) and Hymenoptera (5.4%). The dominant orders at the medium burnt carcass were Coleoptera (38.5%), Diptera (33.3%) and Hymenoptera (28%). At the heavily burnt carcass Coleoptera (51.4%) and Diptera (28.6%) were dominant. Hymenoptera (18.7%) did not have a direct influence on decomposition, since they functioned as predators. *Chrysomya albiceps* was the dominant Calliphoridae species at the control and medium burnt carcasses and *Chrysomya marginalis* at the slightly and heavily burnt carcass. Representative samples of larvae collected during decomposition revealed that *C. albiceps* larvae preferred to feed underneath the carcasses, with *C. marginalis* larvae feeding mostly inside and at the top of the carcasses.

The study of excito-repellency phenomenon of *Anopheles stephensi* exposed to nets impregnated with cyfluthrin

H Laddoni, H Alipur, MR Abai,
Department of Medical Entomology, School of Public Health, Tehran University of Medical Sciences, ladani@tumssph.com

The excito-repellency phenomenon is occurred in the vector population following the application of definite insecticides. Based on the field observation, in relation to residual spraying operation, the excito-repellency phenomenon may led to behaviouristic changes of the mosquitoes as diversion either to new hosts or other unsprayed shelters. This occurrence may lead to failure in control program. At these conditions, the mosquitoes leave the sprayed houses to either unsprayed or outdoor shelters before picking up the lethal dose. The result of this investigation will be useful for planning of the control program in the country. For the first time, the standard design of excito-repellency (ER) test box was made of aluminum. The laboratory test was carried out with cyfluthrin treated nets against *An.stephensi* (Beech strain). The result showed that the tendency of the mosquitoes to long resting on the netting of exposure chamber was decreased at high dosage of insecticide, and tried to leave the exposure chamber toward the exit trap. The mean of the feeding rate was least at higher dosage in comparison of lower one.

Human behaviors and environmental factors elevating the risk of exposure to *Ixodes pacificus* nymphs in a hardwood forest

RS Lane, DB Steinlein, J Mun , M Peribañez-Lopez
Division of Insect Biology, 201 Wellman Hall, University of California, Berkeley, California 94720, U.S.A, blane@nature.berkeley.edu

The nymph of the western black-legged tick, *Ixodes pacificus*, has been implicated as the primary vector of the Lyme disease spirochete, *Borrelia burgdorferi*, in northwestern California. In 2002 and 2003, six human behaviors and environmental factors were evaluated as potential risk factors for acquiring nymphal ticks in a dense woodland in this region. The prevalence of *B. burgdorferi* and the causative agents of human anaplasmosis (*Anaplasma phagocytophilum*) and human monocytic ehrlichiosis (*Ehrlichia chaffeensis*) also were determined in nymphs that had been collected from subjects or by agging leaf litter. Time-adjusted tick-acquisition rates demonstrated that sitting on logs was the riskiest behavior followed, in descending rank, by gathering wood, sitting against trees, walking, stirring and sitting on leaf litter, and sitting on litter. The number of ticks acquired appeared to be unrelated to the type of footwear worn. Nymphal ticks were active throughout the daytime over a wide range of micrometeorologic conditions. Overall, about 3-4% of nymphs were infected with *A. phagocytophilum* and *B. burgdorferi*, regardless of the collection method, versus none with *E. chaffeensis*. Co-infection with *B. burgdorferi* and *A. phagocytophilum* was detected for the first time in this life stage of *I. pacificus*. The public health implications of these findings will be discussed briefly.

Genetically modified mosquitoes: a real world view

GC Lanzaro ADDRESS

The concept of controlling mosquito-borne diseases via the development and implementation of genetically modified strains has been under serious consideration since the early 1990's. Although this idea has been met with great enthusiasim in some quarters there remains substantial skepticism in others. The general concept and progress toward the development of such a strategy will be presented. Numerous roadblocks to the development of a GM mosquito plan remain, including (i) lack of gene drivers, (ii) lack of robust effector molecules and mechanisms to manipulate their expression, (iii) poor efficiency of transgenesis, (iv), and (v) no consideration of logistical problems associated with implementation in the field. These will be presented and prospects for overcoming them discussed. Aspects of the ecology and population genetics of targeted species will be discussed as they relate to the successful release and establishment of GM mosquitoes in nature.

Reverse chemical ecology: chemical prospecting of mosquito attractants and repellents

WS Leal, Y Ishida, A Cornel
Department of Entomology, University of California-Davis, Davis CA 95616, USA, wsleal@ucdavis.edu

For a few decades, chemical ecologists have been utilizing insect antennae as the sensing element or biodetector, in electroantennogram (EAG) and gas chromatography-electroantennographic detection (GC-EAD) assays for the identification of minute amounts of pheromones and other semiochemicals. The "molecular" equivalent of these electrophysiology-based "short cut bioassays" is the screening of attractants and repellents based on their binding affinities to odorant-binding proteins (OBPs). OBPs assist hydrophobic semiochemicals to cross an aqueous barrier in the insect sensilla (sensillar lymph) and reach odorant receptors (ORs). Both OBPs and ORs contribute to the high specificity of the insect olfactory system by forming two layers of filters. Although binding per se does not necessarily imply a physiological function, test compounds that do not bind to OBPs can be eliminated from further behavioral studies as they will never "see" the receptors. Reverse chemical ecology is a protein-based approach that requires the full identification of OBPs, cDNA cloning, functional expression of OBPs, and binding assays. In this presentation, we will discuss the latest development of a NIH-funded project* aimed at the development of better attractants and repellents for *Culex* species, the principal vectors of West Nile Virus.* NIH-National Institute of Allergy and Infectious Diseases (1U01AI058267-01).

Developing methodologies for a fungal biopesticide against *Boophilus* microplus, the cattle tick

DM Leemon, NN Jonsson, DJ Merritt
Animal Research Institute, Locked Mail Bag No 4, Moorooka, QLD, 4105, Australia, diana.leemon@dpi.qld.gov.au

The Queensland department of primary industries and fisheries has been investigating fungal biopesticides for livestock ectoparasites as part of a wider strategy to reduce the reliance upon chemicals in livestock industries. Fungal biopesticides have been available for the control of agricultural and horticultural pests for over thirty years and methodologies and accepted protocols for the development of these fungal biopesticides are now well established. Current work with the cattle tick has shown that livestock pests present additional challenges, some of which are due to the inability to conduct *in vitro* assays on obligate parasites, the cost of *in vivo* experiments using animals and the different environments the fungus must operate in when invading the parasitic and free-living phases. In addition, the development of formulation and application methods suitable for penetrating an animal's hair coat and delivering a lethal dose of spores to ticks present further challenges. Solutions to these problems have sometimes been obvious and straightforward but mostly have been arrived at slowly and painstakingly. We have concluded that the development of methodologies for fungal biopesticides of livestock ectoparasites is a multidisciplinary exercise requiring a thoughtful balance of appropriate *in vitro* bioassays with on-animal investigations.

Increased densities of vector mosquitoes in anthropogenic environments in the Kapiti region in New Zealand and potential ecological mechanisms as to why

PT Leisnham
Department of Public Health, Wellington School of Medicine & Health Sciences, PO Box 7343, Wellington South, New Zealand,
leipa321@student.otago.ac.nz

Landuse changes, including deforestation, agriculture and urbanisation, have coincided with increases in mosquito-borne diseases worldwide. Anthropogenic environmental changes can alter mosquito populations by modifying the characteristics of breeding habitats, but we still poorly understand the ecological mechanisms involved. Mosquito breeding habitats were sampled in native forest, pastureland and urbanland in the Kapiti region, New Zealand, and 17 environmental characteristics were measured of each. Higher immature mosquito densities were collected from mainly artificial containers in urbanland and pastureland compared to mainly ground pools in native forest. Nine environmental variables were significantly different between landuses but none of these were significantly related to mosquito density. Principal components analysis partitioned environmental data into seven ecological types. One ecological type was significantly related to both landuse and mosquito density, and positively associated with ammonia, bacteria and dissolved organic carbon (DOC), and negatively associated with nitrate and predatory damselfly larvae. The findings of this study support those from prior surveys in warmer climes of greater vector disease risk in anthropogenically-modified environments because of compromised ecosystem integrity. Unlike most previous field-based work, this study also suggests important mechanisms involved; pinpointing mainly bacteria, DOC, nitrate and damselfly larvae as acting in combination to regulate vector mosquito density.

The final word on the genetic, evolutionary and taxonomic relationship of *Pediculus humanus* and *P. capitis*.

NP Leo, JM Hughes, SC Barker
Department of Microbiology and Parasitology, University of Queensland, Brisbane 4072, Australia, N.Leo@imb.uq.edu.au

Body lice are thought to have diverged from head lice when humans began to wear clothes. This recent evolutionary divergence and incomplete lineage sorting has complicated assessments of whether head lice and body lice are separate species. We used microsatellite markers to test lice from hosts that were infested with head and body lice simultaneously, to see if the head and body lice had interbed. Our results showed that head and body lice had not interbred on a host. Assignment tests revealed that lice that had migrated among hosts always moved from head to head, and body to body, but never between heads and bodies. We conclude that head and body lice are separate species. We speculate that head lice are descended from the lice of neanderthals and modern humans, and that body lice are descended from the lice of modern humans that left Africa about 100,000 ya.

The search for natural repellents from human beings against mosquitoes

JG Logan, MA Birkett, LJ Wadhams, AJ Mordue (Luntz), JA Pickett
Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire AL5 2JQ, james.logan@bbsrc.ac.uk

Blood sucking insects are differentially attracted to human beings. This is likely to be caused by differences in the semiochemical profiles of individual human hosts. Despite substantial research into insect-human interactions, the responsible semiochemicals have not yet been identified. An explanation for this difference is that unattractive individuals either lack attractant chemical compounds or may produce compounds that 'mask' the activity of attractants. A special air entrainment technique was developed and used to collect volatile chemicals from human volunteers, and the extracts analysed by gas chromatography (GC), coupled GC-electroantennography (GC-EAG) and GC-mass spectrometry (GC-MS). For the first time electrophysiological responses of female yellow fever mosquitoes, *Aedes aegypti* to volatiles from air entrainment extracts were recorded, and a number of electrophysiologically active compounds were identified. Previous behavioural studies have confirmed the differential attractiveness of volunteers to biting insects. A quantitative and qualitative analysis of compounds within the extracts, from individuals known to be differentially attractive to biting insects, has revealed significant differences in chemical profiles. The identification of behaviourally active compounds could lead to new and improved control technologies, whereby 'masking' compounds could potentially be incorporated into new, safe and natural repellents against biting insect pests.

Anopheles arabiensis **at the edge of its distribution in Northern State, Sudan**

CA Malcolm, BB El Sayed, ML Hickson, RS Azrag, AME Hassan, B Knols, MQ Benedict, AS Robinson
Biological Sciences, Queen Mary, University of London, London E1 4NS, UK, c.a.malcolm@qmul.ac.uk

Northern state, Sudan is mainly desert, rainfall is rare and most life is found close to the Nile. *Anopheles arabiensis* is the only anopheline and malaria vector found in the area in recent decades. It is present along the Nile downriver to about 200 km south of the Egyptian border, where poor terrain and control efforts prevent its spread further north. Initial results are presented from field and molecular studies to determine the population structure and dynamics of the species and related environmental factors. The receding Nile following the flood contributes most to sustaining *A. arabiensis*. Larval breeding sites can be found on low lying riverbank, ied-up inlets, or channels around islands, through most of the year. Land use is mainly associated with irrigation, but this does not appear to contribute greatly to anopheline numbers, however the extent of human presence and activities do increase the potential for anopheline breeding. Upriver from the fourth cataract and downriver from the third cataract, the terrain is rocky desert and less suitable for both humans and mosquitoes. The *An. arabiensis* population is thus semi-isolated within an approximately 700 km corridor a few kilometres wide and breaks down further into pockets depending on particular river features.

Control of biting midge (Ceratopogonidae) attack on residents of a marine canal estate in Redcliffe (Australia) by residual barrier treatment of Bistar 80SC® to ornamental garden plants in house yards

D McGinn, M Asnicar, C Perel, M Brown.
Griffith University, Brisbane 4111 Queensland Australia, mosquitosi@iprimus.com.au

Biting midge (Ceratopogonidae) breeding in marine sediments associated with engineered canals in a residential community in Redcliffe Australia have been responsible for considerable biting attack and nuisance. Limitations on approved applications of larvicides in breeding sites has historically restricted control to personal protection, midge screening and education of residents. In October 2003 – Feb 04, Redcliffe City Council funded a trial to test the efficacy of Bistar 80SC® (FMC Chemicals Pty Ltd) as a 0.1% AI (Bifenthrin) residual application to ornamental garden vegetation and dwelling external walls. Eight paired randomised treated and untreated premises were assessed for differences in biting midge exposure. The assessment was undertaken using CO_2 and Octenol baited light traps placed in treated and untreated yards. A self administered questionnaire scoring individual household daily experience of biting midge activity was also used. Untreated control premises received a placebo application of water alone to control bias in the resident questionnaire. Analysis of difference in light trap collections between treated and untreated showed a 76.4% reduction in midge (primarily *Culicoides molestus*) from treated premises. Resident survey results indicated occupants of treated premises experienced generally favourable biting midge conditions while residents from untreated homes experienced fluctuating exposure and discomfort corresponding to lunar emergence cycles.

Aerial efficacy assessment of Anvil 10+10 against *Anopheles quaimaculatus*

MV Meisch, DA Dame, JR Brown
319 Agri. Bldg. Fayetteville, AR, 72701, USA, meisch@uark.edu

Aerial ULV applications of Anvil 10+10 were conducted against caged, field-collected *Anopheles quaimaculatus* adults using Beecomist® 360A rotary atomizers. Standard and optimized applications were conducted at 0.62 fl oz (0.0036 lbs a.i.) per acre using stacked passes 3,500 ft and 5,000 ft upwind of the target site. Efficacy of Anvil 10+10 and impact of wind velocity at flight altitude (150 ft) were assessed by bioassay and analysis of collected droplets.

The potential role of aquatic insects in the transmission of Buruli ulcer disease in Africa

RW Merritt, ME Benbow, R Kimbirauskas
Dept. of Entomology, Michigan State University, East Lansing, MI, USA, merrittr@msu.edu

Buruli ulcer is the third most frequent mycobacterial disease in humans, next to tuberculosis and leprosy, often causing serious skin ulcerations, bone deformities, and disability. Unlike TB and leprosy, Buruli ulcer has emerged amatically since the 1980's, with increasing numbers of cases being reported from at least 31 countries, mostly in tropical and subtropical areas, including Africa. Although poorly understood, the epidemiology of Buruli ulcer associates the resurgence with people who live and/or work close to wetlands, especially slow flowing (riverine) or stagnant water bodies (marshes, swamps), often created as a result of some human environmental disturbance. The disease is not known to be contagious between humans, and epidemiological studies have not yet established natural reservoirs or modes of transmission. However, it was recently demonstrated experimentally that *M. ulcerans* could survive and multiply exclusively within salivary glands of aquatic bugs (Naucoridae: *Naucoris* sp.) and they were able to transmit *M. ulcerans* to mice by their bites, suggesting a possible mechanism for human infection. The organism has been found in samples of water, biofilm and detritus. A possible trophic scenario for the natural mode of transmission of *M. ulcerans* is presented based on preliminary work in Ghana by the authors.

Efficacy of a Spinosad suspension concentrate formulation for controlling chewing and sucking lice on cattle under field conditions

JA Meyer
2001 West Main Street, Greenfield, Indiana, 46140, USA, meyerje@lilly.com

Field studies were conducted with cattle in Wisconsin and Illinois between January and April, 2000, to determine the efficacy of 0.04% spray and 2 mg/kg pour-on treatments of a spinosad suspension concentrate formulation against chewing and sucking lice. Positive control substances included in the study were Co-Ral® EC (5.8% coumaphos) and CyLence™ Pour-on (1% cyfluthrin). Animals in the negative control group remained untreated. All lice species were visually sampled on each animal at weekly intervals after treatment, for eight weeks. Individual louse counts were summed over each examination site for each species. A repeated measures analysis using a mixed model (SAS PROC MIXED), was conducted for data pooled across both study sites. Both spinosad treatments and CyLence™ Pour-on provided excellent efficacy (98-100%) against *Bovicola bovis* over the entire study period; Co-Ral® EC efficacy opped below 90% from Weeks 6-8. The efficacy of the spinosad spray treatment against *Linognathus vituli* was >93% for the entire study and >88% for the spinosad pour-on treatment. Co-Ral® EC was >90% efficacious against *L. vituli* during Weeks 1-7, while CyLence™ Pour-on only exceeded 90% for Weeks 3-7. *Solenopotes capillatus* were found only at the Wisconsin site; all treatments were highly efficacious throughout the study period.

The effect of human age on Dengue seroconversion risk in Iquitos, Peru

SL Minnick, AC Morrison, TW Scott
Entomology Dept, University of California Davis, 1 Shields Ave, Davis, CA 95616, USA, slminnick@ucdavis.edu

Basic models of infectious disease often assume that force of infection is independent of host age. This assumption has been shown to be violated for many directly transmitted diseases, but has rarely been examined in vector-borne systems, such as dengue. Data from DNA fingerprinting studies of mosquito bloodmeals indicate that the biting rate of *Aedes aegypti* increases with human age. If risk for dengue infection increases with human age, models assuming an age-independent risk will underestimate the proportion of the population that needs to be vaccinated in order to eliminate disease transmission. A cohort of approximately 3,000 schoolchilen and their families in Iquitos, Peru were followed for up to 5 years (1999-2003) with blood samples collected at 6-month intervals. Sera were tested for dengue virus antibodies by the plaque reduction neutralization test. The effect of human age on risk for dengue seroconversion was evaluated using a multiple logistic regression model, which also included area of residence within the city. Preliminary analysis suggests that risk increased with age and was highest in the southern region of the city. Estimates of age-specific forces of infection can be used to design an optimal immunization program.

Oviposition site selection by mosquitoes in response to drought

A Mokany
School Of Botany And Zoology, Anu, Canberra, Act, 0200, Australia, allie.mokany@anu.edu.au.

Mosquitoes are vectors of many important medical and veterinary diseases. Although outbreaks of mosquito borne disease can be correlated to changes in precipitation in the very short term, precipitation rarely corresponds to mosquito abundance in the long term. Here, I present the results of a field based mesocosm experiment designed to test how water level and drought influence the oviposition behaviour of two species of mosquitoes. I used two water levels (high and low) and two drought treatments (normal and drought). Water for the drought treatments was obtained from ponds that had experienced drying for a period of a month prior to experimentation. The two mosquito species differed markedly in their oviposition response. The egg laying behavior of *Ochlerlatatus notoscriptus* was significantly greater in the drought treatments regardless of water level. However, the egg laying behavior *Anopheles annulipes* showed the opposite response with significantly more larvae present in the high water treatments regardless of whether the treatment water was normal or in drought. My results provide supportive evidence that mosquitoes may show population outbreaks following drought years and that this framework may provide a reliable way of predicting year-to–year variation in mosquito abundances based on individual species oviposition response.

Aedes aegypti surveillance in Iquitos, Peru: a 4- year test of the pupal/demographic survey

AC Morrison, H Astete, A Getis, K Gray, M Sihuincha, J Stancil, J Olson, P Blair, TW Scott
Proyecto Dengue, University of California, Davis, Department of Entomology, Calle Nauta 898, Iquitos, Peru; aegypti@terra.com.pe

We present results from 4 years of pupal/demographic surveys of a circuit of ≈ 6,000 houses surveyed >10 times in the Amazonian city of Iquitos, Peru. We compare traditional larval indices with pupal and adult mosquito indices. We evaluated *Aedes aegypti* production from different container classes, including those based on water management practices overtime and space. A total of 289,941 water-holding containers were characterized, of which 7.3% were positive for *Ae. aegypti*. Although, temporal and geographic variations were detected for all variables examined, consistent production patterns were observed for the lid status (lids: 32% wet containers, 2% pupal production), container location (outdoor: 43% wet containers; 85% pupal production) and method by which the container was filled with water (rain filled: 15% wet containers; 88.3% pupal production). Based on these patterns and additional targeting of containers with highly variable pupal counts we propose a targeted control strategy for Iquitos that would reduce *Ae. aegypti* populations below published but untested threshold values for Iquitos.

Screening medicinal plant extracts for effects on *Aedes aegypti* (Diptera: Culicidae) & toxicity to a non target organism

S Promsiri, A Naksathit, M Kruatrachue, U Thavara
Department of Biology, Faculty of Science, Mahidol University, Rama VI Road, Bangkok 10400, Thailand; grans@mahidol.ac.th

A preliminary study was conducted to find out the effects of the extracts of 112 medicinal plant species, collected from the southern part of Thailand, on *Aedes aegypti*. Studies on larvicidal properties of plant extracts against the third and fourth instar larvae of *Ae. aegypti* showed fourteen species with high toxicity. Six plant species were comparatively more effective against the larvae at very low concentration. These extracts demonstrated no or very low toxicity to guppy fish (*Poecilia reticulata*). Three plants with promising larvicidal activity, *Mammea siamensis*, *Anethum graveolens* and *Annona muricata,* were used to study of the impact of the extracts on the life cycle of *Ae. aegypti*. The results showed that these plants affected the reproductive potential of surviving adults by reducing the number of eggs laid and egg hatchability. The first instar larvae were very susceptible to *A. muricata* and the second instar larvae were susceptible to *A. graveolens* while the third and fourth instar larvae were susceptible to *M. siamensis*. These extracts delayed larval development and inhibited adult emergence.

The mosquito burden in Kenya

HN Njiru
HEADS Alliance P. O. Box 1905, 60100-Embu Kenya; hndwiga@yahoo.com

Kenya is a tropical country with a climate favourable for diverse insect life – both the harmful and the useful alike. Embu District experienced a malaria outbreak between January and February 2001 where more than 300 people were admitted at the main health facility in the District, 70 lives were lost. Malaria is endemic in Embu district with a morbidity of 60% and mortality of 25%. Expectant mothers and chilen are affected most with slide positivity of 30% and 45% respectively. Annually, each household spends around US$ 65 on malaria control and funeral expenses. Larval densities range from 30-40% with peak densities in March, April and May. Despite this, 25% of the community cannot positively identify mosquito as the malaria vector. Only 12% can correctly name the five main symptoms of malaria (fever, chill, sweating, anorexia, joint pains). The ministry of health has issued guidelines on uniform treatment and community sensitisation. Consistent use of bednets, chemoprophylaxis and indoor residual spraying are being encouraged. Plans are underway to start biological adult and larval control. This paper discusses the mosquito burden from the perspectives of larval density, host prevalence index, mortalities and morbidities, bed occupancy and the economics of vector control

Tick vector-pathogen interrelationships

PA Nuttall, M Labuda
NERC Centre for Ecology & Hydrology, Polaris House, North Star Avenue, Swindon SN2 1EU, U.K; pan@ceh.ac.uk

The interrelationships between tick-borne pathogens, their tick vectors and diverse vertebrate hosts, are represented by a triangle of parasitic interactions. The interactions are between (i) tick-pathogen, (ii) pathogen-host, and (iii) tick-host. In (i) the pathogen interacts with its vector, infecting and replicating within tick cells or extracellular spaces. The ability of a particular tick species to act as a vector depends on whether the pathogen can survive and overcome several 'barriers' within the tick. However, this is a simplistic view of the tick vector-pathogen interrelationship as both (ii) and (iii) influence the success of (i). This triangle of interactions is focused at the skin site of tick feeding - the initial site at which pathogens gain access to either their host or vector. For pathogens, the skin-feeding site is an ecologically privileged niche, profoundly modified by the pharmacological activities of bioactive tick saliva molecules. Exploitation of this niche is known as saliva-activated transmission (SAT). Tick saliva molecules that promote SAT have not been identified but appear to differ for different tick vector-pathogen interrelationships. Identifying the SAT factors and their mode of action offers new insights for controlling ticks and tick-borne diseases.

Argentina: veterinary forensic entomology as a potential tool against rustling

A Oliva
Av. A. Gallardo 470, C1405DJR, Buenos Aires, Argentina; aoliva@macn.gov.ar

Cattle rustling entails economic loss to cattle owners and danger to their safety, marketing of uninspected meat and hides and loss to the State from unpaid taxes. In 2003, the Faculty of Veterinary Medicine (Tandil, Buenos Aires province, Argentina) incorporated forensic entomology to a course of legal veterinary medicine aimed at fighting rustling. Preliminary field experiments showed a large proportion of hemisynanthropic insects, most of them Neotropical, which may represent the autochthonous necrophagous fauna, now displaced by synanthropic introduced species in urban environments. Colonization and development times proved longer in the arid climate of Tandil than at Buenos Aires city, where most published data were gathered. Field experiments with bovine bodies and parts are required. Hitherto, bovines have been avoided as a model because of the added complication of the ruminant digestive tract. Since most countries with rustling problems also have a pattern of introduced species displacing the original necrophagous fauna in city environments, they might benefit from knowledge obtained through these studies.

Arboviruses, mosquitoes & rNA interference

KE Olson, EA Travanty, I Sanchez-Vargas, KM Keene, BD Foy, BJ Beaty, CD Blair
Arthropod-borne and Infectious Diseases Laboratory, Department of Microbiology, Immunology and Pathology, Colorado State University, Fort Collins, Colorado 80523 USA; kolson@colostate.edu

The identification of critical arbovirus-vector interactions reveals new insights into vector competence. For instance, flavivirus and alphavirus replication in mosquitoes triggers a natural RNA interference (RNAi) response; however, viral counterdefenses probably allow RNAi evasion and establishment of persistent infections. We can enhance RNAi to dengue virus type 2 (DENV2) in *Aedes* species by administration of double-stranded (ds) RNA derived from the DENV2 genome, either by direct transfection of dsRNA, transient expression from a Sindbis virus (SINV) transducing system, or stable transformation with a plasmid that expresses a hairpin-forming transcript. RNAi is sequence-specific, is maintained by low concentrations of effector RNA, blocks accumulation of intracellular viral RNA, and results in the appearance of 21-25 nt siRNA homologous to the mRNA target. We have identified genes from the Dicer and Argonaute families in 2 mosquito genera and have used RNAi to knock down their expression to determine which genes have a role in virus resistance. We have evidence that DENV2 and some strains of SINV establish persistent infections in mosquitoes by suppression of RNAi, and are investigating mechanisms. We are identifying viral-encoded suppressors by site-specific mutations in infectious cDNA clones. Our work suggests that persistent infections in mosquitoes result from a balance between host RNA silencing and viral counterdefenses and provides new strategies for tipping the balance in favor of the vector host.

Endosymbionts & sex ratios in the human head louse

MA Perotti, HR Braig
School of Biological Sciences, University of Wales, Bangor, Gwynedd, LL57 2UW, UK, bssc13@bangor.ac.uk

At the turn of the 19th century the first observations of a female-biased sex ratio in broods and populations of head lice had been reported. A study by Buxton in 1938 on the sex ratio of lice on prisoners in Ceylon is still today the subject of reanalyses. However, in the last sixty years no data have been collected, especially on more normal levels of infestations. Here we report a female bias of head lice in a survey of 480 school children in Argentina. This bias is independent of lice intensity. These lice as well as lice from pupils in Britain were carrying several, related strains of the endosymbiotic bacterium *Wolbachia*, one of the increasing number of intracellular sex ratio distorters. No lice without *Wolbachia* were detected. Similar *Wolbachia* strains are also present in the pig louse suggesting that this endosymbiont might have marked influence on the biology of the whole order. The sex ratio distortion in head lice that has been reported world wide is stable over time; that is a remarkable deviation from the stability of frequency-dependent selection of Fisher's sex ratio.

Blood feeding in *Cnephia* (Diptera: Simuliidae): molecular phylogeny

KP Pruess
University Of Nebraska, Lincoln, NE 68583-0816, USA; kpruess@unlnotes.unl.edu

Five species of *Cnephia* were studied, three non-biting, one a mammal feeder, and one a bird feeder. Of the non-feeding species, *C. eremite* is Holarctic in distribution and specimens were examined from both Canada and Sweden. *Cnephia pallipes* is a Palearctic non-feeder and *C. dacotensis* a temperate Nearctic non-feeder. *Cnephia pecuarum* is an economically important large mammal feeder in south-central U.S. and *C. ornithophilia* a widely distributed bird feeder in southern and eastern North America. Sequence was obtained from the complete mitochondrial CO-II gene (687 bp) and partial EF1-alpha nuclear gene (1030 bp). Molecular data is discussed in relation to conventional wisdom about relationships among species based on cytological and biological information, geographic distribution and genetic diversity within species. Molecular data strongly support *Cnephia* as a monophyletic clade in the tribe Simuliini. Speciation hypotheses were not fully concordant between molecular and conventional data.

Onchocerciasis in Central America: ecology & control

MA Roíguez-Pérez
Centro de Biotecnología Genómica-IPN, PO Box 152, Reynosa 87710, Tamaulipas, México; mroiguez@ipn.mx

Detection of O. volvulus larvae in vector populations of black flies is of prime importance in the assessment of the effectiveness of ivermectin control programs. Detection of larvae is attained by dissection of individual flies or by PCR (amplification of an Onchocerca 150 bp repeated sequence, followed by hybridization of the PCR products with a species-specific DNA probe) from pools of flies. The PCR was compared with dissection method to estimate the infection rate (p) and the mean larval load (any larval stage) per parous fly (m) in a local vector population. Both methods produced statistically similar estimates, thus PCR is an alternative and efficient method for entomological surveillance. Sample sizes required to estimate m from p for fixed levels of precision were calculated using Mexican and Guatemalan data, assuming that k (an aggregation parameter from the larval distribution among parous flies) is known. Optimal sampling and PCR was used to evaluate the impact of ivermectin on m, p and transmission potentials in Mexico. The data suggest that substantial progress towards the goal of suppressing transmission has been accomplished. In southern Chiapas, entomological estimates decreased in comparison with the baseline data, but PCR positivity was still detectable. In northern Chiapas and Oaxaca, with no baseline data, there was an absence or near absence of infected and infective flies.

Malaria vectors, *Anopheles hyrcanus* **group (Culicidae, Diptera): morphological comparisons & molecular analysis**

LM Rueda, RC Wilkerson, C Li, HC Kim, TA Klein, GH Song, D Strickman
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA; ruedapol@msc.si.edu

Anopheles hyrcanus group consists of at least 30 species, with several species including *Anopheles sinensis, lesteri, pullus*, that are known or potential malaria vectors. The morphological diagnostic features and molecular identities of malaria vector *hyrcanus* group species are determined. Larvae, pupae and adults of selected species were described morphologically, and their ITS2 and DNA sequences from our laboratory and GenBank were compared.

Distribution & bionomics of malaria mosquito vectors, *Anopheles (Anopheles)* in Japan, Korea & other parts of Asia

LM Rueda, TA Klein, HC Kim, J Pecor, M Iwakami, M O'Guinn, B Prendergast, M Mogi, T Toma, I Miyagi, RC Wilkerson
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA; ruedapol@msc.si.edu.

Mosquito specimens of *Anopheles (Anopheles)* from collections conducted in Japan (2002-03), Korea (1999-2003), Philippines (2002), HongKong (2001), mainland China (2001-03) were identified using morphological and molecular techniques, and recorded. Larval, pupal and adult rearings of field collected samples were conducted for morphological and molecular analysis. Detailed locations of various collection sites and habitats were characterized for known and potential malaria vectors of different countries. Habitats of vectors include ricefields, irrigated ditches, temporary and permanent pools, ponds, streams, others.

Dengue mosquito vectors, *Aedes* and *Ochlerotatus*: morphological identifications & distribution

LM Rueda
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA; ruedapol@msc.si.edu.

The diagnostic morphological features of mosquito vectors of dengue viruses are compared for various *Aedes (Diceromyia, Stegomyia)* and *Ochlerotatus (Finlaya, Gymnometopa)* species found in four regions of the world, namely Oriental Region, Pacific and Australian Region, Afrotropical Region, and the Americas. Morphological characters are indicated to separate both larvae and adults of the vector species of each region. The distribution and bionomics of *Aedes* and *Ochlerotatus* vector species are included.

New & resurgent arboviral disease threatening humans in Australia

RC Russell
Department of Medical Entomology, University of Sydney and ICPMR, Westmead Hospital, Westmead, NSW 2145, Australia; rrussell@usyd.edu.au

Australia has a range of indigenous arboviruses and an introduced few that are of public health concern; all are mosquito-borne. Endemic encephalitogenic viruses (Murray Valley Encephalitis, Kunjin) are annually active and responsible for occasional cases in the northwest but, despite widespread vector distribution, only rare activity and no epidemics in the southeast since 1974. The most common arboviruses, Ross River annually infecting many thousands nation-wide causing polyarthritis, and Barmah Forest (a similar syndrome) on the increase and responsible for outbreaks of hundreds regionally, have a spectrum of coastal saline and inland freshwater vectors. The most important exotics are the returning dengue viruses with outbreaks of hundreds confined to Queensland by vector distribution but with virus endemicity and vector spread threatening, and the recently introduced Japanese Encephalitis virus causing only a few deaths in northern Queensland but with virus persistence and its affinity for a local vector threatening. Environmental factors drive arbovirus activity by influencing vector populations, which vary with virus and circumstance, although little is known of the role of reservoir hosts. Tourism and development activities that increase human/vector/virus contact, and climate changes that promote vector and virus proliferation, threaten to exacerbate the disease threat to the public health.

Repellents for integrated tsetse management

RK Saini, A Hassanali
International Center of Insect Physiology and Ecology (ICIPE), PO Box 30772 Nairobi, Kenya; rsaini@icipe.org

ICIPE is in the forefront in identifying potent repellents, both synthetic analogues of natural tsetse repellents and natural repellent blends from un-preferred animals like waterbuck and zebras. One potent synthetic repellent for savannah tsetse species, developed by molecular optimization studies, acts as an olfactory antagonist of a key phenolic kairomone, which flies use to locate the host for feeding (Saini & Hassanali; patent application). This repellent substantially reduce tsetse challenge (> 80%) and feeding efficiency (>80%) on cattle. A prototype dispenser which is placed around the neck of an animal has been developed. Field trials indicate that the repellent can provide effective protection to cattle but all animals in a herd need to be protected or else significantly higher infection occurs in unprotected animals. Experiments are ongoing to evaluate how repellents can be integrated with other existing tsetse control techniques. A 'push-pull' strategy that deploys repellents (to 'push') and baited traps / targets (to 'pull') to enhance suppression rates is being evaluated. A variant of this may involve the use of a proportion of cattle with 'pour on' insecticides as live baits. A business plan for commercial production and distribution of repellent products is also being developed.

Mitochondrial genome organization of lice is highly variable

R Shao, C Covacin, SC Barker
Department of Microbiology and Parasitology, The University of Queensland, QLD, 4072, Australia; r.shao@uq.edu.au

Mitochondrial (mt) genome organization is extremely conserved in mammals, vertebrates and most arthropods, e.g., humans and frogs have the same mt genome organization; so have fruit flies and water fleas. We have sequenced the entire mt genomes of the wallaby louse (Phthiraptera: Amblycera) and the pigeon louse (Ischnocera), and part of the mt genomes of the human louse (Anoplura) and four other amblyceran lice. Unlike most arthropods, the mt genome organization of these lice is highly variable. Lice share only 1-2 gene boundaries with fruit flies. No gene boundaries were shared among lice of the three suborders. Mt genome organization differs even among three genera within the suborder Amblycera. Changes in the mt genome organization of lice include gene translocation, inversion, separation of rRNA genes and loss or multiplication of non-coding regions. In addition to lice, we found mt genome organization was variable or highly variable in other two hemipteroid orders, Psocoptera (psocids) and Thysanoptera (thrips), but is strictly conserved in the order Hemiptera (bugs). We speculate that the changes in the mt genome organization in lice, psocids and thrips may be related to their life-history traits such as small body size, small colony size, and high degree of inbreeding.

Forensic entomology in cars

IR Dadour *and S Forbes*
Centre for Forensic Science, University of Western Australia, Nedlands, 6009, Australia: idadour@cyllene.uwa.edu.au

To determine the entomological succession on a decomposing pig inside a vehicle following its sacrifice by CO poisoning (suicide pig), to calculate the time of decomposition of a suicide pig and determine temperature fluctuations inside vehicles. The significance of this research is the requirement by police and the justice system for accurate information on the Post Mortem Interval (PMI) of cadavers, particularly in regard to homicides and suicides. Most suicides conducted in vehicles happen in isolated areas where the vehicle is parked in wooded areas for the purposes of concealment. Generally this is a shaded area or an area with minimal exposure to the sun. The methodology includes sacrificing 40/45kg pigs using CO gas. Following death the pigs are quickly dressed and placed inside a vehicle. CO gas is pumped into the vehicle for another 5 hours. Decomposition is recorded using infrared video cameras as well as daily observations of insect activity. Decomposition rates are compared with two other pigs (one pig sacrificed by CO poisoning and the other by head bolt) decomposing under normal conditions. Each pig has a datalogger placed inside its throat, abdomen and colon. The temperature inside the car is also measured and compared with the recorded ambient temperature.

The results of a clinical trial of a novel pediculicide

SC Barker
University of Queensland, Brisbane, 4072 Australia

Few families & medical practitioners in westernised countries are spared the challenge of curing an infection of head lice. Indeed, around 1 in 4 to 1 in 3 primary school children in Australia & other westernised countries may have lice and/or eggs (dead or alive) at any point in time. I report on the first ICH-GCP double-blind randomised controlled trial (RCT) of a pediculicides & the first double-blind RCT of essential-oils pediculicide.

Successful Outreach in Entomology - Packaging the Product

T Turpin,
Purdue University, West Lafayette, IN 47902

Successful entomology outreach depends on attracting the consumer to the activity or product. Such marketing is similar to that used by industry to sell ideas and materials. Humor, novel activities, and costumes are effective tools to create interest in entomology.

Assessment of bacteriophage WO involvement in *Wolbachia*-induced CI within the *Culex pipiens* complex

YO Sanogo, A. Eitam, SL Dobson
Department of Entomology, University of Kentucky, S-225 Agricultural Science Center North, Lexington, KY-40546, USA yibosee@yahoo.com

The *Culex pipiens* complex includes some of the most medically important mosquitoes due to their cosmopolitan distribution and their capacity to vector infectious diseases. Members of the complex differ in their ecology, behavior, physiology and vector competence. To date, no consensus has been achieved about the taxonomical status of representatives of this group. Opinions of their relationship range from distinct species with no gene flow to physiological forms with considerable introgression. Most populations of *Culex pipiens* are infected with *Wolbachia*, a maternally inherited bacterium, which causes cytoplasmic incompatibility (CI) resulting in embryonic mortality. In prior molecular characterization, we have demonstrated that *Culex* populations differ in the bacteriophage WO that is thought to infect *Wolbachia* (Sanogo and Dobson, 2004). To test the hypothesized involvement of bacteriophage WO in determining CI in *Culex*, crosses have been conducted between nine *Culex* strains that differ in their bacteriophage WO infection types. Here, we will present the crossing results and discuss the correlation between bacteriophage WO and CI type. We will also discuss the results in relation to the restriction of gene flow among naturally occurring *Culex pipiens* populations. Reference: Sanogo YO and SL Dobson. 2004. Insect Molecular Biology (*in Press*)

Monitoring the mosquito *Aedes aegypti*: A novel surveillance method and new entomological indices using the gravid trap MosquiTRAP^{â} and a synthetic oviposition attractant (Atr*Aedes*^{â})

AE Eiras, IM Silva, CF Costa, RG Antonacci, A Roses, M Geier
Federal University of Minas Gerais, Belo Horizonte, Brazil; alvaro@icb.ufmg.br

MosquiTRAP^{â} is a novel, simple, easy, low cost, and efficient trap especially developed to catch *Aedes.* mosquitoes. It relies on visual cues and synthetic oviposition attractants (Atr*Aedes*^{â}), based on volatiles identified from grass infusions. Compared to ovitraps, MosquiTRAP^{â} allows the identification of the mosquito species in the field, thus saving time and avoiding laboratory routine such as counting eggs and larval identification. Trapped mosquitoes can also be used for virus diagnosis. New entomological indices are (a) the Positive MosquiTRAP Index (PMI), the percentage of positive traps, and (b) the Adult Density Index for *A. aegypti* and for *A. albopictus*. Field data can be collected using hand-held PDAs and then loaded directly into a Geographical Information System (GIS), for an efficient determination of local entomological indices. At the moment, a national monitoring program in Brazil using this technology is being established.

Tsetse.org and Tsetse Plan: interactive programmes to assist planning control of tsetse.

SJ Torr, GA Vale, DR Hall, A. Cork
Natural Resources Institute, University of Greenwich, ME4 4TB, UK; a.cork@gre.ac.uk

"A range of techniques is available for the effective control of tsetse flies - so why are tsetse still a problem over much of Africa? Part of the answer is that control operations have not been planned and executed with sufficient understanding. Non-specialists play an increasingly important role in planning and implementing tsetse control operations, but the diminishing number of specialist entomologists makes gaining expert advice ever more difficult. Handbooks to ensure better use of available technologies exist, but these are no substitute for the specialist advice required to develop a strategy suited to local circumstances. To address this knowledge gap, the interactive programme 'Tsetse Plan' has been developed. The programme is a computerised simulation of the interactive help that would be available if a farmer or NGO was able to talk with a specialist on-site, to assess the local situation, draw up a control strategy, identify technical specifications and prepare a budget. The programme is underpinned by a simulation model of a tsetse population which allows the user to compare the impacts of various control operations. The programme is available via a website (http://www.tsetse.org) which provides further technical advice and slide shows on use of control technologies.
"

An instructional DVD on collecting entomological evidence for court

RK Kimbirauskas, RW Merritt, ME Benbow, JR Wallace, JK Tomberlin
Dept. of Entomology, Michigan State University, East Lansing, MI, USA; kimbira1@msu.edu

This DVD was created by forensic entomologists to fulfill the immediate need to standardize practices for collecting entomological evidence. The material is intended to instruct forensic investigators on how to collect specimen samples and field data in a way that will be scientifically valuable and credible in court. The DVD includes an overview of forensic entomology and the decomposition of an animal model has been time-lapsed to demonstrate the association of insects with various stages of decay. Insects commonly found with human remains are shown and factors that influence insect activity and development are described. Crime scene photographs and video are used to aid in the recognition of what information should be collected during death investigations. A list of equipment needed to process entomological evidence is given, and the collection and preservation of insect specimens has been clearly demonstrated in a step-by-step procedure. The main purpose of this DVD is to standardize the practices which are critical to the development of postmortem intervals and the utilization of insects as evidence during criminal investigations. The entire training video is 45 minutes; however, the multi-media format provides self-paced instruction and allows the viewer select specific modules for quick referencing.

The mosquitoes of Europe - an identification and teaching software

G Angel, J Brunhes, B Geoffroy, A Rhaiem, JP Hervy, F Schaffner
"EID Méditerranée, 165 av. Paul-Rimbaud , F-34184 Montpellier Cedex 4, France; fschaffner@eid-med.org"

The bilingual CD-ROM (English/French) proposes identification software, which allows the identification of 100 species of Culicidae (larvae, female and male adults of the genera *Aedes, Anopheles, Culex, Culiseta, Coquillettidia, Ochlerotatus, Orthopodomyia* and *Uranotaenia*) and a knowledge base on these mosquitoes. The study area includes 37 countries of geographical Europe plus Madeira. Contrary to the dichotomy keys, the "identiciel" allows an identification by permanent and intuitive multicriterial approach. With each step, the user selects one of the criteria suggested among morphology, ecology and distribution. He progresses towards the identification of the species by successive choices suggested by images. At the end of the process, taxonomic cards authorise a meticulous checking of the result as well as a comparison with close species. More than 800 original illustrations are provided, the software also gives synthetic information and brings up to date data on taxonomy, bio-ecology, distribution, medical or veterinary importance of these dangerous hematophagous insects, as well as methods of control. An indexed bibliography of 325 references is also included. Easily used, this CD-ROM is intended for teachers, students, medical entomologists, parasitologists, and all agents of human health or veterinary surgeons in charge of monitoring and control of mosquitoes.

Bionomics of *Anopheles hyrcanus* in resurgent and endemic foci of malaria in Iran

MR Abai, H Vatandoost, AH Zahirnia, K Akbar-Zadeh, M Nazarai, MA Oshaghi, H Ashraf
School of Public Health & Institute of Health Research, Tehran University of Medical Sciences, P.O.Box: 6446-14155, Tehran Iran;
abaiiahm@sina.tums.ac.ir

An.hyrcanus group is reported from different parts of Iran. This species plays a role in malaria transmission in neighboring countries. The adult and larvae were collected from different parts of Iran using WHO's methods. This species is found in shaded part of rice-lands and irrigation canals and shaded stagnant water in Nikshahr and Pars-Abad and Poldasht districts. Its peak of activity occurs in midnight whereas s area three peaks of biting can be observed, mainly sunset and midnight according to locality. Light trap is able to collect the adult. This species tend to rest indoor when temperature is falling dawn. The peak of its activity is mainly in August. From the field study it was concluded that *An.hyrcanus* population found in different resurgent and malaria endemic area of Iran. Their seasonal activity, biting habitat, larval density, and abdominal condition is varied in different localities. It seems that in some area due to high population density and antropophilicity of this species it may play a role in malaria transmission. At the future, further molecular and biochemical studies will be done to confirm different sibling species of this species as in studied area.

Behavioral responses of *Culex* to oviposition site odors

SA Allan, UR Bernier, DA Carlson
USDA/ARS, CMAVE, PO Box 14565, 1600 SW 23rd, Gainesville, FL 32604, USA; sallan@gainesville.usda.ufl.edu

Culex mosquitoes, as important vectors of arboviruses in North America, are effectively sampled by gravid female traps baited with infusions such as hay infusion. Using several methods, a wide range of volatile compounds have been identified from hay and grass infusions and dairy effluent. The purpose of this study was to evaluate the behavioral responses of gravid *Culex* to these compounds as oviposition site attractants in a dual-port olfactometer assay. Responses obtained to individual compounds and then in binary and/or tertiary blends were compared to hay infusion. The efficacy of lures incorporating these mixtures were also evaluated in the olfactometer and compared to hay infusion standards. These results contribute to the development of standardized lures for gravid *Culex*.

Effect of fire on recovery and identification of entomological evidence at a homicide scene

GS Anderson
School of Criminology, Simon Fraser University, Burnaby, British Columbia, Canada, V5A 1S6; ganderso@sfu.ca

Insects are valuable in determining elapsed time since death in a homicide. However, the killer may attempt to disguise the crime by setting fire to the crime scene. Experiments were conducted to determine the effect of arson on entomological evidence. Three freshly killed pigs (*Sus scrofa* L.) were placed in separate rooms in a house in Edmonton, Alberta. Extensive blow fly (Diptera: Calliphoridae) colonization occurred, and the remains were allowed to decompose to the advanced decay stage. At the time of the fires, large numbers of larval Calliphoridae, pupae and empty puparia, as well as teneral flies were present. Four successive simulated arson fires were set then extinguished. The first fire was ignited using gasoline poured on the carcass, the second used common household accelerants such as newspaper, the third was set in the basement and the final fire involved the entire house. After each fire was extinguished, the carcasses were examined for entomological evidence. In all, cases, enough entomological evidence was recovered after each fire, including the final destruction of the house, to allow an entomologist to analyze the evidence and to determine elapsed time since death. In several cases, live insects were recovered.

Novel strategies for arbovrius surveillance in response to WNV

CS Apperson
Department of Entomology, Box 7647, North Carolina State University, Raleigh, NC 27695-7647 USA; charles_apperson@ncsu.edu

The outbreak of West Nile virus (WNV) in 1999 in Queens, New York USA was an unprecedented public health event on the North American continent. Albeit, the epidemic has stimulated development of only a few novel vector/virus surveillance tools. The VecTest® is the best-known novel technology resulting from the outbreak of West Nile virus. This lateral flow or dipstick test is used to detect West Nile virus antigen in homogenized mosquitoes. The VecTest has also been used successfully to detect viral antigens in extracts of cloacal swabs taken from moribund WNV-infected birds. Another more recent diagnostic test, the RAMP West Nile Virus Test, detects WNV antigen in mosquitoes and birds. This test is based on latex particles that are tagged with fluorescent antibodies to WNV. Sentinel animals have been used to detect the occurrence of WNV. The virus is highly lethal to some birds, such as American crows and blue jays. Field surveillance of WNV activity involves a strategy of systematically collecting and testing dead corvids for WNV infection. Counts of dead corvids have also been used to estimate the intensity of local transmission of WNV.

Weather station ambient temperature corrections in forensic entomology

MS Archer
"The Victorian Institute of Forensic Medicine, 57-83 Kavanagh St, Southbank VIC 3006, Australia, melaniea@vifm.org"

Weather station data is used by forensic entomologists to estimate ambient temperatures at body discovery sites. Correlation data from sites may also be collected to correct for site and station differences. This experiment tested the accuracy over time of retrospective weather data correction using linear regression between stations and sites. Temperatures were logged at six hypothetical body discovery sites during a seven day period for which a hypothetical body lay *in situ*, and a further four correlation periods. The accuracy of weather data for hypothetical body *in situ* periods improved after correction in 22 of 24 correlations, however, mean predicted body *in situ* temperatures for sites differed significantly between correlation periods. Predicted temperatures generally rose with time after body removal, which correlated with rising site temperatures accompanying seasonal change. Therefore, practitioners should be cautious in making correlations if weather patterns during correlation differ greatly from those while the body was *in situ*.

Biometrics and behavior in mosquito repellent assays

DR Barnard, RD Xue
"USDA-ARS-CMAVE, P. O. Box 14565, Gainesville, Florida 32604 U.S.A., dbarnard@gainesville.usda.ufl.edu"

Biotic and environmental factors influence the outcome and interpretation of repellent bioassays. Mosquito-related test factors include larval nutrition, carbohydrate availability, age/parity of females, blood engorgement status, and diel blood-feeding patterns. Environmental/human subject-relevant factors are light, temperature, humidity, repellent dose and exposure time, absorption, penetration, evaporation, abrasion, and/or washing of repellent from skin (by perspiration), and the innate repellency of human/animal test subjects. In laboratory tests, cage configuration is critical. With small cage/modular-types of test apparatus (<1000 cm^3), treatment effects may be confounded with "edge effects", because of the position of a feeding port or module, whereas tests repeated using the same human subject comprise pseudo-replication. In large cage (>1000 cm^3) tests, complete protection times are based on the responses of mosquitoes in the upper extreme of the frequency distribution for repellent tolerance, rather than on the average population response; large cage techniques are not useful for determining the Estimated Median Dose (ED$_{50}$), or other percentiles of interest. Variation in repellent assays can be minimized by rearing and testing mosquitoes in a standardized environment, by choosing appropriate sample sizes, by selecting a biologically-relevant assay method, and by careful and diligent oversight of test proceedings.

Vector and viral genetic determinants of epidemic dengue and dengue hemorrhagic fever in Mexico

B Beaty, N Gorrochotegui-Escalante, K Bennett, I Salazar-Sanchez, S Lozano-Fuentes, K Olson, I Fernandez-Salas, M De Lourdes Muñoz, J Farfan-Ale, M Lorono-Pino, B Blitvich, C Blair, W Black.
Department of Microbiology, Immunology and Pathology, Colorado State University Fort Collins, CO 80523.

To elucidate vector determinants of dengue transmission in Mexico, ~1,600 *Ae. aegypti* collected from throughout North America and individually phenotyped for dengue 2 (DEN2) virus midgut and disseminated infections. DNA from each of these mosquitoes was archived for association mapping of candidate genes that condition vector competence. Dramatic differences in vector competence in the *Aedes aegypti* populations were demonstrated, and vector competence was correlated with dengue seroprevalence. Studies to reveal the genetic basis of *Aedes aegypti* vector competence identified two candidate genes (Early Trypsin and Abundant Trypsin) that condition dengue virus infection of vectors. RNAi silencing of the Early Trypsin gene resulted in reduced vector competence of *Aedes aegypti*. To determine the epidemiological relevance of these genes, a population genomics approach using association mapping was used to reveal the statistical relationship between genetic polymorphisms and vector competence phenotype in these genes. An association was found between the *Abundant Trypsin* and DEN2 disseminated infection rates DEN2 infection phenotypes in these American *Aedes aegypti* populations. Such information is important in risk assessment for epidemic dengue and DHF/DSS. During these studies, a new DEN2 virus of the American-Asian genotype was introduced in Yucatan State, causing an epidemic of DHF/DSS. This virus is being compared with other DEN2 viruses, which have previously circulated in the Yucatan State, for its ability to infect, replicate in, and be transmitted by *Aedes aegypti* and for its epidemic potential.

Chemical analysis and laboratory bioassays of host odors to identify compounds that attract and inhibit the attraction of mosquitoes

UR Bernier, SA Allan, DA Carlson
USDA-ARS, Center for Medical, Agricultural, and Veterinary Entomology, Gainesville, FL 32608, ubernier@gainesville.usda.ufl.edu

Using various sampling techniques and gas chromatography/mass spectrometry (GC/MS), a comprehensive chemical profile of host odors can be obtained. The differences in chemicals emanated by different hosts may provide a clue to the structures of compounds used by anthropophilic mosquitoes, compared to those used by zoophilic mosquitoes, for host location. Screening of candidate compounds is accomplished in our laboratory by using a triple-cage dual-port olfactometer. Bioassays of single compounds and blends of compounds have resulted in the development of attractive synergistic binary blends for anthropophilic mosquitoes. Further improvement to the blends has resulted in a three-component blend that is more attractive than some human individuals in laboratory bioassays. During the development of these attractive odor blends, some compounds were observed to inhibit the host-seeking capability of mosquitoes, possibly my masking the attractive odors. Inclusion of these compounds (attraction-inhibitors) in attractive blends, results in a substantial decrease in the ability of mosquitoes to locate the attractive odor source in the olfactometer. Laboratory bioassays are being used to develop a system that demonstrates the possibility of concealing a host with attraction-inhibitors and driving mosquitoes to choose an attractant blend over a live human or animal host.

Sexual dimorphism of antennal gene expression in the malaria vector *Anopheles gambiae*

H Biessmann, RW Justice, S Dimitratos, MF Walter, DF Woods
"Developmental Biology Center, University of California, Irvine, CA 92697, USA, hbiessma@uci.edu, "

To obtain a better understanding of the olfactory processes that allow mosquitoes to identify human hosts, a molecular study has been performed to identify and characterize molecules in the olfactory signaling pathway of the African malaria vector *Anopheles gambiae*. cDNA libraries from antennae of females and males were established, from which a collection of cDNAs encoding odorant binding proteins (OBPs) and other novel antennal proteins were isolated and characterized, representing various families of putative carrier proteins with homologues in other insects. Using filter array hybridizations and quantitative RT PCR, regulation and gender specificity of expression of these genes was investigated. Although male and females appear to express the same olfactory genes, significant differences in steady state levels of some of these putative carrier protein genes were detected between the sexes and after blood feeding in females. Results of microarray experiments of gender-specific expression of olfactory carrier proteins and receptors will be reported. Our ultimate goal is to identify and characterize molecules in the odor reception pathway of this mosquito vector species with the intent of facilitating the development of better methods to interfere with the mosquito-host interaction.

Study of decomposition rates of pig carcasses and viability of *Calliphora vicina* in the UK climate

AP Brandt
Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, a.brandt@nhm.ac.uk

The estimation of post mortem interval (PMI) in a country such as the UK which experiences fluctuating temperatures, both seasonally and daily, is considerably more complicated than in those countries with fairly constant temperatures. In order to assess the effects of the different seasons on decomposition rates and insect species composition, piglet carcasses were put out at The Natural History Museum in Central London. Significant differences were recorded from carcasses put out at different times of the year, and between those laid outside on a roof, and those inside the building, where insects had limited access to the carcasses. Although oviposition by the primary invaders occurred at the same time on both the indoor and outdoor carcasses, the rate of development of *Calliphora vicina* on the outdoor carcasses was significantly slowed down due to the cold temperatures experienced, thus limiting the decomposition rate considerably. Further laboratory based studies were carried out to assess the effect of cold temperatures on the different life stages of *Calliphora vicina*.

Molecular basis of resistance to pediculicides

"WG Brogdon, G Groner, AE Lenhart, RA Wirtz"
Entomology Branch F42, DPD, NCID, Centers for Disease Control and Prevention, 4770 Buford Highway NE, Atlanta, Georgia 30341, USA, wgb1@cdc.gov

Head and body lice develop resistance to pediculicides through mutations of insecticide target sites, such as the voltage-gated sodium channel, and increased activity of detoxification enzymes such as oxidases and esterases. The difficulties of conducting bioassays on field-collected lice make molecular analysis of insecticide resistance an especially attractive option. Here are described the molecular details of resistance that has appeared in lice together with a discussion of ongoing work to develop methods to detect and assess these mechanisms through molecular analysis. A useful approach to measuring all of these mechanisms is fluorometric PCR. This method allows detection of resistance mechanisms based on point mutations at the insecticide target site, resistance gene amplification, or increased expression of resistance genes. Knowledge of resistance gene sequence is a prerequisite in the development of these methods. Our knowledge to date of louse resistance gene sequences is summarized. The same molecular methods that serve to detect resistance are also central to the determination of population genetic relationships of the resistance alleles. We discuss our present state of knowledge of louse molecular markers and the louse genome as they relate to insecticide resistance.

Environmental change and lyme disease risk

JS Brownstein, D Fish
Yale School of Medicine, 60 College St., New Haven, CT 06520-8034, USA, john.brownstein@yale.edu

An understanding of the influence of environmental change on Lyme disease in North America is a fundamental component in assessing changes the spatial distribution of human risk. Because disease risk may be influenced both by large-scale climate change and local-scale landscape modification, we developed a multi-scale approach to dissecting the influence of environment. First, we used a climate suitability model for the tick vector *Ixodes scapularis* to examine the potential effects of global climate change on future Lyme disease risk in North America. The model reveals a significant expansion of *I. scapularis* north into Canada and central United States as well as a retraction of the vector from southern United States. With higher resolution remotely sensed data, we evaluated the impact of local-scale landscape structure on both entomologic risk and human exposure. Landscape fragmentation resulting from suburban development was compared to both human and tick surveillance data from Connecticut and showed that landscape mosaic plays a significant role in defining disease risk. In spite of higher tick densities, human incidence of Lyme disease was found to be lower in fragmented contexts. The synthesis of such environmental models will allow for improved predictions of Lyme disease emergence.

Influence of the structure of host-odor plumes on the orientation maneuvers of flying mosquitoes

RT Cardé, T Dekker
"Department of Entomology, University of California, Riverside, CA 92521, United States of America, ring.carde@ucr.edu"

Host finding in mosquitoes is typically subdivided into two sequential stages: attraction at long range that is induced by host-released odors, principally assumed to be carbon dioxide. Orientation at close range is assumed to be regulated by the interactions of carbon dioxide with other host odors, humidity, heat, and visual cues. In our work with *Aedes aegypti* in a wind tunnel, upwind fight along the carbon dioxide plume required the sequential encounter with filaments of carbon dioxide, as would normally occur in a plume diffusing in wind. A single brief encounter with a filament of carbon dioxide odor induced a surge toward upwind. A relatively homogeneous cloud of carbon dioxide, in contrast, activated flight, but did not stimulate upwind movement. Conversely, orientation to human skin odor seems to require a longer term encounter than occurs with exposure to an odor filament. The threshold for response to skin odor is itself modulated by an encounter with carbon dioxide: a brief exposure to carbon dioxide lowers the threshold of response to skin odor by five-fold. Together the interactions of carbon dioxide and skin odor explain several features of host orientation, and provide support for the hypothesis of sequential stages of odor utilization.

Development of lure for the dengue mosquito

RR Coler, A Mafra-Neto, T Dekker
"2060 Chicago Ave, Suite C2, Riverside, CA 92507 – USA, rcoler@iscatech.com"

Instead of proceeding with the traditional isolation and identification from hosts of individual mosquito attractants, ISCA Technologies, Inc. created compositions which mimic the skin of the specific vertebrate hosts. Most mosquitoes apparently exhibit some level of host 'preference', i.e., they do not feed indiscriminately on any vertebrate host. In some studies host-feeding patterns within a closely related species complex is odor mediated and was attributed to differential response to CO_2 and other skin odors. The actual bait, created through a process patented by ISCA, provides the parasitic arthropod (host seeking *Aedes aegypti*) a much more complete "olfactory sensation" associated to a specific "host" (human) than any other attractants on the market. Traps lured with this bait containing artificial "sensory correct" profiles of human hosts trigger rapid responses from females *Ae aegypti* inducing the full set of host seeking and feeding behaviors, from activation to imbibing. The current ISCA prototype trap has proven to be superior to the Fay-Prince and Wilton traps and other commercial traps set-up in competitive laboratory trap tests. Laboratory studies indicate the capture rate of this prototype baited with this new lure closely approximates the rates obtained from human biting counts for the same mosquito density.

2-Oxocarboxylic acids elicit landing responses from female *Anopheles gambiae*

TP Healy, MJW Copland, A Cork, A Pyrzyborowska, JM Halket
"Natural Resources Institute, Central Avenue, Chatham Maritime, KENT 4TB, UK, a.cork@gre.ac.uk "

Landing and probing responses were elicited from female *Anopheles gambiae* in wind tunnel bioassays by 2-oxocarboxylic acids. The most significant responses were elicited by 2-oxopentanoic acid although 2-oxo-butanoic, 2-oxo-3-methylbutanoic, 2-oxo-3-methylpentanoic, 2-oxo-4-methylpentanoic and 2-oxo-hexanoic acids also elicited responses. 2-Oxo-propanoic (pyruvic), 2-oxo-octanoic, 2-hydroxy-propanoic (lactic) and 2-hydroxy-pentanoic acids were inactive. The response to 2-oxopentanoic acid was dose and temperature dependent with 30 µg and body temperature (34^{o}C) eliciting the most significant responses. Responses decreased over time but this was thought to be due to evaporation. Chemical analysis of a suitably derivatized human sweat sample confirmed the presence of pyruvic, 2-oxo-3-methylbutanoic, 2-oxo-3-methylpentanoic and (*E*)-oxo-4-methylpentanoic acids. The three methyl-branched acids, previously identified in human body fluids, are metabolically linked to the amino acids valine, leucine and isoleucine *via* a reversible trans-amination. However, the most active compounds, 2-oxopentanoic and 2-oxohexanoic acid were not identified in human sweat. Taken together the research suggests that C_4-C_6 2-oxocarboxylic acids represent a class of compounds that provide female *An. gambiae* with close range, host-specific odour cues.

Distribution of blood feeding within the subgenus *Inseliellum* (Diptera: Simuliidae)

CA Douglas
Department of Biological Sciences, University of Alberta, Edmonton, Canada T6G 2E9, d.craig@ualberta.ca

Simulium (*Inseliellum*) *buissoni* in Nuku Hiva, Marquesas Islands, Polynesia, has been referred to as the "scourge of the Pacific". It is a sufficiently serious blood feeder on humans that it resulted in the administrative centre of the Marquesas being moved from Nuku Hiva, south to Hiva Oa. *Simulium buissoni* is also a serious bird biter and attempts to eradicate this black fly were made in the early 1990's. *Simulium* (*I.*) *gallinum,* distributed on other Marquesas Islands, however, feeds only on birds. Distribution of blood feeding within *Inseliellum* will be discussed in light of a reconstructed phylogeny for the subgenus. Also discussed will be the "Miracle of the Nono" from the 1930's, where it is reputed that serious biting of humans by black flies on the southern Marquesas Islands, ceased ostensibly, overnight.

Evolution of blood-feeding behavior in black flies (Diptera: Simuliidae)

CC Douglas
Centre for Biodiversity and Conservation Biology, Royal Ontario Museum, 100 Queen's Park, Toronto, Ontario, CANADA, M5S 2C6, dcurrie@zoo.utoronto.ca

Phylogenetic-, paleontological-, and host specificity data are combined to reveal patterns of blood feeding behavior among black flies. The fossil record reveals that simuliids originated before the radiation of birds and mammals, suggesting that other warm-blooded hosts were exploited by the earliest members of the family. Ornithophily probably evolved independently in the Prosimuliini and Simuliini, with numerous, independent, reversals to mammalophily in the latter tribe. Although host-switching events in black flies have been predominantly from ornithophily to mammalophily, there is a least one example of the reverse among certain members of the *Simulium* (*s.str.*) *slossonae* species-group. Obligatory autogeny (i.e., females that lack biting mouth parts), is a derived trait that evolved numerous times independently from both mammalophilic and ornithophilic progenitors. Such non-bloodsucking species, which constitute only about 2.5% of the world species, live predominantly in high latitude or high altitude environments. Tarsal claw morphology has utility for inferring host preference among anautogenous black flies; however, the current practice of coding claws as either "simple" or "bifid" does not exploit the full panoply of variation present in this character system. Detailed comparative studies are needed in order to identify useful characters for species recognition and phylogenetic studies.

Landscape epidemiology of malaria in Tumkur (Karnataka), India, as monitored by satellite remote sensing

RC Dhiman
Malaria Research Centre (ICMR), 22 Sham Nath Marg, DELHI-110054, India, dhiman1@vsnl.com

Study was conducted in selected villages of 3 Primary Health Centres of Tumkur (Karnataka)with varying endemicity to find out the landscape elements critical to malaria endemicity at village level using satellite remote sensing.. Ground data on the presence of breeding habitats, monitoring of larval density, adult *Anopheles culicifacies* (malaria vector) from indoor resting sites and ecological features within 1.5 km radius from the centre of each village were generated in 2001 and 2002. Data of Indian Remote Sensing satellite with 23.8 metre and 5.8 metre resolution respectively were procured for the dates of ground survey and analyzed for generation of images and statistics of land use features within a buffer zone of 1.5 km around each village. Delineation of tanks, streams, ponds, marshy areas, the main breeding habitats of *An. culicifacies* was possible by Remote sensing by merging LISS III and PAN products. The breeding habitats in the vicinity of human settlements within 500 metres were found more productive for *An. culicifacies.*

Quantification of land use features revealed that extent of water bodies, permanent vegetation cover, less barren/scrub and rocky areas were associated with high malaria endemicity. Identification of villages into high/low risk of malaria is possible leading to village level stratification for development of village specific selective and cost effective spraying strategy for integrated vector management programme for targeting malaria control.

Aedes aegypti **behavior in manipulated domestic environments in Thailand**

JD Edman, LC Harrington, TW Scott
"Center for Vectorborne Diseases, School of Veterinary Medicine, University of California, Davis, CA 95616, jdedman@ucdavis.edu"

Aedes aegypti, a low-density mosquito, lives in or near human dwellings, feeds frequently and specifically on people, and efficiently transmits dengue viruses. Field experiments with wild mosquitoes are risky in endemic areas and population augmentation to increase sample sizes causes ethical concerns. We circumvented both issues by screening the entire house and yard of rented homes in order to safely conduct relatively natural behavioral experiments using females collected in the village as pupae. Host size, location, and orientation effects on feeding were studied using 4 rotated subjects. Released mosquitoes (~25%) were recovered using pack-pack aspirators and the origin of their blood meals scored by DNA fingerprinting. There was strong correlation between host size and feeding with the largest individuals consistently feeding the most mosquitoes. *Ae. aegypti* fed most often on people inside house but body orientation appeared unimportant. Timing of oviposition and the impact of container size on egg number were evaluated in various sized jars lined with germination paper. Papers were changed at regular intervals and eggs counted. Most eggs were laid in late afternoon. Larger diameter containers consistently received more eggs whether located inside or outside. Indoor females preferred containers without preexisting eggs.

Behavioural responses of gravid *Aedes aegypti* (Diptera: Culicidae) to synthetic oviposition attractants identified from grass infusions volatiles.

AE Eiras, IM Silva, RA Roque, IM Matosinhos, M Geier
Federal University of Minas Gerais, Belo Horizonte, Brazil, alvaro@icb.ufmg.br

Grass infusions have been used as oviposition attractants and/or stimulants for enhancing ovitrap efficacy. However, the infusion procedures are very time-consuming and extremely labour-intensive. Thus, the volatiles released from grass infusions that attract gravid mosquitoes *Aedes aegypti* to ovitrap were identified by coupled gas chromatography-electroantennogram detection (GC-EAD), coupled gas chromatography-masspectometry (GC-MS), electroantennography (EAG) and field trapping. Six candidate compounds were identified and evaluated in the field and in laboratory. Electrophysiological studies showed that antennas of gravid mosquitoes are sensitive to all synthetic compounds but only few individual compounds elicited behavioral responses within a dual port olfactometer. Laboratory and field studies showed that the lures and dispensers are still attractive after 30 days old in the environment. Video recording analysis of the behavior response of gravid *A. aegypti* to adult mosquito trap (MosquiTRAP^{â}) baited with the oviposition lure (Atr*Aedes*^{â}) showed that chemical and physical structures of odor plumes have great influence on the trap catch performance. At the moment, the MosquiTRAP^{â} and the Atr*Aedes*^{â} are being evaluated for *A. aegypti* national monitoring program in Brazil.

Laboratory and field evaluation of mosquito repellents in Australia

SP Frances
Australian Army Malaria Institute, Gallipoli Barracks, Enoggera, Brisbane, Queensland, 4051, Australia, steve.frances@defence.gov.au

This paper will review laboratory and field studies conducted in Australia and Papua New Guinea to evaluate mosquito repellent formulations. The response of *Anopheles* spp. in the field to *N,N*-diethyl-*3*-methylbenzamide (deet) is variable, and several species are tolerant of current formulations. In contrast, deet repellents are quite effective in providing protection against Culicine mosquitoes in this region. Additional studies on the laboratory and field response of mosquitoes to a comparatively new active ingredient, (1-methyl-propyl 2-(2-hydroxyethyl)-1-piperidinecarboxylate), known as picaridin, will also be presented.

Role of defensin in tick-pathogen interaction

K Fujisaki, N Tsuji, B Battsetseg, D Boldbaatar, T Miyoshi
Obihiro, Hokkaido 080-8555 Japan, fujisaki@obihiro.ac.jp

Antimicrobial peptides are major components of host innate immunity, a well-conserved, evolutionarily ancient defensive mechanism. Infectious disease-bearing vector ticks are thought to possess specific defense molecule that have been acquired in the process of their evolution against the transmitted pathogens. We found a parasiticidal peptide evolved from a common ancestral peptide resembling spider and scorpion toxins from *Haemaphysalis longicornis*, the obligatory vector for *Babesia* parasite transmission. This protein, named longicin, displayed bactericidal and fungicidal properties resembling those of defensin homlogues from invertebrates and vertebrates. Longicin showed a remarkable ability to inhibit the proliferation of merozoites, an erythrocyte-blood stage of equine *B. equi*, by killing the parasites. Longicin was localized at the surface of the parasites, as demonstrated by confocal microscopic analysis. In an *in vivo* experiment, longicin induced significant inhibition of parasitemia in animals infected with the zoonotic and murine *B. microti*. Our findings suggest that longicin is a promising candidate for designing antibabesia therapeutics.

Attractive host odours for mosquitoes: the blend ratio makes the difference

M Geier, A Rose, A Eiras
"Institut für Zoologie, Universität Regensburg, Universitätsstr. 31, 93040 Regensburg, Germany,
martin.geier@biologie.uni-regensburg.de"

Mosquito species differ with respect to their host preferences, and some discern not only different species of vertebrate hosts but also different individuals of a given species. Olfactory cues derived from the hosts determine to a large extend the host choice, and it is an intriguing question how these insects accomplish the necessary fine odour discrimination. Emanations from vertebrate hosts consist of complex blends. Attention has focused on the identification of kairomones that guide mosquitoes to their hosts. Here we show that odour blends rather than their single constituents attract the anthropophilic yellow fever mosquito *Aedes aegypti* (L.). Highly attractive blends consist of L-(+)-lactic acid, ammonia, and distinct fatty acids which were essential to maximise the attractiveness of the blend. The mosquitoes' responses, however, depended markedly on the ratio of these compounds. In a direct competition bioassay a distinct blend ratio turned out to be as attractive as an average human hand. When added to natural human skin emanations some compounds also altered significantly the attractiveness of the host. The data show that the blend ratio of a few distinct compounds is crucial for the attraction of mosquitoes to human hosts.

Specific monitoring tools for anthropohilic mosquitoes

M Geier, A Rose, C Baptista, SA Richie, A Eiras
Institute of Zoology, University of Regensburg, Universitätsstr. 31, 93053 Regensburg, Germany, martin.geier@biologie.uni-regensburg.de

For a better estimation of the risks of mosquito-transmitted disease epidemics, it is vital to quickly assess the density of the host seeking mosquito population. A simple, specific, and effective trapping tool would overcome some of the disadvantages of the currently used methods to estimate the density of mosquito populations. We introduce an new monitoring suction trap with an attractive lure for anthropohilic mosquitoes. The lure releases a cocktail of volatiles that also emanate from human skin. The attractiveness of the mixture strongly depends on the mixing ratio of the compounds. Release rates and blend ratio can be optimised to suit a number of anthropophilic mosquitoes. Although CO_2 is not essentially necessary for the effectiveness of the new attractant, it enhances the catching rate of the blend.

The design of the trap combines the generation of a specific plume shape for an optimum effectiveness of the attractants with visual cues to enhance the catch of the attracted mosquitoes. The trap is optimised for the new attractive blend, easy to produce and simple to use. It can be applied indoors as well as outdoors and is currently tested in the laboratory and in the field in Brazil, Asia, Australia and Europe with a range of mosquito species.

Forensic entomology and artificial intelligence: which is the relation?

L Gomes, CJ Von Zuben
Departament of Zoology, UNESP, Av. 24A, 1515, Zip Code: 13506-900, Rio Claro, SP, Brazil, leugomes@yahoo.com.br

Blowflies of genus *Chrysomya* are so important in forensic entomology to indicate the Post Mortem Interval (PMI). Moreover, the larvae of these insects have an aggregation behaviour when are feeding of the tissues in human and animal corpses which each one influence the other one during this process of feeding and post- feeding, and still after, during the post- feeding larval dispersal searching for pupation sites. The results of this influence is a self-organization in this process which is studied in computer programs (Cellular Automata) using the data from this behaviour and the program produced from these data to be applied in the development of programs of Artificial Intelligence and improve the performance of navigation systems in robots by the environment. These studies were done with about 10,000 larvae of *Chysomya megacephala* and *Chrysomya albiceps* in arenas simulating the environment conditions. Therefore, the study of some biological systems just as the studies in Forensic Entomology could be so important to develop programs in Artificial Intelligence.

Role of tick lectins in pathogen transmission

L Grubhoffer, V Kovar, P Kopacek
Institute of Parasitology, Academy of Sciences of the Czech Republic, University of South Bohemia, Branisovska 31, 370 05 Ceske Budejovice, Czech Republic, liborex@paru.cas.cz

Tissue specific lectin/haemagglutinin activities of both soft and hard ticks have been investigated. Some tick lectins are proteins with binding affinity for sialic acid, various derivatives of hexosamines, and different glycoconjugates. Most tick lectin/haemagglutinin activities are blood meal enhanced, and could serve as molecular factors of self/non-self recognition in defence reactions against bacteria or fungi, as well as in pathogen/parasite transmission. Dorin M, the plasma lectin of *Ornithodoros moubata*, **is the first tick lectin purified so far from tick haemolymph, and the first that has been fully characterized. Partial characterization of other tick lectins/haemagglutinins has been performed mainly with respect to their carbohydrate binding specificities and immunochemical features. Few papers have been published on tick lectins so far, and therefore more data is needed to complete the mosaic of knowledge of their structural and functional properties in terms of their role in pathogen transmission. (Supported by the Grant Agency of the Czech Republic No. 206/03/1323.)**

A three dimensional pharmacophore model for discovery of new insect repellent compounds

RJ Gupta, AK Bhattacharjee, W Dhenanetra
Office of the Director, Research Plans and Programs, US Army Medical Research and Materiel Command, Fort Detrick, MD. Department of Medicinal Chemistry and Department of Entomology, Walter Reed Army Institute of Research, Washington, DC.

In pursuit for a better understanding of insect repellent property of molecules we have generated a three-dimensional pharmacophore model using 3D-Catalyst from a training set of eleven diverse insect repellent compounds including DEET. Protection time data for repellent activity of the training set were taken from an earlier published study. Three hydrophobic sites and a hydrogen-bond acceptor site in the molecule appear to be critical for potent insect repellent activity. Calculated stereoelectronic properties such as molecular electrostatic potentials on DEET and some of these molecules in the training set are consistent with our observation. The pharmacophore shows a fairly good correlation (correlation=0.9) between protection time afforded by the compounds in the training set and their predicted protection time. The validity of the pharmacophore model goes beyond the list in the training set and is found to map well on a variety of other insect repellents. By mapping this model on a potent insect repellent compound we have generated a three-dimensional shape based template. A search of in-house database using the pharmacophore template resulted in the discovery of new potential candidate repellent compounds.

Making the case: frequently-contested aspects of forensic entomology evidence

R Hall
"Research, 205 Jesse Hall, Univ. Missouri, Columbia, MO USA, hallr@missouri.edu"

As forensic entomology evidence is introduced at trial, there are a few predictable aspects that frequently are at the heart of controversy regarding either admissibility or weight. Essentially all of these relate to the argument that, whereas forensic entomology is "good science" generally and applied in the present instance by a qualified expert, that as applied to the facts of the case at bar, the opinion under consideration is not based on reliable data (standards of the U.S. Federal Rules of Evidence or various state codifications thereof). Of those objections related to such "reliable data," the most common related to forensic entomology center around the use of remote temperatures. Few homicide victims are located proximate to weather stations, and fewer still decompose while investigators make measurements. Consequently, in virtually all instances, it is necessary to analyze the thermal development of insect species in the context of temperature data obtained during routine operations of weather stations that typically are located at some distance remote from the site where the decedent was found. Whether these data are analyzed as accumulated degree-days (ADD) or degree-hours (ADH), the same objections are continually raised in court: that the data do not accurately reflect conditions at the decomposition scene (because of uncertainty due to distance, differences in altitude, eccentricities of air flow, cooling effects of adjacent water bodies, heating effect of bright sunlight, or similar concerns). Generally, such objections can be forestalled by simple temperature measurements verifying concordance between the weather stations and body site. Related weaknesses include arithmetic errors in tabulating thermal units, misapplication of ADD to calculate ADH, failure to understand how ADD/ADH are applied in the context of existing dipteran developmental data, failure to consider base temperatures below which development essentially ceases, failure to consider the possible effects of "maggot mass," or putative failure to consider the effect of unique drying conditions on corpses. The forensic entomologist should analyze cases in the context of such potential arguments and be prepared to defend conclusions. Curiously, allegations regarding possible misidentification of insect species are seldom raised.

Blood feeding behavior of west nile virus mosquito vectors in Northeastern USA

LC Harrington, KM Mullen
Department of Entomology, Cornell University, Ithaca, NY 14853, lch27@cornell.edu

Control and prevention strategies for West Nile virus (WNV) can only be optimized once the most important human vectors have been identified. Although enzootic vectors of WNV have been identified, the epizootic human and horse-feeding vectors are not clear. A three-year study was conducted to investigate the host-feeding patterns of mosquitoes in areas where humans are active and avian reservoirs are nearby. Resting collections, using specially designed vegetation aspirators, were conducted in Upstate New York and New York City. After identification to species, engorged abdomens were analyzed using antibody sandwich ELISA to identify host blood sources. Blood meals also were tested with the precipitin method against antisera for 20 different species of mammals, birds, and reptiles. More than one host in a blood meal was detected in a small number of samples. These results provide a picture of the temporal and geographic variation in feeding patterns of mosquito species commonly included in surveillance programs as well as those that have not been considered important vectors of pathogens in the Northeast USA. The greatest frequency of human blood feeding was found in *Ochlerotatus triseriatus, Oc. aurifer, Aedes cinerius, Oc. fitchii/stimulans, Culex restuans, Cx. salinarius, Cx. territans, Ae. albopictus* and *Oc. japonicus.*

Going global: Taking molecular forensic entomology the next step

ML Harvey, IR Dadour, MW Mansell, MH Villet
Centre for Forensic Science, University of Western Australia, Mailbag M420, Nedlands, 6009, Australia, mharvey@cyllene.uwa.edu.au

In recent years, the importance of DNA-based techniques for application to the identification of insects, particularly blowfly larvae (Calliphoridae: Diptera) has been widely established. Research has frequently been locality specific, considering the distinction of different species within isolated populations or groups of populations within a small area. While small scale studies are beneficial in development of protocols for accurate molecular identification of insects in specific localities, a global approach to molecular study of forensically significant species facilitates consideration of such issues as species status. This study considers genetic variation in the cytochrome oxidase I (COI) encoding region of mitochondrial DNA (mtDNA) from calliphorids collected throughout Southern Africa and Australia. Alternate regions of DNA are explored for their value in providing an insight to intraspecific variation within several cosmopolitan species. Flies from New Zealand, the United States, Thailand, Taiwan, Brazil and Italy are considered, in addition to Australian and southern African individuals. The study indicates the potential of DNA to provide not only a means of more efficient and accurate identification of insects, but also to analyse the genetic processes occurring within some species, and potential applications and pitfalls for forensic entomology.

The potential for traditional plant-based insect repellents & fumigants as a means of reducing malaria in remote areas

N Hill, S Moore, M Cameron, Z Zhang, X Min
"Disease Control & Vector Biology Unit, London School of Hygiene & Tropical Medicine, Keppel Street, London, WC1E 7HT, UK, nigel.hill@lshtm.ac.uk "

Insect repellents and mosquito coils are widely accepted as beneficial for travelers in regions of vector-borne disease transmission. However, their efficacy at preventing malaria has never been established and is one reason why such methods have never been extended into disease control programmes. Isolated communities in remote regions are often at increased risk of malaria due to problems in provision of even basic malaria control programmes. For example, *P. falciparum* cases in China are increasing dramatically among minority peoples living in the border regions of Laos, Myanmar and Vietnam, or among migrant forest workers in the Bolivian Amazon. In such areas, particularly where there is an abundant floral habitat such as the SE Asia rainforests or the Amazon, there often remains dwindling historical knowledge of traditional plant-based anti-mosquito measures. By working with such communities it may be possible to identify and develop a means of disease control at the individual, household or village level. Such methods, if effective, could be both cheap and sustainable if local plant species are identified as having repellent, fumigant or insecticidal properties which could be exploited. Surveys of plant use among 25 minority peoples in China are reported and the potential for malaria control assessed.

Incidence, prevalence, and seasonality of *Choanotaenia* and *Raillietina* poultry tapeworms in arthropod and vertebrate hosts

NC Hinkle, L Luong, EG Platzer
Department of Entomology, University of Georgia, Athens, GA, USA, NHinkle@uga.edu

Confined animal production facilitates arthropod transmission of disease agents by increasing host-vector interactions, fostering sustained exposures, and providing optimal habitat. Poultry tapeworms, *Choanotaenia infundibulum* and *Raillietina cesticillus*, infest domestic and wild fowl throughout the world. Research at the University of California demonstrated that two insect species collected from caged laying hen operations, the hide beetle, *Dermestes maculatus*, and the house fly, *Musca domestica*, were naturally infected with tapeworm cysticercoids. Tapeworm incidence and prevalence fluctuated independently of host populations, with no distinct seasonal pattern. Extrinsic incubation was shown to be temperature-dependent, with development to infective cysticercoids requiring only 5 days at 33C. As husbandry practices change to optimize facilities for food animal productivity, conditions conducive for arthropod populations simultaneously develop. As intensive production increases, infestation rates can be expected to climb as well.

Issues in the control of sheep lice (*Bovicola ovis*)

PJ James
Department of Primary Industries and Fisheries, Animal Research Institute, LMB No 4, Moorooka, QLD, 4105 Australia, peter.james@dpi.qld.gov.au

Sheep lice are among the three main parasitic diseases of sheep in Australia. Historically sheep lice have been controlled by government regulation and the application of chemical insecticides. However, where regulatory powers still exist they are now seldom exercised and there is increasing sensitivity to the use of chemicals in major wool markets, amongst woolgrowers and in society at large. Woolgrowers face continuing cost of production pressures and the effectiveness of some widely used products has been compromised by the development of resistance. These constraints necessitate a more integrated approach to control. Barriers to change include poor knowledge of the biology of *B. ovis*, difficulty in detecting lice in the early stages of an infestation, lack of availability of alternative control methods and sociological factors. These issues are explored and parallels awn with human head lice control.

Regulation of head lice treatments in Australia

SI James
88 Wakley Crescent, Wantirna South VIC 3152 Australia, dsjames@bigfoot.com

Head lice treatments in Australia are regulated by the Therapeutic Goods Administration (TGA) via a two-tiered system. Head lice treatments containing herbal ingredients identified as "low risk" (e.g. melaleuca oil) require **listing** on the Australian Register of Therapeutic Goods (ARTG) These products do not undergo efficacy evaluation prior to listing, although sponsors are required to hold evidence to support label claims. Treatments making "high" level claims, or containing ingredients such as malathion, permethrin or pyrethrins require **registration** on the ARTG, involving evaluation of safety, efficacy and quality of the goods. However, a number of currently registered products were available before the onset of the listing/registration process in 1991. Products available before this time may not have been evaluated, although the potential for the TGA to request evaluation of these "grandfathered" products exists. The regulation of head lice treatments in Australia was reviewed in 2002/2003. A number of recommendations resulted from the review including specific recommendations about label claims and the level of evidence required to support registration or listing of a new head lice treatment product. The recommendations take into account the practical requirements of sponsors and the limitations of the current two-tiered regulation system.

A new device for recording host-seeking rhythms of mosquitoes using a photoelectric sensor

H Kawada, M Takagi,
"Department of Vector Ecology & Environment, Institute of Tropical Medicine, Nagasaki University, Nagasaki, Nagasaki 852-8523, Japan, vergiss@net.nagasaki-u.ac.jp"

A new automatic device capable of recording the host-seeking behavior of mosquitoes was designed using a photoelectric sensor. The host-seeking rhythms of several mosquito species were recorded in the laboratory. The use of CO_2, in addition to heating and contrast of black and white color, was essential to the functioning of the present recording device. The diel rhythms of non-blood fed *Aedes albopictus*, *Ae. aegypti*, *Culex quinquefasciatus*, *Cx. tritaeniorhynchus*, and *Anopheles stephensi* females recorded by the device corresponded closely with the flight activity levels, as measured by human landing counts and light traps, observed in the field for the same species. This simple automatic recording device also proved to be useful for evaluating the natural host seeking behavior of field-collected mosquitoes.

Astounding success in controlling *Aedes aegypti* in Vietnam using a new strategy

BH Kay, VS Nam
"Australian Centre for International and Tropical Health and Nutrition at the Queensland Institute of Medical Research, Brisbane, Australia and National Institute of Hygiene and Epidemiology, Hanoi, Vietnam, briank@qimr.edu.au"

From 1989, Vu Sinh Nam and Brian Kay have worked together with a team of collaborators including John Aaskov and Truong Uyen Ninh to deliver community based *Aedes aegypti* control using predacious copepods, the programs being managed by the Australian Foundation of Peoples of Asia and the Pacific. The four elements of the new strategy are (1) vertical and horizontal approaches to build up community understanding, (2) quantitative sampling methodologies designed to prioritize control, (3) inoculation of locally acquired *Mesocyclops* into large water storage containers, and (4) vector control activities at community level. By 2003, *Aedes aegypti* has been eliminated from 42 of 46 communes in north and central Vietnam, involving the protection of some 400,000 people. This is a world first achievement as no insecticide was used. The implications of this model are exciting as this approach is applicable to many countries where water has to be stored for survival.

Seasonal studies on the influence of clothing and wrapping on carcass decomposition and arthropod succession

JA Kelly, TC van der Linde, GS Anderson
Department of Zoology and Entomology, University of the Free State, P.O. Box 339, Bloemfontein, 9300, South Africa, kellyja@telkomsa.net

Six pig (*Sus scrofa* L.) carcasses, three wrapped and clothed carcass and three wrapped and naked, were sampled i) daily ii) after five days and iii) after ten days. Two more carcasses, one naked and not wrapped, and one clothed but not wrapped were sampled daily as controls. Differences in decomposition between the clothed or wrapped carcasses included the distribution and size of maggot masses and significant delay in drying out of the carcasses for all seasons. The maggot masses were primarily dominated by *Chrysomya marginalis* (Wiedemann) and *C. albiceps* (Weidemann), in autumn and summer. *Chrysomya chloropyga* (Weidemann) and *Calliphora vicina* Robineau-Devoidy in winter, with *C. chloropyga* and *C. albiceps* in spring. There was no delay in oviposition except in winter where a five day delay occurred on the wrapped carcasses. Extremely high internal temperatures in the warmer seasons caused significant maggot mortality on the wrapped carcasses. The predation of *C. marginalis* maggots by *C. albiceps* maggots was observed in autumn. In summer, maggot masses of these species were observed in separate groups. The coleopteran community was dominated by *Thanathopilus micans* L. larvae, succeeded by *Dermestes maculatus* De Geer, larvae. Adult *D. maculatus* and *Necrobia rufipes* De Geer, were present on the carcasses throughout all seasons.

Ectoparasites and arthropod-borne parasites of brown rat, *Rattus norvegicus*, in Ahvaz, southwest Iran

EB Kia, Z Telmadarraiy, H Vatandoost, A Farahnak, MM Homayouni, M Satvat, M Jedari, F Kasiri
School of Public Health & Institute of Health Research, Tehran University of Medical Sciences, P.O.Box: 6446-14155, Tehran, Iran, eshratkia@yahoo.com

Arthropods play an important role in the transmission of infectious agents to human and animals, such as rodents. Ahvaz, southwest Iran, is encountered with high density of rodents, especially *R. norvegicus*. In this study, 72 *R.norvegicus* were captured from different sites of Ahvaz, using live traps. Their ectoparasites were collected and identified. Thin and thick blood smears were prepared. After dissection of rats, their different organs were examined for any endoparasites, applying specific techniques. In general ectoparasites comprised 2 species of flea, *Xenopsylla astia* and *X. nubica*, 1 species of louse, *Polyplax spinula* and 1 species of mite *Laelaps nuttalli*. Among endoparasites, 9 species utilize arthropods as vector or intermediate host in their indirect life cycles. These included 1 species of protozoan parasite, *Trypanosoma lewisi* and 8 species of helminth parasites. The potential risk of each of these identified species to the health of human and animals will be discussed.

Applications of GIS and remote sensing for surveillance and control of mosquito borne diseases

Uriel Kitron
University of Illinois, Urbana , IL 61801, USA, ukitron@uiuc.edu

The risk of transmission of mosquito borne diseases depends on the spatial distribution of vector species in relation to the distribution of human hosts and, in case of mosquito-borne zoonoses, the distribution of vertebrate reservoir hosts. These distributions and temporal changes in these spatial patterns depend on environmental and climate/weather conditions. Satellite imagery provides means to gather vast amount of landscape/landcover and meteorological data that are proximate determinants of vector distribution and risk of disease transmission. Geographical information systems allow for the integration of environmental, entomological, epidemiological and demographic data and provide a framework for surveillance and control on scales ranging from local health departments and mosquito control districts to national and international programs. Products of applications of these tools and quantitative analysis of spatial data include data management tools, disease risk maps, and decision making tools for location and time of interventions. Examples from studies in the U.S. Israel, Trinidad and Kenya will be presented, including malaria cases in relation to *Anopheles* larval sites in Trinidad and Israel, dengue and dengue haemorrhagic fever in Trinidad, eastern equine encephalitis outbreaks in Michigan, USA, and La Crosse encephalitis transmission and the effect of introduction of *Aedes albopictus* in Illinois, USA.

Suppression of dengue transmission by application of integrated vector control measures at sero-positive GIS-based foci: Demonstration of a cost-effective model

P Kittayapong, S Yoksarn, U Chansang, C Chansang, A Bhumiratana
Center for Vectors and Vector-Borne Diseases and Department of Biology, Faculty of Science, Mahidol University, Rama 6 Road, Bangkok 10400, Thailand, grpkt@mahidol.ac.th

A serological survey of approximately 2,000 primary school children from six schools in Chachoengsao, Thailand, was performed at the end of the peak dengue transmission period. GIS analysis of sero-positive cases was carried out to determine transmission foci in high IgG-IgM positive villages. Vector control implementation was conducted in the foci and also within 100 meters around the foci, including schools attended by children in the treated areas, with collaboration from local public health and school authorities. Vector control measures included source reduction by routine garbage pickup organized by local government, the use of locally made screen covers, a combination of local Bti and *Mesocyclops*, and locally made lethal ovitraps. Implementation of vector control measures in the foci was continued until the end of the rainy season. Vector control efficiency was monitored using both entomological and serological parameters. Results showed a significant reduction of dengue vectors in treated areas when compared to untreated areas. Despite overall higher dengue incidences in the second year when compared to the first year, IgG-IgM positive students in the treated areas decreased from 13.46% to 0% while those from untreated areas increased from 9.43% to 19.15%.

Novel Mosquito Traps: Do They Really Work

Daniel L Kline

"USDA-ARS, CMAVE, 1600 SW 23rd, Gainesville, FL, USA, dkline@gainesville.usda.ufl.edu"

A diversity of commercial traps for mosquito control have become available during the past five years. Most are marketed to homeowners. Many models have been evaluated in a large outdoor screened enclosure against two species (*Aedes aegypti* and *Ochlerotatus taeniorhynchus*) of laboratory reared mosquitoes to determine their relative efficacy. Several models were selected for field testing against natural populations. Ongoing research is trying to answer the question: Can mosquitoes be trapped out? Different management strategies are being evaluated, e.g. control potential on isolated islands versus urban/suburban residential settings. In urban/residential settings traps are being evaluated as a protective barrier around a city block and in individual yards. Preliminary results indicate that protective trap barriers provide excellent control (>90%) on isolated islands, but only moderate (50% reduction) control in urban/suburban areas. A single trap in a single yard provided no measurable mosquito control.

The mode of action of deet, SS220, and Bayrepel® arthropod repellents against *Aedes aegypti*, *Anopheles stephensi*, and *Phlebotomus papatasi*

JA Klun, A Khrimian, M Debboun
"USDA, ARS, 10300 Baltimore Ave. Beltsville, MD, 20705, USA, klunj@ba.ars.usda.gov"

Laboratory bioassays were conducted with human subjects using six-celled K&D modules and the known arthropod repellents, N,N-diethyl-3-methylbenzamide (Deet), (1S, 2'S)-methylpiperidinyl-3-cyclohexene-1-carboxamide (SS220) and 2-(2-hydroxyethyl)-1-piperidine carboxylic acid 1-methylpropyl ester (Bayrepel) against *Aedes aegypti* (Linnaeus), *Anopheles stephensi* Liston mosquitoes and the sand fly, *Phlebotomus papatasi* which are vectors of human diseases. When five females of each species were simultaneously exposed to one half repellent-treated (4.8×10^{-2}μmol/cm^2) and one half untreated skin beneath the opening of a 3x4 cm cell, they bit exclusively on untreated skin. When treated and untreated skin was covered with cloth to preclude tactile contact with skin surfaces, the insects bit only through cloth covering untreated skin. The tests proved that each species was exquisitely capable of avoiding the compounds in their close-range feeding behavior and this was accomplished by olfactory chemical sensing. When cloth, untreated and repellent treated, was placed over the skin all species avoided the compounds and fed through the cloth only where repellent was absent. In the presence of any the three repellents within a cell, biting responses were reduced by about 50% relative to controls. Thus, besides inhibiting feeding on repellent-treated skin, the compounds also exhibited spatial-repellent activity.

The influence of burning on the decomposition and insect succession of pig carcasses

JH Kolver, TC van der Linde, MW Mansell
"Department of Zoology and Entomology, University of the Free State, P.O. Box 339, Bloemfontein 9300, South Africa, KolverJH.sci@mail.uovs.ac.za"

Recent casework raised the question whether burning has an influence on the decomposition and insect succession of bodies. This was investigated by dousing three pig carcasses with different volumes of petrol and burning them to different degrees (Slight = 1.5L Medium =5L, Heavily = 10L). The insect succession onto these carcasses was compared to a control carcass. The control carcass decomposed at the fastest rate with the heavily burnt carcass at the slowest rate. Adult insects comprised the following: At the control carcass Diptera (60.8%), Coleoptera (29.9%) and Hymenoptera (8.8%). At the slightly burnt carcass Coleoptera (55.8%), Diptera (38.6%) and Hymenoptera (5.4%). The dominant orders at the medium burnt carcass were Coleoptera (38.5%), Diptera (33.3%) and Hymenoptera (28%). At the heavily burnt carcass Coleoptera (51.4%) and Diptera (28.6%) were dominant. Hymenoptera (18.7%) did not have a direct influence on decomposition, since they functioned as predators. *Chrysomya albiceps* was the dominant Calliphoridae species at the control and medium burnt carcasses and *Chrysomya marginalis* at the slightly and heavily burnt carcass. Representative samples of larvae collected during decomposition revealed that *C. albiceps* larvae preferred to feed underneath the carcasses, with *C. marginalis* larvae feeding mostly inside and at the top of the carcasses.

Human behaviors and environmental factors elevating the risk of exposure to *Ixodes pacificus* nymphs in a hardwood forest

RS Lane, DB Steinlein, J Mun, M Peribañez-Lopez
"Division of Insect Biology, 201 Wellman Hall, University of California, Berkeley, California 94720, U.S.A., blane@nature.berkeley.edu"

The nymph of the western black-legged tick, *Ixodes pacificus*, has been implicated as the primary vector of the Lyme disease spirochete, *Borrelia burgdorferi*, in northwestern California. In 2002 and 2003, six human behaviors and environmental factors were evaluated as potential risk factors for acquiring nymphal ticks in a dense woodland in this region. The prevalence of *B. burgdorferi* and the causative agents of human anaplasmosis (*Anaplasma phagocytophilum*) and human monocytic ehrlichiosis (*Ehrlichia chaffeensis*) also were determined in nymphs that had been collected from subjects or by dragging leaf litter. Time-adjusted tick-acquisition rates demonstrated that sitting on logs was the riskiest behavior followed, in descending rank, by gathering wood, sitting against trees, walking, stirring and sitting on leaf litter, and sitting on litter. The number of ticks acquired appeared to be unrelated to the type of footwear worn. Nymphal ticks were active throughout the daytime over a wide range of micrometeorologic conditions. Overall, about 3-4% of nymphs were infected with *A. phagocytophilum* and *B. burgdorferi*, regardless of the collection method, versus none with *E. chaffeensis*. Co-infection with *B. burgdorferi* and *A. phagocytophilum* was detected for the first time in this life stage of *I. pacificus*. The public health implications of these findings will be discussed briefly.

Genetically Modified Mosquitoes: A Real World View

G.C. Lanzaro

The concept of controlling mosquito-borne diseases via the development and implementation of genetically modified strains has been under serious consideration since the early 1990's. Although this idea has been met with great enthusiasm in some quarters there remains substantial skepticism in others. The general concept and progress toward the development of such a strategy will be presented. Numerous roadblocks to the development of a GM mosquito plan remain, including (i) lack of gene drivers, (ii) lack of robust effector molecules and mechanisms to manipulate their expression, (iii) poor efficiency of transgenesis, (iv), and (v) no consideration of logistical problems associated with implementation in the field. These will be presented and prospects for overcoming them discussed. Aspects of the ecology and population genetics of targeted species will be discussed as they relate to the successful release and establishment of GM mosquitoes in nature.

Reverse chemical ecology: chemical prospecting of mosquito attractants and repellents

WS Leal, Y Ishida, A Cornel
"Department of Entomology, University of California-Davis, Davis CA 95616, USA, wsleal@ucdavis.edu"

For a few decades, chemical ecologists have been utilizing insect antennae as the sensing element or biodetector, in electroantennogram (EAG) and gas chromatography-electroantennographic detection (GC-EAD) assays for the identification of minute amounts of pheromones and other semiochemicals. The "molecular" equivalent of these electrophysiology-based "short cut bioassays" is the screening of attractants and repellents based on their binding affinities to odorant-binding proteins (OBPs). OBPs assist hydrophobic semiochemicals to cross an aqueous barrier in the insect sensilla (sensillar lymph) and reach odorant receptors (ORs). Both OBPs and ORs contribute to the high specificity of the insect olfactory system by forming two layers of filters. Although binding per se does not necessarily imply a physiological function, test compounds that do not bind to OBPs can be eliminated from further behavioral studies as they will never "see" the receptors. Reverse chemical ecology is a protein-based approach that requires the full identification of OBPs, cDNA cloning, functional expression of OBPs, and binding assays. In this presentation, we will discuss the latest development of a NIH-funded project* aimed at the development of better attractants and repellents for *Culex* species, the principal vectors of West Nile Virus.M

* NIH-National Institute of Allergy and Infectious Diseases (1U01AI058267-01).

Developing methodologies for a fungal biopesticide against *Boophilus* microplus, the cattle tick

DM Leemon, NN Jonsson, DJ Merritt
Animal Research Institute, Locked Mail Bag No 4, Moorooka, QLD, 4105, Australia, diana.leemon@dpi.qld.gov.au

The Queensland department of primary industries and fisheries has been investigating fungal biopesticides for livestock ectoparasites as part of a wider strategy to reduce the reliance upon chemicals in livestock industries. Fungal biopesticides have been available for the control of agricultural and horticultural pests for over thirty years and methodologies and accepted protocols for the development of these fungal biopesticides are now well established. Current work with the cattle tick has shown that livestock pests present additional challenges, some of which are due to the inability to conduct *in vitro* assays on obligate parasites, the cost of *in vivo* experiments using animals and the different environments the fungus must operate in when invading the parasitic and free-living phases. In addition, the development of formulation and application methods suitable for penetrating an animal's hair coat and delivering a lethal dose of spores to ticks present further challenges. Solutions to these problems have sometimes been obvious and straightforward but mostly have been arrived at slowly and painstakingly. We have concluded that the development of methodologies for fungal biopesticides of livestock ectoparasites is a multidisciplinary exercise requiring a thoughtful balance of appropriate *in vitro* bioassays with on-animal investigations.

Increased densities of vector mosquitoes in anthropogenic environments in the Kapiti region in New Zealand and potential ecological mechanisms as to why

PT Leisnham
"Department of Public Health, Wellington School of Medicine & Health Sciences, PO Box 7343, Wellington South, New Zealand, leipa321@student.otago.ac.nz"

Landuse changes, including deforestation, agriculture and urbanisation, have coincided with increases in mosquito-borne diseases worldwide. Anthropogenic environmental changes can alter mosquito populations by modifying the characteristics of breeding habitats, but we still poorly understand the ecological mechanisms involved. Mosquito breeding habitats were sampled in native forest, pastureland and urbanland in the Kapiti region, New Zealand, and 17 environmental characteristics were measured of each. Higher immature mosquito densities were collected from mainly artificial containers in urbanland and pastureland compared to mainly ground pools in native forest. Nine environmental variables were significantly different between landuses but none of these were significantly related to mosquito density. Principal components analysis partitioned environmental data into seven ecological types. One ecological type was significantly related to both landuse and mosquito density, and positively associated with ammonia, bacteria and dissolved organic carbon (DOC), and negatively associated with nitrate and predatory damselfly larvae. The findings of this study support those from prior surveys in warmer climes of greater vector disease risk in anthropogenically-modified environments because of compromised ecosystem integrity. Unlike most previous field-based work, this study also suggests important mechanisms involved; pinpointing mainly bacteria, DOC, nitrate and damselfly larvae as acting in combination to regulate vector mosquito density.

The final word on the genetic, evolutionary and taxonomic relationship of *Pediculus humanus* and *P. capitis*

NP Leo, JM Hughes, SC Barker
Department of Microbiology and Parasitology, University of Queensland, Brisbane 4072, Australia, N.Leo@imb.uq.edu.au

Body lice are thought to have diverged from head lice when humans began to wear clothes. This recent evolutionary divergence and incomplete lineage sorting has complicated assessments of whether head lice and body lice are separate species. We used microsatellite markers to test lice from hosts that were infested with head and body lice simultaneously, to see if the head and body lice had interbred. Our results showed that head and body lice had not interbred on a host. Assignment tests revealed that lice that had migrated among hosts always moved from head to head, and body to body, but never between heads and bodies. We conclude that head and body lice are separate species. We speculate that head lice are descended from the lice of neanderthals and modern humans, and that body lice are descended from the lice of modern humans that left Africa about 100,000 ya.

The search for natural repellents from human beings against mosquitoes

JG Logan, MA Birkett, LJ Wadhams, AJ Mordue (Luntz), JA Pickett
Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire AL5 2JQ, james.logan@bbsrc.ac.uk

Blood sucking insects are differentially attracted to human beings. This is likely to be caused by differences in the semiochemical profiles of individual human hosts. Despite substantial research into insect-human interactions, the responsible semiochemicals have not yet been identified. An explanation for this difference is that unattractive individuals either lack attractant chemical compounds or may produce compounds that 'mask' the activity of attractants. A special air entrainment technique was developed and used to collect volatile chemicals from human volunteers, and the extracts analysed by gas chromatography (GC), coupled GC-electroantennography (GC-EAG) and GC-mass spectrometry (GC-MS). For the first time electrophysiological responses of female yellow fever mosquitoes, *Aedes aegypti* to volatiles from air entrainment extracts were recorded, and a number of electrophysiologically active compounds were identified. Previous behavioural studies have confirmed the differential attractiveness of volunteers to biting insects. A quantitative and qualitative analysis of compounds within the extracts, from individuals known to be differentially attractive to biting insects, has revealed significant differences in chemical profiles. The identification of behaviourally active compounds could lead to new and improved control technologies, whereby 'masking' compounds could potentially be incorporated into new, safe and natural repellents against biting insect pests.

Anopheles arabiensis at the edge of its distribution in northern state, Sudan

CA Malcolm, BB El Sayed, ML Hickson, RS Azrag, AME Hassan, B Knols, MQ Benedict, AS Robinson
"Biological Sciences, Queen Mary, University of London, London E1 4NS, UK, c.a.malcolm@qmul.ac.uk"

Northern state, Sudan is mainly desert, rainfall is rare and most life is found close to the Nile. *Anopheles arabiensis* is the only anopheline and malaria vector found in the area in recent decades. It is present along the Nile downriver to about 200 km south of the Egyptian border, where poor terrain and control efforts prevent its spread further north. Initial results are presented from field and molecular studies to determine the population structure and dynamics of the species and related environmental factors. The receding Nile following the flood contributes most to sustaining *A. arabiensis*. Larval breeding sites can be found on low lying riverbank, ied-up inlets, or channels around islands, through most of the year. Land use is mainly associated with irrigation, but this does not appear to contribute greatly to anopheline numbers, however the extent of human presence and activities do increase the potential for anopheline breeding. Upriver from the fourth cataract and downriver from the third cataract, the terrain is rocky desert and less suitable for both humans and mosquitoes. The *An. arabiensis* population is thus semi-isolated within an approximately 700 km corridor a few kilometres wide and breaks down further into pockets depending on particular river features.

Control of biting midge (Ceratopogonidae) attack on residents of a marine canal estate in Redcliffe (Australia) by residual barrier treatment of Bistar 80SC® to ornamental garden plants in house yards

D McGinn, M Asnicar, C Perel, M Brown
Griffith University, Brisbane 4111 Queensland Australia, mosquitosi@iprimus.com.au

Biting midge (Ceratopogonidae) breeding in marine sediments associated with engineered canals in a residential community in Redcliffe Australia have been responsible for considerable biting attack and nuisance. Limitations on approved applications of larvicides in breeding sites has historically restricted control to personal protection, midge screening and education of residents. In October 2003 – Feb 04, Redcliffe City Council funded a trial to test the efficacy of Bistar 80SC® (FMC Chemicals Pty Ltd) as a 0.1% AI (Bifenthrin) residual application to ornamental garden vegetation and dwelling external walls. Eight paired randomised treated and untreated premises were assessed for differences in biting midge exposure. The assessment was undertaken using CO_2 and Octenol baited light traps placed in treated and untreated yards. A self administered questionnaire scoring individual household daily experience of biting midge activity was also used. Untreated control premises received a placebo application of water alone to control bias in the resident questionnaire. Analysis of difference in light trap collections between treated and untreated showed a 76.4% reduction in midge (primarily *Culicoides molestus*) from treated premises. Resident survey results indicated occupants of treated premises experienced generally favourable biting midge conditions while residents from untreated homes experienced fluctuating exposure and discomfort corresponding to lunar emergence cycles.

Aerial efficacy assessment of Anvil 10+10 against *Anopheles quaimaculatus*

MV Meisch, DA Dame, JR Brown
319 Agri. Bldg. Fayetteville, AR, 72701, USA, meisch@uark.edu

Aerial ULV applications of Anvil 10+10 were conducted against caged, field-collected *Anopheles quaimaculatus* adults using Beecomist® 360A rotary atomizers. Standard and optimized applications were conducted at 0.62 fl oz (0.0036 lbs a.i.) per acre using stacked passes 3,500 ft and 5,000 ft upwind of the target site. Efficacy of Anvil 10+10 and impact of wind velocity at flight altitude (150 ft) were assessed by bioassay and analysis of collected droplets.

The potential role of aquatic insects in the transmission of buruli ulcer disease in Africa

RW Merritt, ME Benbow, R Kimbirauskas
Dept. of Entomology, Michigan State University, East Lansing, MI, USA, merrittr@msu.edu

Buruli ulcer is the third most frequent mycobacterial disease in humans, next to tuberculosis and leprosy, often causing serious skin ulcerations, bone deformities, and disability. Unlike TB and leprosy, Buruli ulcer has emerged dramatically since the 1980's, with increasing numbers of cases being reported from at least 31 countries, mostly in tropical and subtropical areas, including Africa. Although poorly understood, the epidemiology of Buruli ulcer associates the resurgence with people who live and/or work close to wetlands, especially slow flowing (riverine) or stagnant water bodies (marshes, swamps), often created as a result of some human environmental disturbance. The disease is not known to be contagious between humans, and epidemiological studies have not yet established natural reservoirs or modes of transmission. However, it was recently demonstrated experimentally that *M. ulcerans* could survive and multiply exclusively within salivary glands of aquatic bugs (Naucoridae: *Naucoris* sp.) and they were able to transmit *M. ulcerans* to mice by their bites, suggesting a possible mechanism for human infection. The organism has been found in samples of water, biofilm and detritus. A possible trophic scenario for the natural mode of transmission of *M. ulcerans* is presented based on preliminary work in Ghana by the authors.

Efficacy of a Spinosad Suspension Concentrate Formulation for Controlling Chewing and Sucking Lice on Cattle Under Field Conditions

C Jones, LL Smith, DE Snyder, DE Hutchens, Z Cui, D Mowrey, LD Firkins, AJ Paul, JA Meyer
"2001 West Main Street, Greenfield, Indiana, 46140, USA, meyerje@lilly.com"

Field studies were conducted with cattle in Wisconsin and Illinois between January and April, 2000, to determine the efficacy of 0.04% spray and 2 mg/kg pour-on treatments of a spinosad suspension concentrate formulation against chewing and sucking lice. Positive control substances included in the study were Co-Ral® EC (5.8% coumaphos) and CyLence™ Pour-on (1% cyfluthrin). Animals in the negative control group remained untreated. All lice species were visually sampled on each animal at weekly intervals after treatment, for eight weeks. Individual louse counts were summed over each examination site for each species. A repeated measures analysis using a mixed model (SAS PROC MIXED), was conducted for data pooled across both study sites. Both spinosad treatments and CyLence™ Pour-on provided excellent efficacy (98-100%) against *Bovicola bovis* over the entire study period; Co-Ral® EC efficacy opped below 90% from Weeks 6-8. The efficacy of the spinosad spray treatment against *Linognathus vituli* was >93% for the entire study and >88% for the spinosad pour-on treatment. Co-Ral® EC was >90% efficacious against *L. vituli* during Weeks 1-7, while CyLence™ Pour-on only exceeded 90% for Weeks 3-7. *Solenopotes capillatus* were found only at the Wisconsin site; all treatments were highly efficacious throughout the study period.

The effect of human age on dengue seroconversion risk in Iquitos, Peru

SL Minnick, AC Morrison, TW Scott
Entomology Dept, University of California Davis, 1 Shields Ave, Davis, CA 95616, USA, slminnick@ucdavis.edu

Basic models of infectious disease often assume that force of infection is independent of host age. This assumption has been shown to be violated for many directly transmitted diseases, but has rarely been examined in vector-borne systems, such as dengue. Data from DNA fingerprinting studies of mosquito bloodmeals indicate that the biting rate of *Aedes aegypti* increases with human age. If risk for dengue infection increases with human age, models assuming an age-independent risk will underestimate the proportion of the population that needs to be vaccinated in order to eliminate disease transmission. A cohort of approximately 3,000 schoolchildren and their families in Iquitos, Peru were followed for up to 5 years (1999-2003) with blood samples collected at 6-month intervals. Sera were tested for dengue virus antibodies by the plaque reduction neutralization test. The effect of human age on risk for dengue seroconversion was evaluated using a multiple logistic regression model, which also included area of residence within the city. Preliminary analysis suggests that risk increased with age and was highest in the southern region of the city. Estimates of age-specific forces of infection can be used to design an optimal immunization program.

Oviposition Site Selection by Mosquitoes in Response to drought

Allie Mokany
School Of Botany And Zoology, Anu, Canberra, Act, 0200, Australia, allie.mokany@anu.edu.au

Mosquitoes are vectors of many important medical and veterinary diseases. Although outbreaks of mosquito borne disease can be correlated to changes in precipitation in the very short term, precipitation rarely corresponds to mosquito abundance in the long term. Here, I present the results of a field based mesocosm experiment designed to test how water level and drought influence the oviposition behaviour of two species of mosquitoes. I used two water levels (high and low) and two drought treatments (normal and drought). Water for the drought treatments was obtained from ponds that had experienced ying for a period of a month prior to experimentation. The two mosquito species differed markedly in their oviposition response. The egg laying behavior of *Ochlerlatatus notoscriptus* was significantly greater in the drought treatments regardless of water level. However, the egg laying behavior *Anopheles annulipes* showed the opposite response with significantly more larvae present in the high water treatments regardless of whether the treatment water was normal or in drought. My results provide supportive evidence that mosquitoes may show population outbreaks following drought years and that this framework may provide a reliable way of predicting year-to–year variation in mosquito abundances based on individual species oviposition response.

Aedes aegypti **surveillance in Iquitos, Peru: a 4- year test of the pupal/demographic survey**

AC Morrison, H Astete, A Getis, K Gray, M Sihuincha, J Stancil, J Olson, P Blair, TW Scott
"Proyecto Dengue, University of California, Davis, Department of Entomology, Calle Nauta 898, Iquitos, Peru, aegypti@terra.com.pe"

We present results from 4 years of pupal/demographic surveys of a circuit of ≈ 6,000 houses surveyed >10 times in the Amazonian city of Iquitos, Peru. We compare traditional larval indices with pupal and adult mosquito indices. We evaluated *Aedes aegypti* production from different container classes, including those based on water management practices overtime and space. A total of 289,941 water-holding containers were characterized, of which 7.3% were positive for *Ae. aegypti*. Although, temporal and geographic variations were detected for all variables examined, consistent production patterns were observed for the lid status (lids: 32% wet containers, 2% pupal production), container location (outdoor: 43% wet containers; 85% pupal production) and method by which the container was filled with water (rain filled: 15% wet containers; 88.3% pupal production). Based on these patterns and additional targeting of containers with highly variable pupal counts we propose a targeted control strategy for Iquitos that would reduce *Ae. aegypti* populations below published but untested threshold values for Iquitos.

Screening medicinal plant extracts for effects on *Aedes aegypti* (Diptera : Culicidae) and toxicity to a non target organism

S Promsiri, A Naksathit, M Kruatrachue, U Thavara
Department of Biology, Faculty of Science, Mahidol University, Rama VI Road, Bangkok 10400, Thailand, grans@mahidol.ac.th

A preliminary study was conducted to find out the effects of the extracts of 112 medicinal plant species, collected from the southern part of Thailand, on *Aedes aegypti*. Studies on larvicidal properties of plant extracts against the third and fourth instar larvae of *Ae. aegypti* showed fourteen species with high toxicity. Six plant species were comparatively more effective against the larvae at very low concentration. These extracts demonstrated no or very low toxicity to guppy fish (*Poecilia reticulata*). Three plants with promising larvicidal activity, *Mammea siamensis*, *Anethum graveolens* and *Annona muricata,* were used to study of the impact of the extracts on the life cycle of *Ae. aegypti*. The results showed that these plants affected the reproductive potential of surviving adults by reducing the number of eggs laid and egg hatchability. The first instar larvae were very susceptible to *A. muricata* and the second instar larvae were susceptible to *A. graveolens* while the third and fourth instar larvae were susceptible to *M. siamensis*. These extracts delayed larval development and inhibited adult emergence.

Tick vector-pathogen interrelationships

PA Nuttall, M Labuda
"NERC Centre for Ecology & Hydrology, Polaris House, North Star Avenue, Swindon SN2 1EU, U.K., pan@ceh.ac.uk"

The interrelationships between tick-borne pathogens, their tick vectors and diverse vertebrate hosts, are represented by a triangle of parasitic interactions. The interactions are between (i) tick-pathogen, (ii) pathogen-host, and (iii) tick-host. In (i) the pathogen interacts with its vector, infecting and replicating within tick cells or extracellular spaces. The ability of a particular tick species to act as a vector depends on whether the pathogen can survive and overcome several 'barriers' within the tick. However, this is a simplistic view of the tick vector-pathogen interrelationship as both (ii) and (iii) influence the success of (i). This triangle of interactions is focused at the skin site of tick feeding - the initial site at which pathogens gain access to either their host or vector. For pathogens, the skin-feeding site is an ecologically privileged niche, profoundly modified by the pharmacological activities of bioactive tick saliva molecules. Exploitation of this niche is known as saliva-activated transmission (SAT). Tick saliva molecules that promote SAT have not been identified but appear to differ for different tick vector-pathogen interrelationships. Identifying the SAT factors and their mode of action offers new insights for controlling ticks and tick-borne diseases.

Argentina: veterinary forensic entomology as a potential tool against rustling

A Oliva
Av. A. Gallardo 470 – C1405DJR – Buenos Aires – Argentina, aoliva@macn.gov.ar

Cattle rustling entails economic loss to cattle owners and danger to their safety, marketing of uninspected meat and hides and loss to the State from unpaid taxes. In 2003, the Faculty of Veterinary Medicine (Tandil, Buenos Aires province, Argentina) incorporated forensic entomology to a course of legal veterinary medicine aimed at fighting rustling. Preliminary field experiments showed a large proportion of hemisynanthropic insects, most of them Neotropical, which may represent the autochthonous necrophagous fauna, now displaced by synanthropic introduced species in urban environments. Colonization and development times proved longer in the arid climate of Tandil than at Buenos Aires city, where most published data were gathered. Field experiments whith bovine bodies and parts are required. Hitherto, bovines have been avoided as a model because of the added complication of the ruminant digestive tract. Since most countries with rustling problems also have a pattern of introduced species displacing the original necrophagous fauna in city environments, they might benefit from knowledge obtained through these studies.

Arboviruses, mosquitoes, and RNA interference

KE Olson, EA Travanty, I Sanchez-Vargas, KM Keene, BD Foy, BJ Beaty, CD Blair
Arthropod-borne and Infectious Diseases Laboratory, Department of Microbiology, Immunology and Pathology, Colorado State University, Fort Collins, Colorado 80523, kolson@colostate.edu

The identification of critical arbovirus-vector interactions reveals new insights into vector competence. For instance, flavivirus and alphavirus replication in mosquitoes triggers a natural RNA interference (RNAi) response; however, viral counterdefenses probably allow RNAi evasion and establishment of persistent infections. We can enhance RNAi to dengue virus type 2 (DENV2) in *Aedes* species by administration of double-stranded (ds) RNA derived from the DENV2 genome, either by direct transfection of dsRNA, transient expression from a Sindbis virus (SINV) transducing system, or stable transformation with a plasmid that expresses a hairpin-forming transcript. RNAi is sequence-specific, is maintained by low concentrations of effector RNA, blocks accumulation of intracellular viral RNA, and results in the appearance of 21-25 nt siRNA homologous to the mRNA target. We have identified genes from the Dicer and Argonaute families in 2 mosquito genera and have used RNAi to knock down their expression to determine which genes have a role in virus resistance. We have evidence that DENV2 and some strains of SINV establish persistent infections in mosquitoes by suppression of RNAi, and are investigating mechanisms. We are identifying viral-encoded suppressors by site-specific mutations in infectious cDNA clones. Our work suggests that persistent infections in mosquitoes result from a balance between host RNA silencing and viral counterdefenses and provides new strategies for tipping the balance in favor of the vector host.

Endosymbionts and sex ratios in the human head louse

MA Perotti, HR Braig
School of Biological Sciences, University of Wales, Bangor, Gwynedd, LL57 2UW, UK, bssc13@bangor.ac.uk

At the turn of the 19th century the first observations of a female-biased sex ratio in broods and populations of head lice had been reported. A study by Buxton in 1938 on the sex ratio of lice on prisoners in Ceylon is still today the subject of reanalyses. However, in the last sixty years no data have been collected, especially on more normal levels of infestations. Here we report a female bias of head lice in a survey of 480 school children in Argentina. This bias is independent of lice intensity. These lice as well as lice from pupils in Britain were carrying several, related strains of the endosymbiotic bacterium *Wolbachia*, one of the increasing number of intracellular sex ratio distorters. No lice without *Wolbachia* were detected. Similar *Wolbachia* strains are also present in the pig louse suggesting that this endosymbiont might have marked influence on the biology of the whole order. The sex ratio distortion in head lice that has been reported world wide is stable over time; that is a remarkable deviation from the stability of frequency-dependent selection of Fisher's sex ratio.

Blood Feeding in *Cnephia* (Diptera: Simuliidae): Molecular Phylogeny

KP Pruess
University Of Nebraska, Lincoln, NE 68583-0816, U.S., kpruess@unlnotes.unl.edu

Five species of *Cnephia* were studied, three non-biting, one a mammal feeder, and one a bird feeder. Of the non-feeding species, *C. eremite* is Holarctic in distribution and specimens were examined from both Canada and Sweden. *Cnephia pallipes* is a Palearctic non-feeder and *C. dacotensis* a temperate Nearctic non-feeder. *Cnephia pecuarum* is an economically important large mammal feeder in south-central U.S. and *C. ornithophilia* a widely distributed bird feeder in southern and eastern North America. Sequence was obtained from the complete mitochondrial CO-II gene (687 bp) and partial EF1-alpha nuclear gene (1030 bp). Molecular data is discussed in relation to conventional wisdom about relationships among species based on cytological and biological information, geographic distribution and genetic diversity within species. Molecular data strongly support *Cnephia* as a monophyletic clade in the tribe Simuliini. Speciation hypotheses were not fully concordant between molecular and conventional data.

Onchocerciasis in Central America: Ecology & Control

MA Rodríguez-Pérez,
Centro de Biotecnología Genómica-IPN, PO Box 152, Reynosa 87710, Tamaulipas, México, mroiguez@ipn.mx

Detection of O. volvulus larvae in vector populations of black flies is of prime importance in the assessment of the effectiveness of ivermectin control programs. Detection of larvae is attained by dissection of individual flies or by PCR (amplification of an Onchocerca 150 bp repeated sequence, followed by hybridization of the PCR products with a species-specific DNA probe) from pools of flies. The PCR was compared with dissection method to estimate the infection rate (p) and the mean larval load (any larval stage) per parous fly (m) in a local vector population. Both methods produced statistically similar estimates, thus PCR is an alternative and efficient method for entomological surveillance. Sample sizes required to estimate m from p for fixed levels of precision were calculated using Mexican and Guatemalan data, assuming that k (an aggregation parameter from the larval distribution among parous flies) is known. Optimal sampling and PCR was used to evaluate the impact of ivermectin on m, p and transmission potentials in Mexico. The data suggest that substantial progress towards the goal of suppressing transmission has been accomplished. In southern Chiapas, entomological estimates decreased in comparison with the baseline data, but PCR positivity was still detectable. In northern Chiapas and Oaxaca, with no baseline data, there was an absence or near absence of infected and infective flies.

New and resurgent arboviral disease threatening humans in Australia

RC Russell
Department of Medical Entomology, University of Sydney and ICPMR, Westmead Hospital, Westmead, NSW 2145, Australia, rrussell@usyd.edu.au

Australia has a range of indigenous arboviruses and an introduced few that are of public health concern; all are mosquito-borne. Endemic encephalitogenic viruses (Murray Valley Encephalitis, Kunjin) are annually active and responsible for occasional cases in the northwest but, despite widespread vector distribution, only rare activity and no epidemics in the southeast since 1974. The most common arboviruses, Ross River annually infecting many thousands nation-wide causing polyarthritis, and Barmah Forest (a similar syndrome) on the increase and responsible for outbreaks of hundreds regionally, have a spectrum of coastal saline and inland freshwater vectors. The most important exotics are the returning dengue viruses with outbreaks of hundreds confined to Queensland by vector distribution but with virus endemicity and vector spread threatening, and the recently introduced Japanese Encephalitis virus causing only a few deaths in northern Queensland but with virus persistence and its affinity for a local vector threatening. Environmental factors drive arbovirus activity by influencing vector populations, which vary with virus and circumstance, although little is known of the role of reservoir hosts. Tourism and development activities that increase human/vector/virus contact, and climate changes that promote vector and virus proliferation, threaten to exacerbate the disease threat to the public health.

Repellents for integrated tsetse management

RKSaini, A Hassanali
International Center of Insect Physiology and Ecology (ICIPE), P.O. Box 30772 Nairobi, KENYA, rsaini@icipe.org

ICIPE is in the forefront in identifying potent repellents, both synthetic analogues of natural tsetse repellents and natural repellent blends from un-preferred animals like waterbuck and zebras. One potent synthetic repellent for savannah tsetse species, developed by molecular optimization studies, acts as an olfactory antagonist of a key phenolic kairomone, which flies use to locate the host for feeding (Saini & Hassanali; patent application). This repellent substantially reduce tsetse challenge (> 80%) and feeding efficiency (>80%) on cattle. A prototype dispenser which is placed around the neck of an animal has been developed. Field trials indicate that the repellent can provide effective protection to cattle but all animals in a herd need to be protected or else significantly higher infection occurs in unprotected animals. Experiments are ongoing to evaluate how repellents can be integrated with other existing tsetse control techniques. A 'push-pull' strategy that deploys repellents (to 'push') and baited traps / targets (to 'pull') to enhance suppression rates is being evaluated. A variant of this may involve the use of a proportion of cattle with 'pour on' insecticides as live baits. A business plan for commercial production and distribution of repellent products is also being developed.

Mitochondrial genome organization of lice is highly variable

R Shao, C Covacin, SC Barker
Department of Microbiology and Parasitology, The University of Queensland, QLD, 4072, Australia, r.shao@uq.edu.au

Mitochondrial (mt) genome organization is extremely conserved in mammals, vertebrates and most arthropods, e.g., humans and frogs have the same mt genome organization; so have fruit flies and water fleas. We have sequenced the entire mt genomes of the wallaby louse (Phthiraptera: Amblycera) and the pigeon louse (Ischnocera), and part of the mt genomes of the human louse (Anoplura) and four other amblyceran lice. Unlike most arthropods, the mt genome organization of these lice is highly variable. Lice share only 1-2 gene boundaries with fruit flies. No gene boundaries were shared among lice of the three suborders. Mt genome organization differs even among three genera within the suborder Amblycera. Changes in the mt genome organization of lice include gene translocation, inversion, separation of rRNA genes and loss or multiplication of non-coding regions. In addition to lice, we found mt genome organization was variable or highly variable in other two hemipteroid orders, Psocoptera (psocids) and Thysanoptera (thrips), but is strictly conserved in the order Hemiptera (bugs). We speculate that the changes in the mt genome organization in lice, psocids and thrips may be related to their life-history traits such as small body size, small colony size, and high degree of inbreeding.

West Nile virus activity in the USA and regional differences in vectors and transmission dynamics

HM Savage
Centers for Disease Control, P.O. Box 2087, Fort Collins, CO 80522, USA

In the USA, West Nile virus (WNV) was first detected in New York City in 1999. By the fall of 2003, WNV had spread south and west to 45 states. During 1999–2003, 13,405 human cases of WNV disease were reported. Principal enzootic and epidemic vectors of WNV in the USA are *Culex (Culex)* mosquitoes. In the Northeast and upper Midwest, *Cx. pipiens* L. including form molestus, *Cx. salinarius* Coquillett and *Cx. restuans* Theobald are the most important vectors. In the South, *Cx. quinquefasciatus* Say and *Cx. salinarius* are the most important vectors. In Florida and the southern portions of LA, MS, and AL, *Cx. nigripalpus* Theobald is a potential vector. In the Rocky Mountain and High Plans states, *Cx. tarsalis* Coquillett and *Cx. pipiens* are the primary vectors. In the arid Southwest, *Cx. tarsalis* is the primary vector with *Cx. quinquefasciatus* playing a role in urban areas. Across much of the mid-latitudes, *Cx. pipiens* and *Cx. quinquefasciatus* hybridize and both taxa and hybrids are important vectors. California will experience WNV disease in the future and important vectors are likely to be *Cx. tarsalis* and members of the *Cx. pipiens* complex, with *Cx. stigmatosoma* Dyar and *Cx. erythrothorax* Dyar being focally important. Important avian host vary with regional abundance, however, the house sparrow (*Passer domesticus*) appears important in virus transmission throughout the USA.

Measures of *Aedes aegypti* density and the risk of dengue virus transmission.

TW Scott, AC Morrison, H Astete, A Getis, K Gray, M Sihuincha, J Stancil, J Olson, P Blair, JW Jones, R Sithiprasasna, S Koenraadt, M Mammen.
"Department of Entomology, University of California, Davis, CA, 95616, USA. twscott@ucdavis.edu "

In two large, cohort-based prospective studies we are defining entomological risk and characterizing its relationship to human dengue infection. Based on results from more than 5 years of field research in the Amazonian city of Iquitos, Peru we are determining the appropriate scale (spatial and temporal) at which to measure entomological risk and dengue virus transmission. A new research program in Khamphaeng Phet, Thailand is an extension of the Iquitos project and will explicitly link in time and space various measures of entomological risk to human dengue infections

Aedes aegypti **genomics**

DW Severson, DL Knudson, BM Soares, BJ Loftus
137 Galvin Life Sciences, University of Notre Dame, Notre Dame, IN 46556, USA, severson.1@nd.edu

"We have initiated a genome project for *Aedes aegypti* that will ultimately lead to complete sequence information. We are sequencing both ends of genomic DNA Bacterial Artificial Chromosome (BAC) clones and random cDNAs representing a variety of tissues, and physically mapping selected BAC clones. BAC clone end-sequencing is completed and the data are available at GenBank. We plan to sequence and analyze both ends of ~80,000 cDNAs derived from normalized libraries produced from 4 specific mRNA sources and one library enriched for full-length sequences. Individual libraries are in various stages of construction, with one competed (*Brugia malayi*-infected) and 29,824 ESTs generated, and sequencing of a second (*Plasmodium gallinaceum*-infected) nearly completed. The third library (females exposed to a dengue virus) has just been completed and we are in the process of constructing libraries from 1) fat body and 2) combined developmental stages. We have incorporated all sequences from our genome project with gene sequences available in GenBank into an *A. aegypti* Gene Index available at TIGR (www.tigr.org/tdb/tgi/aegi/). We have recently (2/13/2004) been notified that NIH-NIAID has selected *A. aegypti* for full genome sequencing. We anticipate this will include an 8X coverage that should provide a high quality genome assembly.
"

Mitochondrial genome organization of lice is highly variable

R Shao, Ms Cath Covacin and Associate SC Barker
Department of Microbiology and Parasitology, The University of Queensland, QLD, 4072, Australia, r.shao@uq.edu.au

Mitochondrial (mt) genome organization is extremely conserved in mammals, vertebrates and most arthropods, e.g., humans and frogs have the same mt genome organization; so have fruit flies and water fleas. We have sequenced the entire mt genomes of the wallaby louse (Phthiraptera: Amblycera) and the pigeon louse (Ischnocera), and part of the mt genomes of the human louse (Anoplura) and four other amblyceran lice. Unlike most arthropods, the mt genome organization of these lice is highly variable. Lice share only 1-2 gene boundaries with fruit flies. No gene boundaries were shared among lice of the three suborders. Mt genome organization differs even among three genera within the suborder Amblycera. Changes in the mt genome organization of lice include gene translocation, inversion, separation of rRNA genes and loss or multiplication of non-coding regions. In addition to lice, we found mt genome organization was variable or highly variable in other two hemipteroid orders, Psocoptera (psocids) and Thysanoptera (thrips), but is strictly conserved in the order Hemiptera (bugs). We speculate that the changes in the mt genome organization in lice, psocids and thrips may be related to their life-history traits such as small body size, small colony size, and high degree of inbreeding.

Simuliid taxonomy in relation to transmission of human onchocerciasis and mansonelliasis in Brazil.

AJ Shelley, SBL Luz, M Maia-Herzog, APA Luna Dias, LM Hernández.
Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK, ajs@nhm.ac.uk.

Mansonelliasis was recorded as widespread in the southern Amazon over 50 years ago and human onchocerciasis 35 years ago in a discrete area in the northern Amazon region of Brazil. Incrimination of the simuliid vectors that transmit the filarial parasites responsible for these diseases has only been possible during the last three decades, largely due to the logistical difficulty in collecting species in these regions and the complex taxonomy of members of the *Simulium amazonicum* group to which several belong. This has been caused by the morphological similarity between vector and non vector species of the group. The use of digital image analysis has facilitated the morphological definition of species in the group, recently augmented by cytological and molecular studies. Our current classification of the group based on these techniques is presented together with distribution maps of vector species that suggest that disease dispersal to non endemic areas may be occurring as infected individuals migrate from the disease foci as rural areas of the Amazon are developed.

Polymerase chain reaction-based differentiation of members of the *Anopheles culicifacies* complex

OP Singh, G Goswami, Nutan Nanda, K Raghavendra, D Chandra, SK Subbarao
Malaria Research Centre (ICMR), 22 SHAM NATH MARG, Delhi-110054, India, singh@mrcindia.org

Anopheles culicifacies, the principal vector of malaria in India, is responsible for over 65% of total malaria in India and is a complex of 5 cryptic species designated as species A, B, C, D, and E. These members are morphologically indistinguishable at any stage of life and can be identified by examining species-specific inversions in polytene chromosome and mitotic karyotype of Y-chromosome of male progeny. In an attempt to develop a simple alternative to cyto-taxonomy, we have developed an Allele-Specific Polymerase Chain Reaction (ASPCR) assay targeted to D3 domain of 28S ribosomal DNA, which unambiguously differentiates *An. culicifacies* species A and D from species B, C, and E. The assay was evaluated using chromosomally-identified specimens of *An. culicifacies* originating from different geographical regions of India representing different sympatric associations and was found to be specific. The culicifacies-specific primers used in the assay did not cross-react to other anophelines as tested against all members of *An. fluviatilis* complex (species S, T, and U), *An. minimus* (species A), *An. stephensi* and *An. subpictus.* The search of genomic database using culicifacies-specific primers sequences revealed that these primers are specific to *An. culicifacies* only. The possible use of this diagnostic assay in disease vector control programme for discrimination of vector species from non-vector will be discussed.

Insecticides don't kill lice but formulations of insecticides do!

JA Staton
Technical Consultancy Services Pty Ltd PO Box 1022, Rockdale, NSW, 2216, Australia, john@techconsult.com.au

Head lice treatment preparations are labelled according to the qualitative and quantitative content of their active ingredients. A recent review of this group of products by the Medicines Evaluation Committee of Australian Therapeutic Goods Administration concluded that "There is a paucity of good quality information on the effects of different formulations on the efficacy of head lice products". This presentation will review the available evidence and identify some of the issues which may impact on dosage form design of head lice preparations.

Potency and avidity of tick paralysis antitoxin in Australia

BF Stone
"University of Queensland, School of Molecular and Microbial Sciences, St Lucia, QLD 4072, Australia, b.stone@uq.edu.au"

Tick paralysis due to the Australian paralysis tick, *Ixodes holocyclus* is a potentially-lethal syndrome affecting domestic pets, livestock and humans along the east coast of Australia mainly during late spring and early summer. There is no vaccine available at present. Prevention in animals largely depends on acaricidal treatment. Treatment of paralysis is based on a commercially-available antiserum, raised in hyperimmune dogs by progressive and cumulative antibody stimulation by repeated infestation with adult female ticks. This serum constitutes a specific, antitoxin widely used by veterinarians and to a limited extent by physicians to treat cases of tick paralysis. Standardisation at the minimum arbitrary level of 500 antitoxin units per ml is legally required. Variability occurs in potency and particularly in avidity (the well-known relative variability on dilution to neutralise an active toxin [in this case, holocyclotoxin] *in vivo* and *in vitro*). A modified method using dilution of antitoxin as opposed to the earlier method of dilution of toxin, may be used to study this variability. This variability will be discussed and possible explanations proposed.

Global expression profiling of the major detoxification enzyme families in the major African malaria vector *Anopheles gambiae*

C Strode, JP David, J Hemingway, J Vontas, H Ranson
Vector Research Group, Liverpool School of Tropical Medicine, Pembroke Place, Liverpool, L3 5QA, UK. cpcs@liverpool.ac.uk

Vector control programs based on the use of insecticides, whether it be by residual house spraying or treated bed nets, are being challenged by the emergence of insecticide resistance. For example, there is wide scale resistance to pyrethroids in mosquitoes from West Africa, which are the major insecticides used in malaria control. One reason for this is the increased detoxification of insecticides by three major enzyme families; glutathione *S*-transferases, cytochrome P450 monooxygenases and the carboxylesterases. The recent publication of the complete genome sequence of the major malaria vector *Anopheles gambiae,* has allowed us to construct a highly specific 'detoxification chip', which contains fragments of all the genes putatively implicated in insecticide resistance in this mosquito. We have used microarray technology to monitor the expression of genes in insecticide-susceptible and resistant mosquito strains to pin-point the genes responsible for resistance. Furthermore, to generate a more detailed profile, their expression has also been assessed in the various life stages of the mosquito and in male and female insects. The detoxification chip is an excellent tool to provide a platform with which to go on and determine the function of these enzymes.

Odour blends in the host-seeking behaviour of the malaria vector *Anopheles gambiae*.

YT Qiu, RC Smallegange, A Galimard, M Jawara, JJA van Loon, TA. van Beek, W Takken
Laboratory of Entomology, Wageningen University, PO Box 8031, 6700 EH Wageningen, The Netherlands, willem.takken@wur.nl

The mosquito *Anopheles gambiae* is the most important malaria vector in Africa primarily because of its strong anthropophilic behaviour. We have studied factors affecting host-seeking behaviour of this mosquito, notably the olfactory cues with which human hosts are being detected. Responses of the mosquitoes to human skin emanations were studied with electrophysiological and behavioural essays. We demonstrated that important olfactory stimuli for *An. gambiae* are ammonia, L-lactic acid and several aliphatic carboxylic acids. EAG and single sensillum recordings demonstrated significant dose-responses in olfactory cells of grooved peg and trichoid sensilla. Behavioural responses were observed with single and mixed odours in an olfactometer. *An. gambiae* always responded to ammonium, although as a single component ammonium could not compete with the natural odours from human skin. Ammonia was an essential synergist to cause activity of lactic acid and/or carboxylic acids. Laboratory results were complemented by field studies in West Africa, where it was found that wild *An. gambiae* were attracted to a synthetic blend of volatiles from a distance. The same blend of odours that caused high attraction in the olfactometer, attracted most mosquitoes to odour-baited traps. The results are discussed with consideration for the development of olfaction-based technologies for malaria control.

Novel mosquito repellents derived from essential oils of plants in Thailand

"A Tawatsin, U Thavara, J Bansiddhi, P Wongsinkongman, T Boonruad, N Komalamisra, MS Mulla "
National Institute of Health, 88/7 Tiwanon Rd., Nonthaburi 11000, Thailand, apiwat@dmsc.moph.go.th

Mosquito-borne diseases, such as dengue, malaria and filariasis are serious public health problems in many countries, especially in the tropical regions of the world. These diseases are caused by pathogens that are transmitted to man through mosquito biting only, thus personal protection from mosquito bites is then considered as one of the strategies to prevent them. Efforts to develop alternatives to replace chemical repellents have been increasingly considered, including extracting and evaluating plant products for repellent activity. The development and use of locally available plant products showing repellent activity thus avails an alternative strategy for prevention of mosquito-borne diseases. In this study we evaluated and reported repellent effects of essential oils extracted from plants against 4 mosquito vectors: *Aedes aegypti*, *Ae. albopictus*, *Anopheles dirus* and *Culex quinquefasciatus* under laboratory conditions using human volunteers. The essential oils were extracted from various parts of 22 plant species, belonging to 10 families, and the oils were prepared as 10% solution in absolute ethanol and some additives. The essential oils showing high degree of repellency were subsequently formulated as topical repellents and tested against day- and night-biting mosquitoes under field conditions. The results obtained from both laboratory and field evaluations will be presented.

Evaluation and development of cockroach repellents derived from essential oils of plants

U Thavara, A Tawatsin, J Chompoosri, P Asavadachanukorn, MS Mulla
National Institute of Health, 88/7 Tiwanon Rd., Nonthaburi 11000, Thailand, usavadee@dmsc.moph.go.th

Cockroaches are common insects found throughout the world, especially in the tropical regions. They are generally recognized as not only household pests but also pose a high health hazard to humans. Various aspects of cockroach control including chemical and non-chemical methods have been researched on an ongoing basis. Repellents against cockroaches are considered as one of alternatives to eliminate cockroaches from dwellings and other harborage places. Attempts have been made to find and develop cockroach repellents derived from plant extracts. We evaluated 20 essential oils extracted from various plants such as basil, black pepper, eucalyptus, galanga, guava, kaffir lime, etc., for repellency against two cockroach species: the American cockroach (*Periplaneta americana*) and the German cockroach (*Blatella germanica*). The experiments were carried out against adult cockroaches in the laboratory. It was found that the tested essential oils provided various degrees of repellency against cockroaches, ranging from 40 to 100%. The essential oil extracted from kaffir lime leaves showed excellent activity, manifesting 100% repellency against both cockroach species. The essential oils providing high degrees of repellency (>80%) were subsequently formulated as cockroach repellents and tested against cockroaches in the field. Data from both laboratory and field tests will be presented.

Recent trends in louse control in the USA

RG Todd
"Insect Control & Research, Inc. 1330 Dillon Heights Avenue, Baltimore, MD 21228-1199, USA inscontrolres@aol.com"

Since the advent of permethrin resistance among head lice (*Pediculus h. capitis*) in the 1990's in the USA, the hegemony of permethrin and synergized-pyrethrin products has given way to a more diverse array of louse control products. Many of the new products use 'natural' ingredients since consumers are anxious to avoid applying insecticides to their chilen, but efficacy is often questionable. Products for nit removal, for repelling lice and for louse detection are all available. The synergized-pyrethrins and permethrin-based products still have a dominant position. New active ingredients and novel technologies have been, and are, being evaluated for louse control – information on most are not yet publicly available. Products now on the market are discussed. FDA requirements are summarized Market size and product market-share are estimated. Future trends are predicted.

The *Simulium ochraceum* (species complex) (Diptera: Simuliidae) and its distribution in relation to onchocerciasis transmission in Latin America.

LM Hernández Triana, AJ Shelley, APA. L Dias, M Maia-Herzog
"Department of Entomology, The Natural History Museum, Cromwell Road, SW& 5BD, London, UK. luih@nhm.ac.uk."

Simulium ochraceum is the primary vector of the disease in Central America and it could be responsible for sporadic transmission of the disease in mainland Ecuador. It consists of three cytotypes which probably have different biting behaviour and susceptibility to the parasite. The morphological variation of this species along its distribution range and its rôle in onchocerciasis transmission are here discussed. The female of *S. ochraceum s.l.* is recognised by thorax orange with 1+1 white pruinose, sub-median cunae (light source anterior). Within the complex, variation in the length of white pruinose vittae and coloration of postnotum and legs occur. *Simulium ochraceum s.l.* shows marked differences in its biting behaviour, being anthropophilic in Central and South America and largely zoophilic in the Caribbean Islands. It bites man occasionally in Brazil and Venezuela. The use of integrated taxonomic techniques is suggested to discover the meaning of morphological variations in terms of cytotypes. The host capacity of *S. ochraceum s.l.* is low because of the presence of cibarial teeth, but it is an efficient vector in hyperendemic areas for the disease. Other factors affecting the vector capacity of this species in the transmission of onchocerciasis in Latin America are discussed.

Emergence of epidemic dengue in Kerala State, southern India, with an account of establishment and dominance of the vector mosquito *Aedes albopictus* (Skuse)

BK Tyagi, J Hiriyan, SC Tewari, V Thenmozhi
Centre for Research in Medical Entomology (ICMR), 4-Sarojini Street, Chinna Chokkikulam, Madurai 625 002, TN, India; bk_tyagi@sify.com

Dengue (including dengue hemorrhagic fever and dengue shock syndrome) has emerged as a major health hazard in India in recent decades as it is being increasingly reported in epidemic proportions from even States hitherto largely *terra incognito* for epidemic dengue, e.g. Kerala State in south India. Several focal outbreaks of dengue fever have been reported from Kerala in recent years, originating in the sylvatic and mountainous terrains of Kottayam, Idukki and Ernakulam, and spreading to coastal districts. The enormity of problem is gauged from the fact that the incidence hiked steeply from merely 14 cases and 4 deaths in 1997 to 3377(241-fold increase) and 66 (>16-fold increase) by November, 2003. While the principal dengue vector, *Aedes aegypti*, was insignificantly prevalent in density mostly along the coastal belt urban areas, *Ae. albopictus* has dominated in prevalence (71.2%), followed by *Armigeres subalbatus* (20.7%), *Aedes aegypti* (4.4%) and *Culex uniformis* (1.5%) amongst all the 22 species under seven genera occurring in the State. Twice the dengue virus had been detected in *Ae. albopictus* adults reared from the field-collected immatures from Western Ghat region. *Aedes aegypti* is, however, yet to be incriminated from Kerala State.

The truth is out there: application of new technology for the understanding and surveillance of mosquito-borne arboviruses

AF van den Hurk, SA Ritchie, BL Montgomery, AT Pyke, GA Smith, JS Mackenzie
"Department of Microbiology and Parasitology, School of Molecular and Microbial Sciences, University of Queensland, St Lucia, QLD, 4072, Australia, anew_hurk@health.qld.gov.au"

Since 1995, Japanese encephalitis virus (JEV) has emerged as an annual threat to northern Australia. To monitor for future incursions of JEV, a sentinel pig programme was established in the Torres Strait and on Cape York Peninsula. While this system has been successful in detecting the virus, it is not ideal: deployment of the pigs is expensive, dangerous to handlers, and, as pigs are the primary amplifying hosts of JEV, they could serve as a source of virus. We outline the development of a mosquito-based sentinel system for the detection of JEV activity in remote areas of northern Australia. This approach is based on application of new generation mosquito traps, such as the propane-powered Mosquito Magnet™, for collection of mosquitoes, and a real time TaqMan RT-PCR for specific detection of viral RNA. In a field trial of the system, it was demonstrated that a single JEV-infected mosquito could be detected in pools of <5000 mosquitoes, maintained for <14 days in tropical conditions. Since 2002, 10 mosquito pools have been positive for JEV at the same time sentinel pigs have seroconverted to the virus. The relative efficacy of the mosquito-based system for detection of JEV and other arboviruses will be discussed.

The New Year's party that went terribly wrong – A case study on the influence of wrapping on decomposition of a body.

TC van der Linde
Department of Zoology & Entomology, University of the Free State, P.O. Box 339, Bloemfontein 9300 South Africa, vdlindet.sci@mail.uovs.ac.za

In this study, an example of unusual disposal of remains is presented with comments on the changes in the resulting patterns of arthropod invasion. A young female disappeared the night of 31st December 2001, after a New Year's party. The evening of 12th January 2002 a suspect was arrested and the body was found. The body was in an advanced stage of decomposition, almost skeletonized. The insects present were late third instar *Chrysomya albiceps* larvae, a few adult *Dermestes maculates* and a few adult Piophilidae. These insects did not correspond to the stage of decomposition. Diptera pupae were also expected. The question arose whether the body might have been kept for a few days, excluding insects, before disposal. It was later established that the body was wrapped in a cotton sheet before it was left in the field. The crime scene was reconstructed, using two pig carcasses, the one wrapped in a sheet and the other unwrapped. Decomposition and insect succession of the two carcasses were monitored and compared. The insects present on the carcasses were the same, but the wrapping of the carcass slowed down the decomposition process, although colonization of the two carcasses occurred at the same time.

The colonization of buried remains at different depths

M Turchetto, S Vanin
Department of Biology, University of Padova, via U. Bassi 58/b, I-35121 Padova, Italy, stefano.vanin@unipd.it
